The **inverse kinematics** problem is to determine the required joint angles \mathbf{q}_i to position the end effector at a prescribed Cartesian position. This corresponds to solving Equation 71.2 for $\mathbf{q} \in \mathfrak{R}^n$ given a desired orientation R and translation \mathbf{p} of the end effector. This is not an easy problem, and may have more than one solution (e.g., think of picking up a coffee cup, one may reach with elbow up, elbow down, etc.). There are various efficient techniques for accomplishing this. One should avoid the functions arcsin, arccos, and use where possible the numerically well-conditioned arctan function.

71.5.1.2 Robot Jacobians

71.5.1.2.1 Transformation of Velocity and Acceleration

When the manipulator moves, the joint variable becomes a function of time t . Suppose there is prescribed a generally nonlinear transformation from the joint variable $\mathbf{q}(t) \in \mathfrak{R}^n$ to another variable $y(t) \in \mathfrak{R}^p$ given by

$$y(t) = h(\mathbf{q}(t)) \quad (71.3)$$

An example is provided by the equation $y = T(\mathbf{q})$, where $y(t)$ is the Cartesian position. Taking partial derivatives one obtains

$$\dot{y} = \frac{\partial h}{\partial \mathbf{q}} \dot{\mathbf{q}} \equiv J(\mathbf{q})\dot{\mathbf{q}} \quad (71.4)$$

where $J(\mathbf{q})$ is the *Jacobian* associated with $h(\mathbf{q})$. This equation tells how the joint velocities are transformed to the velocity \dot{y} .

If $y = T(\mathbf{q})$ the Cartesian end effector position, then the associated Jacobian $J(\mathbf{q})$ is known as the **manipulator Jacobian**. There are several techniques for efficiently computing this particular Jacobian; there are some complications arising from the fact that the representation of orientation in the homogeneous transformation $T(\mathbf{q})$ is a 3×3 rotation matrix and not a three vector. If the arm has n links, then the Jacobian is a $6 \times n$ matrix; if n is less than 6 (e.g., SCARA arm), then $J(\mathbf{q})$ is not square and there is not full positioning freedom of the end effector in 3-D space. The **singularities** of $J(\mathbf{q})$ (where it loses rank), define the limits of the robot workspace; singularities may occur within the workspace for some arms.

Another example of interest is when $y(t)$ is the position in a *camera coordinate frame*. Then $J(\mathbf{q})$ reveals the relationships between manipulator joint velocities (e.g., joint incremental motions) and incremental motions in the camera image. This affords a technique, for instance, for moving the arm to cause desired relative motion of a camera and a workpiece. Note that, according to the velocity transformation 71.4, one has that incremental motions are transformed according to $\Delta y = J(\mathbf{q})\Delta q$.

Differentiating Equation 71.4 one obtains the *acceleration transformation*

$$\dot{y} = J \dot{\mathbf{q}} + \dot{J} \mathbf{q} \quad (71.5)$$

71.5.1.2.2 Force Transformation

Using the notion of virtual work, it can be shown that forces in terms of \mathbf{q} may be transformed to forces in terms of y using

$$\boldsymbol{\tau} = J^T(\mathbf{q})\mathbf{F} \quad (71.6)$$

where $\boldsymbol{\tau}(t)$ is the force in joint space (given as an n -vector of torques for a revolute robot), and \mathbf{F} is the force vector in y space. If y is the Cartesian position, then \mathbf{F} is a vector of three forces $[\mathbf{f}_x \ \mathbf{f}_y \ \mathbf{f}_z]^T$ and three torques $[\tau_x \ \tau_y \ \tau_z]^T$. When $J(\mathbf{q})$ loses rank, the arm cannot exert forces in all directions that may be specified.

71.5.2 Robot Dynamics and Properties

The robot dynamics considers motion effects due to the control inputs and inertias, Coriolis forces, gravity, disturbances, and other effects. It reveals the relation between the control inputs and the joint variable motion $\mathbf{q}(t)$, which is required for the purpose of servocontrol system design.

71.5.2.1 Robot Dynamics

The dynamics of a rigid robot arm with joint variable $\mathbf{q}(t) \in \mathfrak{N}^n$ are given by

$$M(\mathbf{q})\ddot{\mathbf{q}} + V_m(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{F}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{G}(\mathbf{q}) + \boldsymbol{\tau}_d = \boldsymbol{\tau} \quad (71.7)$$

where M is an inertia matrix, V_m is a matrix of Coriolis and centripetal terms, \mathbf{F} is a friction vector, \mathbf{G} is a gravity vector, and $\boldsymbol{\tau}_d$ is a vector of disturbances. The n -vector $\boldsymbol{\tau}(t)$ is the control input. The dynamics for a specific robot arm are not usually given in the manufacturer specifications, but may be computed from the kinematics A matrices using principles of Lagrangian mechanics.

The dynamics of any actuators can be included in the robot dynamics. For instance, the electric or hydraulic motors that move the joints can be included, along with any gearing. Then, as long as the gearing and drive shafts are noncompliant, the form of the equation with arm-plus-actuator dynamics has the same form as Equation 71.7. If the actuators are not included, the control $\boldsymbol{\tau}$ is a torque input vector for the joints. If joint dynamics are included, then $\boldsymbol{\tau}$ might be, for example, a vector of voltage inputs to the joint actuator motors.

The dynamics may be expressed in Cartesian coordinates. The *Cartesian dynamics* have the same form as Equation 71.7, but appearances there of $\mathbf{q}(t)$ are replaced by the Cartesian position $y(t)$. The matrices are modified, with the manipulator Jacobian $J(\mathbf{q})$ becoming involved. In the Cartesian dynamics, the control input is a six vector of forces, three linear forces and three torques.

71.5.2.2 Robot Dynamics Properties

Being a Lagrangian system, the robot dynamics satisfy many physical properties that can be used to simplify the design of servo-level controllers. For instance, the inertia matrix $M(\mathbf{q})$ is symmetric positive definite, and bounded above and below by some known bounds. The gravity terms are bounded above by known bounds. The Coriolis/centripetal matrix V_m is linear in $\dot{\mathbf{q}}$, and is bounded above by known bounds. An important property is the **skew-symmetric** property of rigid-link robot arms, which says that the matrix $(\dot{M} - 2V_m)$ is always skew symmetric.

This is a statement of the fact that the fictitious forces do no work, and is related in an intimate fashion to the *passivity* properties of Lagrangian systems, which can be used to simplify control system design. Ignoring passivity can lead to unacceptable servocontrol system design and serious degradations in performance, especially in teleoperation systems with transmission delays.

71.5.2.3 State-Space Formulations and Computer Simulation

Many commercially available controls design software packages, including MATLAB, allow the simulation of state-space systems of the form $\dot{\mathbf{x}} = f(\mathbf{x}, u)$ using, for instance, Runge–Kutta integration. The robot dynamics can be written in state-space form in several different ways. One state-space formulation is the position/velocity form

$$\begin{aligned}\dot{\mathbf{x}}_1 &= \mathbf{x}_2 \\ \dot{\mathbf{x}}_2 &= -M^{-1}(\mathbf{x}_1)[V_m(\mathbf{x}_1, \mathbf{x}_2)\mathbf{x}_2 + \mathbf{F}(\mathbf{x}_1, \mathbf{x}_2) + \mathbf{G}(\mathbf{x}_1) + \tau_d] + M^{-1}(\mathbf{x}_1)\tau\end{aligned}\quad (71.8)$$

where the control input is $u = M^{-1}(\mathbf{x}_1)\tau$, and the state is $\mathbf{x} = [\mathbf{x}_1^T \ \mathbf{x}_2^T]^T$, with $\mathbf{x}_1 = \mathbf{q}$, and $\mathbf{x}_2 = \dot{\mathbf{q}}$ both n -vectors. In computation, one should not invert $M(\mathbf{q})$; one should either obtain an analytic expression for M^{-1} or use least-squares techniques to determine $\dot{\mathbf{x}}_2$.

71.5.3 Robot Servo-level Motion Control

The objective in robot servo-level motion control is to cause the manipulator end effector to follow a prescribed trajectory. This can be accomplished as follows for any system having the dynamics Equation 71.7, including robots, robots with actuators included, and robots with motion described in Cartesian coordinates. Generally, design is accomplished for robots including actuators, but with motion described in joint space. In this case, first, solve the inverse kinematics problem to convert the desired end effector motion $y_d(t)$ (usually specified in Cartesian coordinates) into a desired joint-space trajectory $\mathbf{q}_d(\mathbf{t}) \in \mathfrak{R}^n$ (discussed subsequently). Then, to achieve tracking motion so that the actual joint variables $\mathbf{q}(t)$ follow the prescribed trajectory $\mathbf{q}_d(t)$, define the *tracking error* $e(t)$ and *filtered tracking error* $r(t)$ as

$$e(t) = \mathbf{q}_d(t) - \mathbf{q}(t) \quad (71.9)$$

$$r(t) = \dot{e} + \Lambda e(t) \quad (71.10)$$

with Λ a positive definite design parameter matrix; it is common to select Λ diagonal with positive elements.

71.5.3.1 Computed Torque Control

One may differentiate Equation 71.10 to write the robot dynamics Equation 71.7 in terms of the filtered tracking error as

$$M\dot{r} = -V_m r + f(\mathbf{x}) + \tau_d - \tau \quad (71.11)$$

where the *nonlinear robot function* is given by

$$f(\mathbf{x}) = M(\mathbf{q})(\ddot{\mathbf{q}}_d + \Lambda\dot{e}) + V_m(\mathbf{q}, \dot{\mathbf{q}})(\dot{\mathbf{q}}_d + \Lambda e) + F(\mathbf{q}, \dot{\mathbf{q}}) + G(\mathbf{q}) \quad (71.12)$$

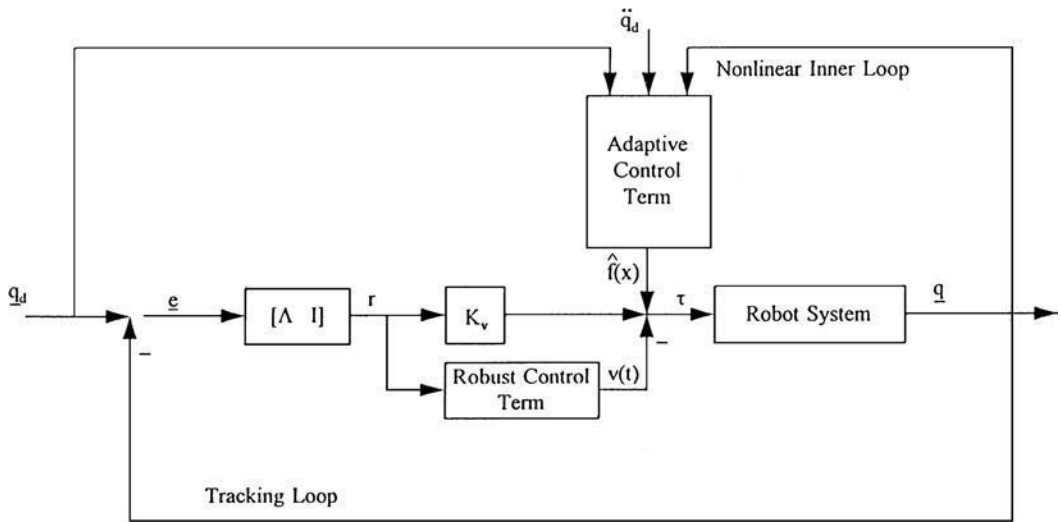

FIGURE 71.13 Robot servo-level tracking controller.

Vector \mathbf{x} contains all of the time signals needed to compute $f(\cdot)$, and may be defined for instance as $\mathbf{x} \equiv [e^T \dot{e}^T \mathbf{q}_d^T \dot{\mathbf{q}}_d^T \ddot{\mathbf{q}}_d^T]^T$. It is important to note that $f(\mathbf{x})$ contains all the potentially unknown robot arm parameters including payload masses, friction coefficients, and Coriolis/centripetal terms that may simply be too complicated to compute.

A general sort of servo-level tracking controller is now obtained by selecting the control input as

$$\tau = \hat{f} + K_v r - v(t) \quad (71.13)$$

with \hat{f} an *estimate* of the nonlinear terms $f(\mathbf{x})$, $K_v r = K_v \dot{e} + K_v \Lambda e$ an *outer proportional-plus-derivative (PD) tracking loop*, and $v(t)$ an auxiliary signal to provide robustness in the face of disturbances and modeling errors. The *multiloop control structure* implied by this scheme is shown in Figure 71.13. The nonlinear inner loop that computes $\hat{f}(x)$ provides *feedforward compensation* terms that improve the tracking capabilities of the PD outer loop, including an *acceleration feedforward term* $M(\mathbf{q})\ddot{\mathbf{q}}_d$, *friction compensation* $\mathbf{F}(\mathbf{q}, \dot{\mathbf{q}})$, and a *gravity compensation term* $\mathbf{G}(\mathbf{q})$.

This controller is a variant of **computed-torque control**, since the torque required for trajectory following is computed in terms of the tracking error and the additional nonlinear robot terms in $f(\mathbf{x})$. An integrator may be added in the outer tracking loop to ensure zero steady-state error, obtaining a PID outer loop.

71.5.3.2 Commercial Robot Controllers

Commercial robot controllers do not implement the entire computed torque law. Most available controllers simply use a PD or PID control loop around each joint, dispensing entirely with the inner nonlinear compensation loop $\hat{f}(x)$. It is not clear exactly what is going on in most commercially available controllers, as they are proprietary and the user has no way to modify the joint tracking loops. However, in some controllers (e.g., Adept Hyperdrive), there appears to be some inner-loop compensation, where some of the terms in $f(\mathbf{x})$ are included in $\tau(t)$. For instance, acceleration feedforward may be included. To implement nonlinear feedback terms that are not already built-in on commercial controllers, it is usually necessary to perform hardware modifications of the controller.

71.5.3.3 Adaptive and Robust Control

There are by now many advanced control techniques for robot manipulators that either estimate the nonlinear robot function or compensate otherwise for uncertainties in $f(\mathbf{x})$. In **adaptive control** the

estimate \hat{f} of the nonlinear terms is updated online in real-time using additional internal controller dynamics, and in **robust control** the robustifying signal $v(t)$ is selected to overbound the system modeling uncertainties. In **learning control**, the nonlinearity correction term is improved over each repetition of the trajectory using the tracking error over the previous repetition (this is useful in repetitive motion applications including spray painting). Neural networks (NN) or fuzzy logic (FL) systems can be used in the inner control loop to manufacture the nonlinear estimate $\hat{f}(\mathbf{x})$ [Lewis et al. 1995]. Since both NN and FL systems have a universal approximation property, the restrictive **linear in the parameters** assumption required in standard adaptive control techniques is not needed, and no *regression matrix* need be computed. FL systems may also be used in the outer PID tracking loop to provide additional robustness.

Though these advanced techniques significantly improve the tracking performance of robot manipulators, they cannot be implemented on existing commercial robot controllers without hardware modifications.

71.5.4 Robot Force/Torque Servocontrol

In many industrial applications it is desired for the robot to exert a prescribed force normal to a given surface while following a prescribed motion trajectory tangential to the surface. This is the case in surface finishing, etc. A hybrid position/force controller can be designed by extension of the principles just presented.

The robot dynamics with environmental contact can be described by

$$M(\mathbf{q})\ddot{\mathbf{q}} + V_m(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{F}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{G}(\mathbf{q}) + \tau_d = \tau + J^T(\mathbf{q})\lambda \quad (71.14)$$

where $J(\mathbf{q})$ is a constraint Jacobian matrix associated with the contact surface geometry and λ (the so-called Lagrange multiplier) is a vector of contact forces exerted normal to the surface, described in coordinates relative to the surface.

The hybrid position/**force control** problem is to follow a prescribed motion trajectory $\mathbf{q}_{1d}(t)$ tangential to the surface while exerting a prescribed contact force $\lambda_d(t)$ normal to the surface. Define the filtered motion error $r_m = \dot{e}_m + \Lambda e_m$, where $e_m = \mathbf{q}_{1d} - \mathbf{q}_1$ represents the motion error in the plane of the surface and Λ is a positive diagonal design matrix. Define the force error as $\lambda = \lambda_d - \lambda$, where $\lambda(t)$ is the normal force measured in a coordinate frame attached to the surface. Then a hybrid position/force controller has the structure

$$\tau = \hat{f} + K_v L(\mathbf{q}_1) r_m + J^T [\lambda_d + K_f \tilde{\lambda}] - v \quad (71.15)$$

where \hat{f} is an estimate of the nonlinear robot function 71.12 and $L(\cdot)$ is an extended Jacobian determined from the surface geometry using the implicit function theorem.

This controller has the basic structure of Figure 71.13, but with an additional *inner force control loop*. In the hybrid position/force controller, the nonlinear function estimate inner loop \hat{f} and the robustifying term $v(t)$ can be selected using adaptive, robust, learning, neural, or fuzzy techniques. A simplified controller that may work in some applications is obtained by setting $\hat{f} = 0$, $v(t) = 0$, and increasing the PD motion gains $K_v \Lambda$ and K_v and the force gain K_f .

It is generally not possible to implement force control on existing commercial robot controllers without hardware modification and extensive low-level programming.

71.5.5 Motion Trajectory Generation

In the section on servo-level motion control it was shown how to design real-time servo-level control loops for the **robot joint** actuators to cause the manipulator to follow a prescribed joint-space trajectory $\mathbf{q}_d(t)$ and, if required by the job, to exert forces normal to a surface specified by a prescribed force trajectory $\lambda_d(t)$. Unfortunately, the higher level **path planner** and job coordinator in Figure 71.7 do not specify the position and force trajectories in the detail required by the servo-level controllers. Most commercial robot controllers operate at a sampling period of 16 ms, so that they require specific desired motion trajectories $\mathbf{q}_d(t)$ sampled every 16 ms. On the other hand, the path planner wishes to be concerned at the

level of abstraction only with general path descriptions sufficient to avoid obstacles or accomplish desired high-level jobs (e.g., move to prescribed final position, then insert pin in hole).

71.5.5.1 Path Transformation and Trajectory Interpolation

71.5.5.1.1 Joint Space vs. Cartesian Space Prescribed Trajectories

The job coordinator in Figure 71.7 passes required path-following commands to the virtual robot in the form of discrete events to be accomplished, which could be in the form of commands to “move to a specified final position passing through prescribed *via points*.” These prescribed path *via points* are given in Cartesian coordinates y , are usually not regularly spaced in time, and may or may not have required times of transit associated with them. *Via points* are given in the form (y_i, \dot{y}_i, t_i) , with y_i the required Cartesian position at point i and \dot{y}_i the required velocity. The time of transit t_i may or may not be specified. The irregularly spaced Cartesian-space *via points* must be *interpolated* to produce joint-space trajectory points regularly spaced at every sampling instant, often every 16 ms. It should be clearly understood that the path and the joint trajectory are both prescribed for each coordinate: the path for three Cartesian position coordinates and three Cartesian orientation coordinates, and the trajectory for each of the n manipulator joints. If n is not equal to 6, there could be problems in that the manipulator might not be able to exactly reach the prescribed *via points*. Thus, in its planning process the path planner must take into account the limitations of the individual robots.

Two procedures may be used to convert prescribed Cartesian path *via points* into desired joint-space trajectory points specified every 16 ms. One may either: (1) use the arm inverse kinematics to compute the *via points* in joint-space coordinates and then perform trajectory interpolation in joint space, or (2) perform interpolation on the *via points* to obtain a Cartesian trajectory specified every 16 ms, and then perform the inverse kinematics transformation to yield the joint-space trajectory $\mathbf{q}_d(t)$ for the servo-level controller. The main disadvantage of the latter procedure is that the full inverse kinematics transformation must be performed every 16 ms. The main disadvantage of the former procedure is that interpolation in joint space often has strange effects, such as unexpected motions or curvilinear swings when viewed from the point of Cartesian space; one should recall that the path planner selects *via points* in Cartesian space, e.g., to avoid obstacles, often assuming linear Cartesian motion between the *via points*. The latter problem may be mitigated by spacing the Cartesian path *via points* more closely together. Thus, procedure 1 is usually selected in robotic workcell applications.

71.5.5.1.2 Trajectory Interpolation

A trajectory specified in terms of *via points*, either in joint space or Cartesian space, may be interpolated to obtain connecting points every 16 ms by many techniques, including interpolation by cubic polynomials, second- or third-order splines, minimum-time techniques, etc. The interpolation must be performed separately for each coordinate of the trajectory (e.g., n interpolations if done in joint space). Cubic interpolation is not recommended as it can result in unexpected swings or overshoots in the computed trajectory.

The most popular technique for trajectory interpolation may be linear functions with parabolic blends (LFPB). Let us assume that the path *via points* are specified in joint space, so that the inverse kinematics transformation from the Cartesian path *via points* obtained from the path planner has already been performed. Then, the path is specified in terms of the *via points* $(\mathbf{q}(t_i), \dot{\mathbf{q}}(t_i), t_i)$; note that the time of transit t_i of point i is specified; the transit times need not be uniformly spaced. Within each path segment connecting two *via points*, one uses constant acceleration or deceleration to obtain the required transit velocity, then zero acceleration during the transit, then constant acceleration or deceleration to obtain the prescribed final position and velocity at the next *via point*. Sample LFPB trajectories are given in Figure 71.14. Note that LFPB results in quadratic motion, followed by linear motion, followed by quadratic motion. The maximum acceleration/deceleration is selected taking into account the *joint actuator torque limits*.

There are standard formulas available to compute the LFPB trajectory passing through two prescribed *via points*, for instance the following. In Figure 71.14 two design parameters are selected: the *blend time* t_b and the *maximum velocity* v_M . Then the joint-space trajectory passing through *via points* i and $(i+1)$,

FIGURE 71.14 LFPB trajectory: (a) acceleration profile, (b) velocity profile, and (c) position profile.

shown in Figure 71.14(c), is given by

$$\mathbf{q}_d(t) = \begin{cases} a + (t - t_i)b + (t - t_i)^2c, & t_i \leq t < t_i + t_b \\ d + v_M t, & t_i + t_b \leq t < t_{i+1} - t_b \\ e + (t - t_{i+1})f + (t - t_{i+1})^2g, & t_{i+1} - t_b \leq t < t_{i+1} \end{cases} \quad (71.16)$$

It is not difficult to determine that the coefficients required to pass through the i th and $(i + 1)$ st via points are given by

$$\begin{aligned} a &= \mathbf{q}(t_i), & b &= \dot{\mathbf{q}}(t_i), & c &= \frac{v_M - \dot{\mathbf{q}}(t_i)}{2t_b} \\ d &= \frac{\mathbf{q}(t_i) + \mathbf{q}(t_{i+1}) - v_M t_{i+1}}{2} \\ e &= \mathbf{q}(t_{i+1}), & f &= \dot{\mathbf{q}}(t_{i+1}) \\ g &= \frac{v_M t_{i+1} + \mathbf{q}(t_i) - \mathbf{q}(t_{i+1}) + 2t_b [\dot{\mathbf{q}}(t_{i+1}) - v_M]}{2t_b^2} \end{aligned} \quad (71.17)$$

One must realize that this interpolation must be performed for each of the n joints of the robot. Then, the resulting trajectory n -vector is passed as a prescribed trajectory to the servo-level controller, which functions as in Robot Servo-level Motion Control subsection to cause trajectory-following arm motion.

71.5.5.2 Types of Trajectories and Limitations of Commercial Robot Controllers

The two basic types of trajectories of interest are motion trajectories and force trajectories. Motion specifications can be either in terms of motion from one prescribed point to another, or in terms of following a prescribed position/velocity/acceleration motion profile (e.g., spray painting).

In robotic assembly tasks point-to-point motion is usually used, without prescribing any required transit time. Such motion can be programmed with commercially available controllers using standard robot programming languages (Section 71.12). Alternatively, via points can usually be taught using a telerobotic teach pendant operated by the user (Section 71.11); the robot memorizes the via points, and effectively plays them back in operational mode. A speed parameter may be set prior to the motion that tells the robot whether to move more slowly or more quickly. Trajectory interpolation is automatically performed by the robot controller, which then executes PD or PID control at the joint servocontrol level to cause the desired motion. This is by far the most common form of robot motion control.

In point-to-point motion control the commercial robot controller performs trajectory interpolation and joint-level PD servocontrol. All of this is transparent to the user. Generally, it is very difficult to modify any stage of this process since the internal controller workings are proprietary, and the controller hardware does not support more exotic trajectory interpolation or servo-level control schemes. Though some robots by now do support following of prescribed position/velocity/acceleration profiles, it is generally extremely difficult to program them to do so, and especially to modify the paths once programmed. Various tricks must be used, such as specifying the Cartesian via points (y_i, \dot{y}_i, t_i) in very fine time increments, and computing t_i such that the desired acceleration is produced.

The situation is even worse for force control, where additional sensors must be added to sense forces (e.g., wrist force-torque sensor, see Section 71.7), kinematic computations based on the given surface must be performed to decompose the tangential motion control directions from the normal force control directions, and then very tedious low-level programming must be performed. Changes in the surface or the desired motion or force profiles require time-consuming reprogramming. In most available robot controllers, hardware modifications are required.

71.6 End Effectors and End-of-Arm Tooling

End effectors and end-of-arm tooling are the devices through which the robot manipulator interacts with the world around it, grasping and manipulating parts, inspecting surfaces, and so on [Wright and Cutkosky 1985]. End effectors should not be considered as accessories, but as a major component in any workcell; proper selection and/or design of end effectors can make the difference between success and failure in many process applications, particularly when one includes reliability, efficiency, and economic factors. End effectors consist of the *fingers*, the *gripper*, and the *wrist*. They can be either standard commercially available mechanisms or specially designed tools, or can be complex systems in themselves (e.g., welding tools or dextrous hands). Sensors can be incorporated in the fingers, the gripper mechanism, or the wrist mechanism. All end effectors, end-of-arm tooling, and supply hoses and cables (electrical, pneumatic, etc.) must be taken into account when considering the manipulator payload weight limits of the manufacturer.

71.6.1 Part Fixtures and Robot Tooling

In most applications the end effector design problem should not be decoupled from the part fixturing design problem. One should consider the wrist, gripper, fingers, and part fixturing as a *single system*. Integrated design can often yield innovative solutions to otherwise intractable problems; nonintegrated design can often lead to unforeseen problems and unexpected failure modes. Coordinated design of fixtures and end effectors can often avoid the use of high-level expensive sensors (e.g., vision) and/or complex feedback control systems that required overall coordinated control of the robot arm motion, the gripper action, and the part pose. An ideal example of a device that allows simplified control strategies is the **remote-center-of-compliance (RCC)** wrist in Figure 71.17(b), if correctly used.

FIGURE 71.15 Angular and parallel motion robot grippers: (a) angular motion gripper and (b) parallel motion gripper, open and closed. (Courtesy of Robo-Tech Systems, Gastonia, NC.)

FIGURE 71.16 Robot grippers: (a) center seeking gripper showing part contact by first finger and final closure by second finger and (b) Versagrip III adjustable three-finger gripper. (Courtesy of Robo-Tech Systems, Gastonia, NC.)

71.6.2 Grippers and Fingers

Commercial catalogs usually allow one to purchase end effector components separately, including fingers, grippers, and wrists. Grippers can be actuated either pneumatically or using servomotors. Pneumatic actuation is usually either open or closed, corresponding to a binary command to turn the air pressure either off or on. Grippers often lock into place when the fingers are closed to offer failsafe action if air pressure fails. Servomotors often require analog commands and are used when finer gripper control is required. Available gripping forces span a wide range up to several hundred pounds force.

71.6.2.1 Gripper Mechanisms

Angular motion grippers, see Figure 71.15a, are inexpensive devices allowing grasping of parts either externally or internally (e.g., fingers insert into a tube and gripper presses them outward). The fingers can often open or close by 90° . These devices are useful for simple pick-and-place operations. In electronic assembly or tasks where precise part location is needed, it is often necessary to use *parallel grippers*, see Figure 71.15b, where the finger actuation affords exactly parallel closing motion. Parallel grippers generally have a far smaller range of fingertip motion that angular grippers (e.g., less than 1 in). In some cases, such as electronic assembly of parts positioned by wires, one requires *center seeking grippers*, see Figure 71.16a, where the fingers are closed until one finger contacts the part, then that finger stops and the other finger closes until the part is grasped.

There are available many grippers with advanced special-purpose mechanisms, including Robo-Tech's Versagrip III shown in [Figure 71.16b](#), a 3-fingered gripper whose fingers can be rotated about a longitudinal axis to offer a wide variety of 3-fingered grasps depending on the application and part geometry. Finger rotation is affected using a fine motion servomotor that can be adjusted as the robot arm moves.

The gripper and/or finger tips can have a wide variety of sensors including binary part presence detectors, binary closure detectors, analog finger position sensors, contact force sensors, temperature sensors, and so on ([Section 71.7](#)).

71.6.2.2 The Grasping Problem and Fingers

The study of the *multifinger grasping problem* is a highly technical area using mathematical and mechanical engineering analysis techniques such as rolling/slipping concepts, friction studies, force balance and center of gravity studies, etc. [Pertin-Trocac 1989]. These ideas may be used to determine the required gripper mechanisms, number of fingers, and finger shapes for a specific application. Fingers are usually specially designed for particular applications, and may be custom ordered from end-effector supply houses. Improper design and selection of fingers can doom to failure an application of an expensive robotic system. By contrast, innovative finger and contact tip designs can solve difficult manipulation and grasping problems and greatly increase automation reliability, efficiency, and economic return.

Fingers should not be thought of as being restricted to anthropomorphic forms. They can have vacuum contact tips for grasping smooth fragile surfaces (e.g., auto windshields), electromagnetic tips for handling small ferrous parts, compliant bladders or wraparound air bladders for odd-shaped or slippery parts, Bernoulli effect suction for thin fragile silicon wafers, or membranes covering a powder to distribute contact forces for irregular soft fragile parts [Wright and Cutkosky 1985].

Multipurpose grippers are advantageous in that a single end effector can perform multiple tasks. Some multipurpose devices are commercially available; they are generally expensive. The ideal multipurpose end effector is the *anthropomorphic dextrous hand*. Several dextrous robot hands are now available and afford potential applications in processes requiring active manipulation of parts or handling of many sorts of tooling. Currently, they are generally restricted to research laboratories since the problems associated with their expense, control, and coordination are not yet completely and reliably solved.

71.6.3 Robot Wrist Mechanisms

Wrist mechanisms couple the gripper to the robot arm, and can perform many functions. Commercial *adapter plates* allow wrists to be mounted to any commercially available robot arm. As an alternative to expensive multipurpose grippers, *quick change wrists* allow end effectors to be changed quickly during an application, and include quick disconnect couplings for mechanical, electrical, pneumatic and other connections. Using a quick change wrist, required tools can be selected from a magazine of available tools/end effectors located at the workcell. If fewer tools are needed, an alternative is provided by inexpensive *pivot gripper wrists*, such as the 2-gripper-pivot device shown in [Figure 71.17a](#), which allows one of two grippers to be rotated into play. With this device, one gripper can unload a machine while the second gripper subsequently loads a new blank into the machine. Other *rotary gripper wrists* allow one of several (up to six or more) grippers to be rotated into play. With these wrists, the grippers are mounted in parallel and rotate much like the chamber of an old-fashioned western Colt 45 revolver; they are suitable if the grippers will not physically interfere with each other in such a parallel configuration.

Safety wrists automatically deflect, sending a fault signal to the machine or job coordinator, if the end-of-arm tooling collides with a rigid obstacle. They may be reset automatically when the obstacle is removed.

Part positioning errors frequently occur due to robot end effector positioning errors, part variations, machine location errors, or manipulator repeatability errors. It is unreasonable and expensive to require the robot joint controller to compensate exactly for such errors. *Compliant wrists* offset positioning errors to a large extent by allowing small passive part motions in response to forces or torques exerted on the

FIGURE 71.17 Robot wrists. (a) Pivot gripper wrist. (Courtesy of Robo-Tech Systems, Gastonia, NC.) (b) Remote-center-of-compliance (RCC) wrist. (Courtesy of Lord Corporation, Erie, PA.)

part. An example is pin insertion, where small positioning errors can result in pin breakage or other failures, and compensation by gross robot arm motions requires sophisticated (e.g., expensive) force-torque sensors and advanced (e.g., expensive) closed-loop feedback force control techniques. The compliant wrist allows the pin to effectively adjust its own position in response to sidewall forces so that it slides into the hole. A particularly effective device is the remote-center-of-compliance (RCC) wrist, Figure 71.17b, where the rotation point of the wrist can be adjusted to correspond, e.g., to the part contact point [Groover et al. 1986]. Compliant wrists allow successful assembly where vision or other expensive sensors would otherwise be needed.

The wrist can contain a wide variety of sensors, with possibly the most important class being the *wrist force-torque sensors* (Section 71.7), which are quite expensive. A general rule-of-thumb is that, for economic and control complexity reasons, robotic force/torque sensing and control should be performed at the lowest possible level; e.g., fingertip sensors can often provide sufficient force information for most applications, with an RCC wrist compensating for position inaccuracies between the fingers and the parts.

71.6.4 Robot/Tooling Process Integration and Coordination

Many processes require the design of sophisticated end-of-arm tooling. Examples include spray painting guns, welding tools, multipurpose end effectors, and so on. Indeed, in some processes the complexity of the tooling can rival or exceed the complexity of the robot arm that positions it. Successful coordination and sequencing of the robot manipulator, the end effector, and the end-of-arm tooling calls for a variety of considerations at several levels of abstraction in Figure 71.7.

There are two philosophically distinct points of view that may be used in considering the robot manipulator plus its end-of-arm tooling. In the first, the robot plus tooling is viewed as a *single virtual agent* to be assigned by an upper-level organizer/manager and commanded by a midlevel job coordinator. In this situation, all machine-level robot/tool coordination may be performed by the internal virtual robot machine coordinator shown in Figure 71.7. This point of view is natural when the robot must perform sophisticated trajectory motion during the task and the tool is unintelligent, such as in pick-and-place operations, surface finishing, and grinding. In such situations, the end effector is often controlled by simple binary on/off or open/close commands through digital input/output signals from the machine coordinator. Many commercially available robot controllers allow such communications and support coordination through their programming languages (Section 71.12).

In the second viewpoint, one considers the manipulator as a dumb platform that positions the tooling or maintains its relative motion to the workpiece while the tooling performs a job. This point of view may be taken in the case of processes requiring sophisticated tooling such as welding. In this situation, the robot manipulator and the tooling may be considered as *two separate agents* which are coordinated by the higher level job coordinator shown in Figure 71.7.

A variety of processes fall between these two extremes, such as assembly tasks which require some coordinated intelligence by both the manipulator and the tool (insert pin in hole). In such applications both machine-level and task-level coordination may be required. The decomposition of coordination commands into a portion suitable for machine-level coordination and a portion for task-level coordination is not easy. A rule-of-thumb is that any coordination that is invariant from process to process should be apportioned to the lower level (e.g., do not open gripper while robot is in motion). This is closely connected to the appropriate definition of robot/tooling behaviors in the fashion of Brooks [1986].

71.7 Sensors

Sensors and actuators [Tzou and Fukuda 1992] function as *transducers*, devices through which the workcell planning, coordination, and control system interfaces with the hardware components that make up the workcell. Sensors are a vital element as they convert states of physical devices into signals appropriate for input to the workcell PC&C control system; inappropriate sensors can introduce errors that make proper operation impossible no matter how sophisticated or expensive the PC&C system, whereas innovative selection of sensors can make the control and coordination problem much easier.

71.7.1 The Philosophy of Robotic Workcell Sensors

Sensors are of many different types and have many distinct uses. Having in mind an analogy with biological systems, *proprioceptors* are sensors internal to a device that yield information about the internal state of that device (e.g., robot arm joint-angle sensors). *Exteroceptors* yield information about other hardware external to a device. Sensors yield outputs that are either analog or digital; digital sensors often provide information about the status of a machine or resource (grripper open or closed, machine loaded, job complete). Sensors produce inputs that are required at all levels of the PC&C hierarchy, including uses for:

- Servo-level feedback control (usually analog proprioceptors)
- Process monitoring and coordination (often digital exteroceptors or part inspection sensors such as vision)
- Failure and safety monitoring (often digital, e.g., contact sensor, pneumatic pressure-loss sensor)
- Quality control inspection (often vision or scanning laser)

Sensor output data must often be processed to convert it into a form meaningful for PC&C purposes. The sensor plus required signal processing is shown as a *virtual sensor* in Figure 71.7; it functions as a *data abstraction*, that is, a set of data plus operations on that data (e.g., camera, plus framegrabber, plus signal processing algorithms such as image enhancement, edge detection, segmentation, etc.). Some sensors, including the proprioceptors needed for servo-level feedback control, are integral parts of their host devices, and so processing of sensor data and use of the data occurs within that device; then, the sensor data is incorporated at the servocontrol level or machine coordination level. Other sensors, often vision systems, rival the robot manipulator in sophistication and are coordinated by the job coordinator, which treats them as valuable shared resources whose use is assigned to jobs that need them by some priority assignment (e.g., dispatching) scheme. An interesting coordination problem is posed by so-called *active sensing*, where, e.g., a robot may hold a scanning camera, and the camera effectively takes charge of the coordination problem, directing the robot where to move it to effect the maximum reduction in entropy (increase in information) with subsequent images.

71.7.2 Types of Sensors

This section summarizes sensors from an operational point of view. More information on functional and physical principles can be found in Fraden [1993], Fu et al. [1987], Groover et al. [1986], and Snyder [1985].

71.7.2.1 Tactile Sensors

Tactile sensors [Nichols and Lee 1989] rely on physical contact with external objects. Digital sensors such as limit switches, microswitches, and vacuum devices give binary information on whether contact occurs or not. Sensors are available to detect the onset of slippage. Analog sensors such as spring-loaded rods give more information. Tactile sensors based on rubberlike carbon- or silicon-based *elastomers* with embedded electrical or mechanical components can provide very detailed information about part geometry, location, and more. Elastomers can contain resistive or capacitive elements whose electrical properties change as the elastomer compresses. Designs based on LSI technology can produce *tactile grid pads* with, e.g., 64×64 *forcels* points on a single pad. Such sensors produce *tactile images* that have properties akin to digital images from a camera and require similar data processing. Additional tactile sensors fall under the classification of force sensors discussed subsequently.

71.7.2.2 Proximity and Distance Sensors

The noncontact proximity sensors include devices based on the Hall effect or inductive devices based on the electromagnetic effect that can detect ferrous materials within about 5 mm. Such sensors are often digital, yielding binary information about whether or not an object is near. Capacitance-based sensors detect any nearby solid or liquid with ranges of about 5 mm. Optical and ultrasound sensors have longer ranges.

Distance sensors include time-of-flight range finder devices such as sonar and lasers. The commercially available Polaroid sonar offers accuracy of about 1 in up to 5 ft, with angular sector accuracy of about 15° . For 360° coverage in navigation applications for mobile robots, both scanning sonars and ring-mounted multiple sonars are available. Sonar is typically noisy with spurious readings, and requires low-pass filtering and other data processing aimed at reducing the false alarm rate. The more expensive laser range finders are extremely accurate in distance and have very high angular resolution.

71.7.2.3 Position, Velocity, and Acceleration Sensors

Linear position-measuring devices include linear potentiometers and the sonar and laser range finders just discussed. Linear velocity sensors may be laser- or sonar-based Doppler-effect devices.

Joint-angle position and velocity proprioceptors are an important part of the robot arm servocontrol drive axis. Angular position sensors include potentiometers, which use dc voltage, and *resolvers*, which use ac voltage and have accuracies of ± 15 min. Optical encoders can provide extreme accuracy using digital techniques. *Incremental optical encoders* use three optical sensors and a single ring of alternating opaque/clear areas, [Figure 71.18a](#), to provide angular position relative to a reference point and angular velocity information; commercial devices may have 1200 slots per turn. More expensive *absolute optical encoders*, [Figure 71.18b](#), have n concentric rings of alternating opaque/clear areas and require n optical sensors. They offer increased accuracy and minimize errors associated with data reading and transmission, particularly if they employ the *Grey code*, where only one bit changes between two consecutive sectors. Accuracy is $360^\circ/2^n$, with commercial devices having $n = 12$ or so.

Gyros have good accuracy if repeatability problems associated with drift are compensated for. Directional gyros have accuracies of about $\pm 1.5^\circ$; vertical gyros have accuracies of 0.15° and are available to measure multiaxis motion (e.g., pitch and roll). Rate gyros measure velocities directly with thresholds of $0.05^\circ/\text{s}$ or so.

Various sorts of accelerometers are available based on strain gauges (next paragraph), gyros, or crystal properties. Commercial devices are available to measure accelerations along three axes.

71.7.2.4 Force and Torque Sensors

Various torque sensors are available, though they are often not required; for instance, the internal torques at the joints of a robot arm can be computed from the motor armature currents. Torque sensors on a drilling tool, for instance, can indicate when tools are dull. Linear force can be measured using load cells or strain gauges. A strain gauge is an elastic sensor whose resistance is a function of applied strain or deformation. The piezoelectric effect, the generation of a voltage when a force is applied, may also be

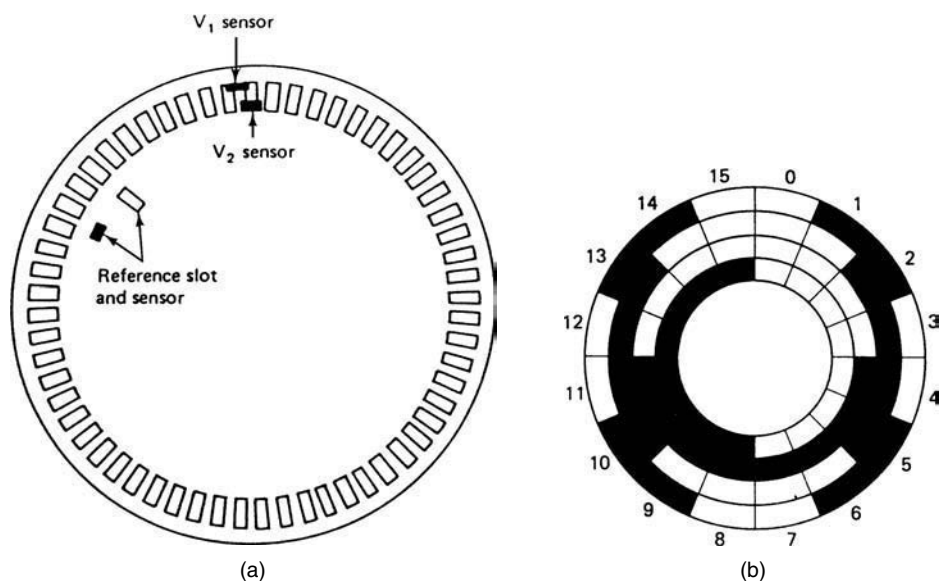

FIGURE 71.18 Optical encoders: (a) incremental optical encoder and (b) absolute optical encoder with $n = 4$ using Grey code (From Snyder, W. E. 1985. *Industrial Robots: Computer Interfacing and Control*. Prentice-Hall, Englewood Cliffs, NJ. With permission.)

used for force sensing. Other force sensing techniques are based on vacuum diodes, quartz crystals (whose resonant frequency changes with applied force), etc.

Robot arm force-torque wrist sensors are extremely useful in dextrous manipulation tasks. Commercially available devices can measure both force and torque along three perpendicular axes, providing full information about the Cartesian force vector \mathbf{F} . Transformations such as Equation 71.6 allow computation of forces and torques in other coordinates. Six-axis force-torque sensors are quite expensive.

71.7.2.5 Photoelectric Sensors

A wide variety of photoelectric sensors are available, some based on fiber optic principles. These have speeds of response in the neighborhood of $50 \mu\text{s}$ with ranges up to about 45 mm, and are useful for detecting parts and labeling, scanning optical bar codes, confirming part passage in sorting tasks, etc.

71.7.2.6 Other Sensors

Various sensors are available for measuring pressure, temperature, fluid flow, etc. These are useful in closed-loop servocontrol applications for some processes such as welding, and in job coordination and/or safety interrupt routines in others.

71.7.3 Sensor Data Processing

Before any sensor can be used in a robotic workcell, it must be *calibrated*. Depending on the sensor, this could involve significant effort in experimentation, computation, and tuning after installation. Manufacturers often provide calibration procedures though in some cases, including vision, such procedures may not be obvious, requiring reference to the published scientific literature. Time-consuming recalibration may be needed after any modifications to the system.

Particularly for more complex sensors such as optical encoders, significant sensor signal conditioning and processing is required. This might include amplification of signals, noise rejection, conversion of data from analog to digital or from digital to analog, and so on. Hardware is usually provided for such purposes

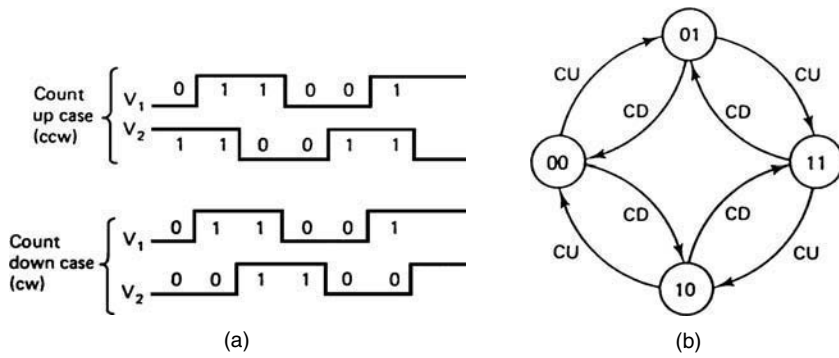

FIGURE 71.19 Signal processing using FSM for optical encoders: (a) phase relations in incremental optical encoder output and (b) finite state machine to decode encoder output into angular position. (From Snyder, W. E. 1985).

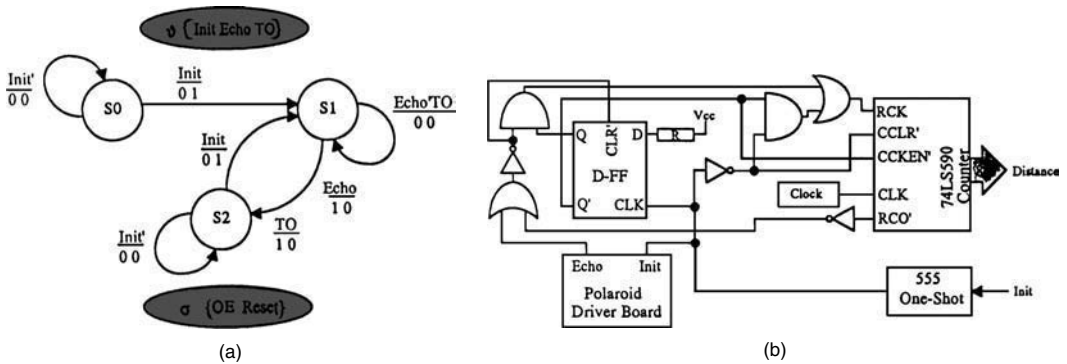

FIGURE 71.20 Hardware design from FSM: (a) FSM for sonar transducer control on a mobile robot and (b) sonar driver control system from FSM.

by the manufacturer and should be considered as part of the sensor package for robot workcell design. The sensor, along with its signal processing hardware and software algorithms may be considered as a data abstraction and is called the *virtual sensor* in Figure 71.7.

If signal processing does need to be addressed, it is often very useful to use *finite state machine* (FSM) design. A typical signal from an incremental optical encoder is shown in Figure 71.19a; a FSM for decoding this into the angular position is given in Figure 71.19b. FSMs are very easy to convert directly to hardware in terms of logical gates. A FSM for sequencing a sonar is given in Figure 71.20a; the sonar driver hardware derived from this FSM is shown in Figure 71.20b.

A particular problem is obtaining angular velocity from angular position measurements. All too often the position measurements are simply differenced using a small sample period to compute velocity. This is guaranteed to lead to problems if there is any noise in the signal. It is almost always necessary to employ a low-pass-filtered derivative where velocity samples v_k are computed from position measurement samples p_k using, e.g.,

$$v_k = \alpha v_{k-1} + (1 - \alpha)(p_k - p_{k-1})/T \quad (71.18)$$

where T is the sample period and α is a small filtering coefficient. A similar approach is needed to compute acceleration.

71.7.4 Vision for Robotics

Computer vision is covered in [Chapter 43](#); the purpose of this section is to discuss some aspects of vision that are unique to robotics [Fu et al. 1987, Lee et al. 1991, 1994]. Industrial robotic workcells often require vision systems that are reliable, accurate, low cost, and rugged yet perform sophisticated image processing and decision making functions. Balancing these conflicting demands is not always easy. There are several commercially available vision systems, the most sophisticated of which may be the Adept vision system, which supports multiple cameras. However, it is sometimes necessary to design one's own system. Vision may be used for three purposes in robotic workcells: inspection and quality control, robotic manipulation, and servo-level feedback control. In quality control inspection systems the cameras are often affixed to stationary mounts while parts pass on a conveyor belt. In *active vision* inspection systems, cameras may be mounted as end effectors of a robot manipulator, which positions the camera for the required shots.

The operational phase of robot vision has six principal areas. *Low-level vision* includes *sensing* and *preprocessing* such as noise reduction, image digitization if required, and edge detection. Medium-level vision includes *segmentation*, *description*, and *recognition*. High-level vision includes *interpretation* and *decision making*. Such topics are discussed in [Chapter 32](#). Prior to placing the vision system in operation, one is faced with several design issues including camera selection and illumination techniques, and the problem of system *calibration*.

71.7.4.1 Cameras and Illumination

Typical commercially available vision systems conform to the RS-170 standard of the 1950s, so that frames are acquired through a framegrabber board at a rate of 30 frames/s. Images are scanned; in a popular U.S. standard, each complete scan or *frame* consists of 525 lines of which 480 contain image information. This sample rate and image resolutions of this order are adequate for most applications with the exception of vision-based robot arm servoing (discussed subsequently). Robot vision system cameras are usually TV cameras: either the solid-state charge-coupled device (CCD), which is responsive to wavelengths of light from below 350 nm (ultraviolet) to 1100 nm (near infrared) and has peak response at approximately 800 nm, or the charge injection device (CID), which offers a similar spectral response and has a peak response at approximately 650 nm. Both *line-scan* CCD cameras, having resolutions ranging between 256 and 2048 elements, and *area-scan* CCD cameras are available. Medium-resolution area-scan cameras yield images of 256×256 , though high-resolution devices of 1024×1024 are by now available. Line-scan cameras are suitable for applications where parts move past the camera, e.g., on conveyor belts. Framegrabbers often support multiple cameras, with a common number being four, and may support black-and-white or color images.

If left to chance, illumination of the robotic workcell will probably result in severe problems in operations. Common problems include low-contrast images, specular reflections, shadows, and extraneous details. Such problems can be corrected by overly sophisticated image processing, but all of this can be avoided by some proper attention to details at the workcell design stage. Illumination techniques include spectral filtering, selection of suitable spectral characteristics of the illumination source, diffuse-lighting techniques, backlighting (which produces easily processed silhouettes), structured-lighting (which provides additional depth information and simplifies object detection and interpretation), and directional lighting.

71.7.4.2 Coordinate Frames and Camera Perspective Transformation

A typical robot vision system is depicted in [Figure 71.21](#), which shows a gimball-mounted camera. There are illustrated the base frame (or world frame) (X, Y, Z) , the gimball platform, the camera frame (x, y, z) , and the *image plane* having coordinates of (ξ, ν) .

71.7.4.2.1 Image Coordinates of a Point in Base Coordinates

The primary tools for analysis of robot vision systems are the notion of *coordinate transforms* and the camera *perspective transformation*. Four-by-four *homogeneous transformations* (discussed earlier) are used, as they provide information on translations, rotations, scaling, and perspective.

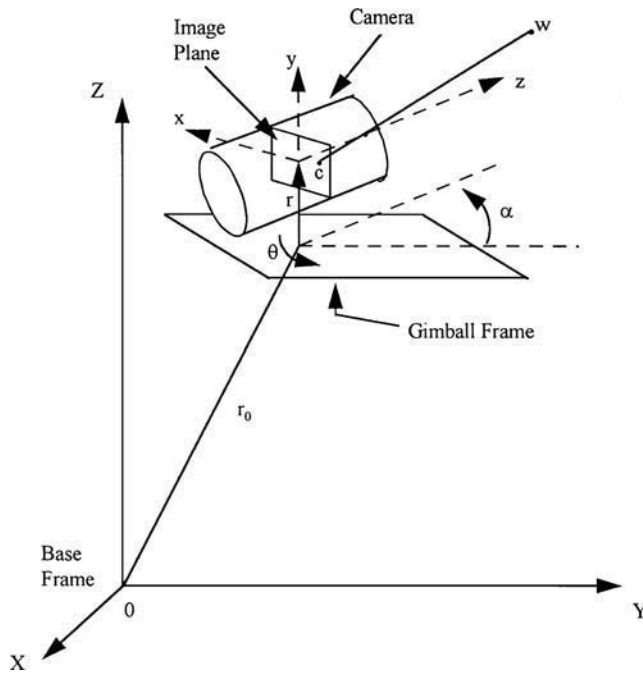

FIGURE 71.21 Typical robot workcell vision system.

FIGURE 71.22 Homogeneous transformations associated with the robot vision system.

Four homogeneous transformations may be identified in the vision system, as illustrated in Figure 71.22. The gimball transformation G represents the base frame in coordinates affixed to the gimball platform. If the camera is mounted on a robot end effector, G is equal to T^{-1} , with T the robot arm T matrix detailed in earlier in Section 71.5; for a stationary-mounted camera G is a constant matrix capturing the camera platform mounting offset $r_0 = [X_0 \ Y_0 \ Z_0]^T$. The pan/tilt transformation R represents the gimball platform with respect to the mounting point of the camera. This rotation transformation is given by

$$R = \begin{bmatrix} \cos \theta & \sin \theta & 0 & 0 \\ -\sin \theta \cos \alpha & \cos \theta \cos \alpha & \sin \alpha & 0 \\ \sin \theta \sin \alpha & -\cos \theta \sin \alpha & \cos \alpha & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad (71.19)$$

with θ the pan angle and α the tilt angle. C captures the offset $r = [r_x \ r_y \ r_z]^T$ of the camera frame with respect to the gimball frame. Finally, the perspective transformation

$$\begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & -\frac{1}{\lambda} & 1 \end{bmatrix} \quad (71.20)$$

projects a point represented in camera coordinates (x, y, z) onto a position (ξ, υ) in the image, where λ is the camera focal length.

In terms of these constructions, the image position of a point w represented in base coordinates as (X, Y, Z) is given by the *camera transform equation*

$$c = PCRGw \quad (71.21)$$

which evaluates in the case of a stationary-mounted camera to the image coordinates

$$\begin{aligned} \xi &= \lambda \frac{(X - X_0) \cos \theta + (Y - Y_0) \sin \theta - r_x}{-(X - X_0) \sin \theta \sin \alpha + (Y - Y_0) \cos \theta \sin \alpha - (Z - Z_0) \cos \alpha + r_z + \lambda} \\ v &= \lambda \frac{-(X - X_0) \sin \theta \cos \alpha + (Y - Y_0) \cos \theta \cos \alpha + (Z - Z_0) \sin \alpha - r_y}{-(X - X_0) \sin \theta \sin \alpha + (Y - Y_0) \cos \theta \sin \alpha - (Z - Z_0) \cos \alpha + r_z + \lambda} \end{aligned} \quad (71.22)$$

71.7.4.2.2 Base Coordinates of a Point in Image Coordinates

In applications, one often requires the inverse of this transformation; that is, from the image coordinates (ξ, v) of a point one wishes to determine its base coordinates (X, Y, Z) . Unfortunately, the perspective transformation P is a *projection* which loses depth information z , so that the inverse perspective transformation P^{-1} is not unique. To compute unique coordinates in the base frame one therefore requires either two cameras, the ultimate usage of which leads to *stereo imaging*, or multiple shots from a single moving camera. Many techniques have been developed for accomplishing this.

71.7.4.2.3 Camera Calibration

Equation 71.22 has several parameters, including the camera offsets r_0 and r and the focal length λ . These values must be known prior to operation of the camera. They may be measured, or they may be computed by taking images of points w_i with known base coordinates (X_i, Y_i, Z_i) . To accomplish this, one must take at least six points w_i and solve a resulting set of nonlinear simultaneous equations. Many procedures have been developed for accomplishing this by efficient algorithms.

71.7.4.3 High-Level Robot Vision Processing

Besides scene interpretation, other high-level vision processing issues must often be confronted, including decision making based on vision data, relation of recognized objects to stored CAD data of parts, recognition of faults or failures from vision data, and so on. Many technical papers have been written on all of these topics.

71.7.4.4 Vision-Based Robot Manipulator Servoing

In standard robotic workcells, vision is not often used for servo-level robot arm feedback control. This is primarily due to the facts that less expensive lower level sensors usually suffice, and reliable techniques for vision-based servoing are only now beginning to emerge. In vision-based servoing the standard frame rate of 30 ft/s is often unsuitable; higher frame rates are often needed. This means that commercially available vision systems cannot be used. Special purpose cameras and hardware have been developed by several researchers to address this problem, including the vision system in Lee and Blenis [1994].

Once the hardware problems have been solved, one has yet to face the design problem for real-time servocontrollers with vision components in the feedback loop. This problem may be attacked by considering the nonlinear dynamical system 71.7 with measured outputs given by combining the camera transformation 71.21 and the arm kinematics transformation 71.2 [Ghosh et al. 1994].

71.8 Workcell Planning

Specifications for workcell performance vary at distinct levels in the workcell planning, coordination, and control architecture in Figure 71.7. At the machine servocontrol level, motion specifications are given in terms of continuous trajectories in joint space sampled every 16 ms. At the job coordination level, motion specifications are in terms of Cartesian path via points, generally nonuniformly spaced, computed

to achieve a prescribed task. Programming at these lower levels involves tedious specifications of points, motions, forces, and times of transit. The difficulties involved with such low-level programming have led to requirements for *task-level programming*, particularly in modern robot workcells which must be flexible and reconfigurable as products vary in response to the changing desires of customers. The function of the workcell planner is to allow task-level programming from the workcell manager by performing *task planning and decomposition* and *path planning*, thereby automatically providing the more detailed specifications required by the job coordinator and servo-level controllers.

71.8.1 Workcell Behaviors and Agents

The virtual machines and virtual sensors in the (PC&C) architecture of [Figure 71.7](#) are constructed using the considerations discussed in previous sections. These involve commercial robot selection, robot kinematics and servo-level control, end effectors and tooling, and sensor selection and calibration. The result of design at these levels is a set of workcell *agents* — robots, machines, or sensors — each with a set of behaviors or *primitive actions* that each workcell agent is capable of. For instance, proper design could allow a robot agent to be capable of behaviors including accurate motion trajectory following, tool changing, force-controlled grinding on a given surface, etc. A camera system might be capable of identifying all Phillips screw heads in a scene, then determining their coordinates and orientation in the base frame of a robot manipulator.

Given the workcell agents with their behaviors, the higher level components in [Figure 71.7](#) must be able to assign tasks and then decompose them into a suitable sequencing of behaviors. In this and the next section are discussed the higher level PC&C components of workcell planning and job coordination.

71.8.2 Task Decomposition and Planning

A *task* is a specific goal that must be accomplished, often by an assigned *due date*. These goals may include completed robotic processes (e.g., weld seam), finished products, and so on. Tasks are accomplished by a sequence of *jobs* that, when completed, result in the achievement of the final goal. *Jobs* are specific primitive activities that are accomplished by a well-defined set of resources or agents (e.g., drill hole, load machine). Once a resource has been assigned to a job it can be interpreted as a behavior. To attain the task goal, jobs must usually be performed in some *partial ordering*, e.g., tasks *a* and *b* are immediate prerequisites for task *c*. The jobs are not usually completely ordered, but have some possibility for concurrency.

At the workcell management level, tasks are assigned, along with their due dates, without specifying details of resource assignment or selection of specific agents. At the job coordination level, the required specifications are in terms of sequences of jobs, with resources assigned, selected to achieve the assigned goal tasks. The function of the workcell planner is to convert between these two performance specification paradigms. In the task planning component, two important transformations are made. First, assigned *tasks are decomposed into the required job sequences*. Second, workcell agents and *resources are assigned* to accomplish the individual jobs. The result is a task plan that is passed for execution to the job coordinator.

71.8.2.1 Task Plan

A *task plan* is a sequence of jobs, along with detailed resource assignments, that will lead to the desired goal task. Jobs with assigned resources can be interpreted as behaviors. Plans should not be overspecified — the required job sequencing is usually only a partial ordering, often with significant concurrency remaining among the jobs. Thus, some decisions based on real-time workcell status should be left to the job coordinator; among these are the final detailed sequencing of the jobs and any *dispatching* and *routing* decisions where shared resources are involved.

71.8.2.2 Computer Science Planning Tools

There are well-understood techniques in computer science that can be brought to bear on the robot task planning problem [Fu et al. 1987]. Planning and scheduling is covered in [Chapter 67](#), decision trees in

Chapter 65, search techniques in Chapter 30, and decision making under uncertainty in Chapter 70; all of these are relevant to this discussion. However, the structure of the robotic workcell planning problem makes it possible to use some refined and quite rigorous techniques in this chapter, which are introduced in the next subsections.

Task planning can be accomplished using techniques from problem solving and learning, especially learning by analogy. By using *plan schema* and other *replanning* techniques, it is possible to modify existing plans when goals or resources change by small amounts. *Predicate logic* is useful for representing knowledge in the task planning scenario and many problem solving software packages are based on production systems.

Several task planning techniques use *graph theoretic* notions that can be attacked using search algorithms such as A^* . *State-space search techniques* allow one to try out various approaches to solving a problem until a suitable solution is found: the set of states reachable from a given initial state forms a graph. A plan is often represented as a finite state machine, with the states possibly representing jobs or primitive actions. *Problem reduction* techniques can be used to decompose a task into smaller subtasks; in this context it is often convenient to use AND/OR graphs. *Means-ends analysis* allows both forward and backward search techniques to be used, solving the main parts of a problem first and then going back to solve smaller subproblems.

For workcell assembly and production tasks, product data in CAD form is usually available. Assembly task planning involves specifying a sequence of assembly, and possibly process, steps that will yield the final product in finished form. *Disassembly planning techniques* work backwards from the final product, performing part disassembly transformations until one arrives at the initial raw materials. Care must be taken to account for part obstructions, etc. The relationships between parts should be specified in terms of symbolic spatial relationships between *object features* (e.g., place $block_1$ - $face_2$ against $wedge_2$ - $face_3$ and $block_1$ - $face_1$ against $wedge_2$ - $face_1$ or place pin in slot). *Constructive solid geometric* techniques lead to graphs that describe objects in terms of features related by set operations such as intersection, union, etc.

71.8.2.3 Industrial Engineering Planning Tools

In industrial engineering there are well-understood design tools used for product assembly planning, process planning, and resource assignment; they should be used in workcell task planning. The *bill of materials* (BOM) for a product is a computer printout that breaks down the various subassemblies and component parts needed for the product. It can be viewed as a matrix B whose elements $B(i, j)$ are set to 1 if subassembly j is needed to produce subassembly i . This matrix is known as *Steward's Sequencing Matrix*; by studying it one can decompose the assembly process into hierarchically interconnected subsystems of subassemblies [Warfield 1973], thereby allowing parallel processing and simplification of the assembly process. The *assembly tree* [Wolter et al. 1992] is a graphical representation of the BOM.

The *resource requirements matrix* is a matrix R whose elements $R(i, j)$ are set equal to 1 if resource j is required for job i . The resources may include machines, robots, fixtures, tools, transport devices, and so on. This matrix has been used by several workers for analysis and design of manufacturing systems; it is very straightforward to write down given a set of jobs and available resources. The *subassembly tree* is an assembly tree with resource information added.

71.8.3 Task Matrix Approach to Workcell Planning

Plans can often be specified as finite state machines. However, in the robot workcell case, FSM are neither general enough to allow versatile incorporation of workcell status and sensor information, nor specific enough to provide all of the information needed by the job coordinator.

A very general robot workcell task plan can be completely specified by four *task plan matrices* [Lewis and Huang 1995]. The *job sequencing matrix* and *job start matrix* are independent of resources and carry the job sequencing information required for task achievement. Resources are subsequently added by constructing the *resource requirements matrix* and the *resource release matrix*. The function of the task planner is to construct these four matrices and pass them to the job coordinator, who uses them for job coordination, sequencing, and resource dispatching. The task plan matrices are straightforward to construct and are

FIGURE 71.23 Product information for task planning: (a) assembly tree with job sequencing information and (b) subassembly tree with resource information added to the jobs.

easy to modify in the event of goal changes, resource changes, or failures; that is, they accommodate task planning as well as *task replanning*.

The task planning techniques advocated here are illustrated through an assembly design example, which shows how to select the four task plan matrices. Though the example is simple, the technique extends directly to more complicated systems using the notions of *block matrix* (e.g., *subsystem*) design. First, job sequencing is considered, then the resources are added.

71.8.3.1 Workcell Task Decomposition and Job Sequencing

In Figure 71.23(a) is given an assembly tree which shows the required sequence of actions (jobs) to produce a product. This sequence may be obtained from stored product CAD data through disassembly techniques, etc. The assembly tree contains information analogous to the BOM; it does not include any resource information. Part *a* enters the workcell and is drilled to produce part *b*, then assembled with part *c* to produce part *d*, which is again drilled (part *e*) to result in part *f*, which is the cell output (*PO* denotes “product out”). The assembly tree imposes only a *partial ordering* on the sequence of jobs. It is important not to overspecify the task decomposition by imposing additional temporal orderings that are not required for job sequencing.

71.8.3.1.1 Job Sequencing Matrix

Referring to Figure 71.23a, define the *job vector* as $\mathbf{v} = [\mathbf{a} \ \mathbf{b} \ \mathbf{c} \ \mathbf{d} \ \mathbf{e} \ \mathbf{f}]^T$. The Steward’s sequencing matrix F_v for the assembly tree in Figure 71.23a is then given by

$$F_v = \begin{matrix} & \mathbf{a} & \mathbf{b} & \mathbf{c} & \mathbf{d} & \mathbf{e} & \mathbf{f} \\ \mathbf{a} & \left[\begin{array}{cccccc} 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{array} \right] & & & & & \\ \mathbf{b} & & & & & & & \\ \mathbf{c} & & & & & & & \\ \mathbf{d} & & & & & & & \\ \mathbf{e} & & & & & & & \\ \mathbf{f} & & & & & & & \\ \mathbf{PO} & & & & & & & \end{matrix} \quad (71.23)$$

In this matrix, an entry of 1 in position (i, j) indicates that job *j* must be completed prior to starting job *i*. F_v is independent of available resources; in fact, regardless of the resources available, F_v will not change.

71.8.3.1.2 Sequencing State Vector and Job Start Equation

Define a *sequencing state vector* \mathbf{x} , whose components are associated with the vector $[\mathbf{a} \ \mathbf{b} \ \mathbf{c} \ \mathbf{d} \ \mathbf{e} \ \mathbf{f} \ \mathbf{PO}]^T$, that checks the conditions of the rules needed for job sequencing. The components of \mathbf{x} may be viewed as

situated between the nodes in the assembly tree. Then, the *job start equation* is

$$\mathbf{v}_s = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} \mathbf{x}_1 \\ \mathbf{x}_2 \\ \mathbf{x}_3 \\ \mathbf{x}_4 \\ \mathbf{x}_5 \\ \mathbf{x}_6 \\ \mathbf{x}_7 \end{bmatrix} \equiv S_v \mathbf{x} \quad (71.24)$$

where \mathbf{v}_s is the job start command vector. In the job start matrix S_v , an entry of 1 in position (i, j) indicates that job i can be started when component j of the sequencing state vector is active.

In this example, the matrix S_v has 1s in locations (i, i) so that S_v appears to be redundant. This structure follows from the fact that the assembly tree is an *upper semilattice*, wherein each node has a unique node above it; such a structure occurs in the manufacturing *re-entrant flowline with assembly*. In the more general *job shop* with variable part routings the semilattice structure of the assembly tree does not hold. Then, S_v can have multiple entries in a single column, corresponding to different routing options; nodes corresponding to such columns have more than one node above them.

71.8.3.2 Adding the Resources

To build a job dispatching coordination controller for shop-floor installation to perform this particular assembly task, the resources available must now be added. The issue of required and available resources is easily confronted as a *separate engineering design issue* from job sequence planning. In Figure 71.23b is given a *subassembly tree* for the assembly task, which includes resource requirements information. This information would in practice be obtained based on the resources and behaviors available in the workcell and could be assigned by a user during the planning stage using interactive software. The figure shows that part input *PIc* and part output (*PO*) do not require resources, pallets (*P*) are needed for part *a* and its derivative subassemblies, buffers (*B1, B2*) hold parts *a* and *e*, respectively, prior to drilling, and both drilling operations need the same machine (*M1*). The assembly operation is achieved by fixturing part *c* in fixture *F1* while robot *R1* inserts part *b*.

Note that drilling machine *M1* represents a *shared resource*, which performs two jobs, so that dispatching decision making is needed when the two drilling jobs are simultaneously requested, in order to avoid possible problems with *deadlock*. This issue is properly faced by the job coordinator in real-time, as shown in Section 71.9, not by the task planner. Shared resources impose *additional temporal restrictions* on the jobs that are not present in the job sequencing matrix; these are concurrency restrictions of the form: both drilling operations may not be performed simultaneously.

71.8.3.2.1 Resource Requirements (RR) Matrix

Referring to Figure 71.23b, define the *resource vector* as $\mathbf{r} = [R1A F1A B1A B2A PA M1A]^T$, where *A* denotes available. In the RR matrix F_r , a 1 in entry (i, j) indicates that resource j is needed to activate sequencing vector component \mathbf{x}_i (e.g., in this example, to accomplish job i). By inspection, therefore, one may write down the RR matrix

$$F_r = \begin{bmatrix} 0 & 0 & 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \quad (71.25)$$

Row 3, for instance, means that resource *F1A*, the fixture, is needed as a precondition for firing x_3 ; which matrix S_v associates with job *c*. Note that column 6 has two entries of 1, indicating that *M1* is a shared resource that is needed for two jobs *b* and *f*. As resources change or machines fail, the RR matrix is easily modified.

71.8.3.2.2 Resource Release Matrix

The last issue to be resolved in this design is that of *resource release*. Thus, using manufacturing engineering experience and Figure 71.23b, select the *resource release matrix* S_r in the resource release equation

$$\mathbf{r}_s = \begin{bmatrix} R1A_s \\ F1A_s \\ B1A_s \\ B2A_s \\ PA_s \\ M1A_s \end{bmatrix} = \begin{bmatrix} 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \\ x_5 \\ x_6 \\ x_7 \end{bmatrix} \equiv S_r \mathbf{x} \quad (71.26)$$

where subscript *s* denotes a command to the workcell to start resource release. In the resource release matrix S_r , a 1 entry in position (*i*, *j*) indicates that resource *i* is to be released when entry *j* of \mathbf{x} has become high (e.g., in this example, on completion of job *j*). It is important to note that rows containing multiple ones in S_r correspond to columns having multiple ones in F_r . For instance, the last row of S_r shows that *M1A* is a shared resource, since it is released after *either* x_4 is high or x_7 is high; that is, after either job *b* or job *f* is complete.

71.8.3.3 Petri Net from Task Plan Matrices

It will be shown in Section 71.9 that the four task plan matrices contain all of the information needed to implement a matrix-based job coordination controller on, for instance, a programmable logic workcell controller. However, there has been much discussion of uses of *Petri nets* in task planning. It is now shown that the four task plan matrices correspond to a Petri net (PN). The job coordinator would not normally be implemented as a Petri net; however, it is straightforward to derive the PN description of a manufacturing system from the matrix controller equations, as shown by the next result.

Theorem 71.1 (*Petri net from task plan matrices*) Given the four task plan matrices F_v, S_v, F_r, S_r , define the activity completion matrix F and the activity start matrix S as

$$F = [F_v \quad F_r], \quad S = \begin{bmatrix} S_v \\ S_r \end{bmatrix} \quad (71.27)$$

Define X as the set of elements of sequencing state vector \mathbf{x} , and A (activities) as the set of elements of the job and resource vectors \mathbf{v} and \mathbf{r} . Then (A, X, F, S^T) is a Petri net.

The theorem identifies F as the input incidence matrix and S^T as the output incidence matrix of a PN, so that the PN incidence matrix is given by

$$W = S^T - F = [S_v^T - F_v \quad S_r^T - F_r] \quad (71.28)$$

Based on the theorem, the PN in Figure 71.24 is easily drawn for this example. In the figure, initial markings have been added; this is accomplished by determining the *number of resources available* in the workcell. The inputs u_{D1}, u_{D2} are required for dispatching the shared resource *M1*, as discussed in Section 71.9. This theorem provides a formal technique for constructing a PN for a workcell task plan and allows all of

FIGURE 71.24 Petri net representation of workcell with shared resource.

the PN analysis tools to be used for analysis of the workcell plan. It formalizes some work in the literature (e.g., top-down and bottom-up design [Zhou et al. 1992]).

Behaviors. All of the PN transitions occur along the *job paths*. The places in the PN along the job paths correspond to jobs with assigned resources and can be interpreted as behaviors. The places off the task paths correspond to resource availability.

71.8.4 Path Planning

The path planning problem [Latombe 1991] may be decomposed into motion path planning, grasp planning, and error detection and recovery; only the first is considered here. *Motion path planning* is the process of finding a continuous path from an initial position to a prescribed final position or goal without collision. The output of the path planner for robotic workcells is a set of path *via points* which are fed to the machine trajectory generator (discussed previously). *Off-line path planning* can be accomplished if all obstacles are stationary at known positions or moving with known trajectories. Otherwise, *on-line or dynamic path planning* is required in real time; this often requires techniques of *collision or obstacle avoidance*. In such situations, paths preplanned off line can often be modified to incorporate collision avoidance. This subsection deals with off-line path planning except for the portion on the potential field approach, which is dynamic planning. See Zhou [1996] for more information.

Initial and final positions may be given in any coordinates, including the robot's joint space. Generally, higher level workcell components think in terms of Cartesian coordinates referred to some world frame. The Cartesian position of a robot end effector is given in terms of three position coordinates and three angular orientation coordinates; therefore, the general 3-D path planning problem occurs in \mathbb{R}^6 . If robot joint-space initial and final positions are given one may work in *configuration space*, in which points are specified by the joint variable vector \mathbf{q} having coordinates \mathbf{q}_j , the individual joint values. For a six-degrees-of-freedom arm, configuration space is also isomorphic to \mathbb{R}^6 . Path planning may also be carried out for initial and final values of *force/torque*. In 3-D, linear force has three components and torque has three components, again placing the problem in \mathbb{R}^6 . Hybrid position/force planning is also possible. In this subsection path planning techniques are illustrated in \mathbb{R}^2 , where it is convenient to think in terms of planning paths for mobile robots in a plane.

If the number of degrees of freedom of a robot is less than six, there could be problems in that the manipulator may not be able to reach the prescribed final position and the via points generated in the planning process. Thus, the path planner must be aware of the limitations of the individual robots in its planning process; in fact, it is usually necessary to select a specific robot agent for a task prior to planning the path in order to take such limitations into account.

(a) cell decomposition

(b) connectivity graph

FIGURE 71.25 Cell decomposition approach to path planning: (a) free space decomposed into cells using the vertical-line-sweep method and (b) connectivity graph for the decomposed space.

71.8.4.1 Cell Decomposition Approach

In the *cell decomposition approach to path planning*, objects are enclosed in polygons. The object polygons are expanded by an amount equal to the radius of the robot to ensure collision avoidance; then, the robot is treated simply as a moving point. The free space is decomposed into simply connected free-space regions within which any two points may be connected by a straight line. When the Euclidean metric is used to measure distance, convex regions satisfy the latter requirement. A sample cell decomposition is shown in Figure 71.25. The decomposition is not unique; the one shown is generated by sweeping a vertical line across the space. Based on the decomposed space, a *connectivity graph* may be constructed, as shown in the figure. To the graph may be added weights or costs at the arcs or the nodes, corresponding to distances traveled, etc. Then, graph search techniques may be used to generate the shortest, or otherwise least costly, path.

71.8.4.2 Road Map Based on Visibility Graph

In the road map approach the obstacles are modeled as polygons expanded by the radius of the robot, which is treated simply as a moving point. A **visibility graph** is a nondirected graph whose nodes are the vertices of the polygons and whose links are straight line segments connecting the nodes without intersecting any obstacles. A *reduced visibility graph* does not contain links that are dominated by other links in terms of distance. Figure 71.26 shows a reduced visibility graph for the free space. Weights may be assigned to the arcs or nodes and graph search techniques may be used to generate a suitable path. The weights can reflect shortest distance, path smoothness, etc.

71.8.4.2.1 Road Map Based on Voronoi Diagram

A **Voronoi diagram** is a diagram where the path segment lines have equal distance from adjacent obstacles. In a polygonal space, the Voronoi diagram consists of straight lines and parabolas: when both adjacent object segments are vertices or straight lines, the equidistant line is straight, when one object is characterized by a vertex and the other by a straight line, the equidistant line is parabolic. In the Voronoi approach, generated paths are generally longer than in the visibility graph approach, but the closest point of approach (CPA) to obstacles is maximized.

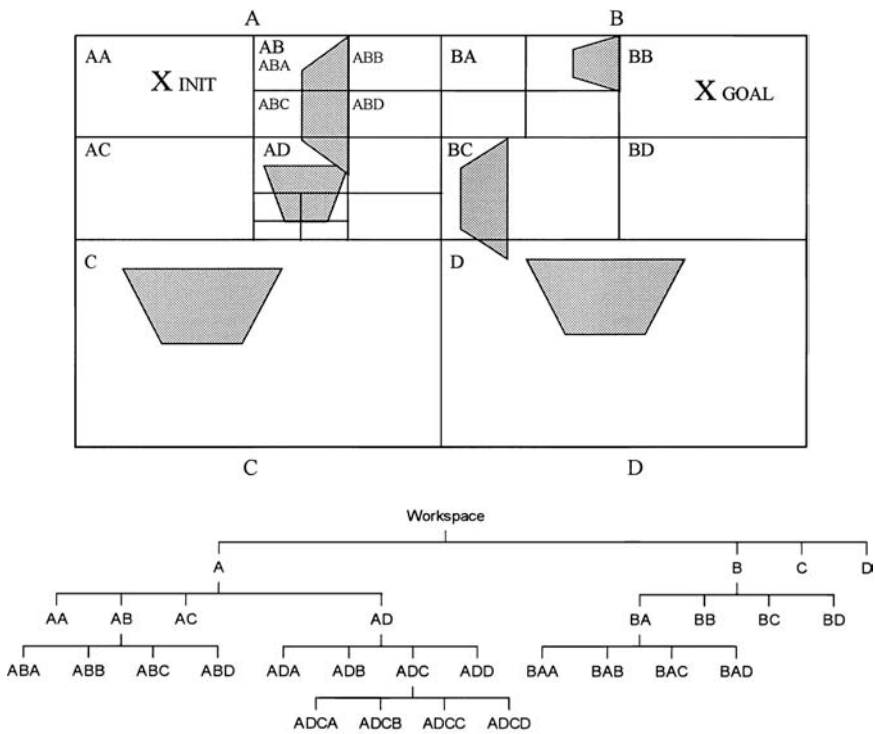

FIGURE 71.27 Quadtree approach to path planning: (a) quadtree decomposition of the work area and (b) quadtree constructed from space decomposition.

71.8.4.3 Quadtree Approach

In the quadtree approach, Figure 71.27a rectangular workspace is partitioned into four equal quadrants labeled A, B, C, D. Suppose the initial point is in quadrant A with the goal in quadrant B. If there are obstacles in quadrant A, it must be further partitioned into four quadrants AA, AB, AC, AD. Suppose the initial point is in AA, which also contains obstacles; then AA is further partitioned into quadrants AAA, AAB, AAC, AAD. This procedure terminates when there are no obstacles in the quadrant containing the initial point. A similar procedure is effected for the goal position. Based on this space decomposition, the quadtree shown in Figure 71.27b may be drawn. Now, tree search methods such as A^* may be used to determine the optimal obstacle-free path.

The quadtree approach has the advantage of partitioning the space only as finely as necessary. If any quadrant contains neither goal, initial point, nor obstacles, it is not further partitioned. If any quadrant containing the initial position or goal contains no obstacles, it is not further partitioned. In 3-D, this approach is called *octree*.

71.8.4.4 Maneuvering Board Solution for Collision Avoidance of Moving Obstacles

The techniques just discussed generate a set of via points between the initial and final positions. If there are moving obstacles within the free-space regions, one may often modify the paths between the via points online in real-time to avoid collision. If obstacles are moving with constant known velocities in the free space, a technique used by the U.S. Navy based on the *maneuvering board* can be used for on-line obstacle avoidance. Within a convex free-space region, generated for instance by the **cell decomposition** approach, one makes a *relative polar plot* with the moving robot at the center and other moving objects plotted as straight lines depending on their relative courses and speeds. A steady bearing and decreasing range (SBDR) indicates impending collision. Standard graphical techniques using a parallel ruler allow one to alter the robot's course and/or speed to achieve a prescribed CPA; these can be converted to explicit formulas for required course/speed changes. An advantage of this technique for mobile robots is that the coordinates of obstacles in the relative polar plot can be directly measured using onboard sonar and/or laser range finders. This technique can be modified into a *navigational technique* when some of the stationary obstacles have fixed absolute positions, such obstacles are known as *reference landmarks*.

71.8.4.5 Potential Field Approach

The potential field approach [Arkin 1989] is especially popular in mobile robotics as it seems to emulate the reflex action of a living organism. A fictitious attractive potential field is considered to be centered at the goal position (Figure 71.28a). Repulsive fields are selected to surround the obstacles (Figure 71.28b). The sum of the potential fields (Figure 71.28c) produces the robot motion as follows. Using $F(\mathbf{x}) = m\mathbf{a}$, with m the vehicle mass and $F(\mathbf{x})$ equal to the sum of the forces from the various potential fields computed at the current vehicle position \mathbf{x} , the required vehicle acceleration $\mathbf{a}(\mathbf{x})$ is computed. The resulting motion avoids obstacles and converges to the goal position. This approach does not produce a global path planned a priori. Instead, it is a real-time on-line motion control technique that can deal with moving obstacles, particularly if combined with maneuvering board techniques. Various methods have been proposed for selecting the potential fields; they should be limited to finite influence distances, or else the computation of the total force $F(\mathbf{x})$ requires knowledge of all obstacle relative positions.

The potential field approach is particularly convenient as the force F may be computed knowing only the *relative positions* of the goal and obstacles from the vehicle; this information is directly provided by onboard sonar and laser readings. The complete potential field does not need to be computed, only the force vector of each field acting on the vehicle. A problem with the potential field approach is that the vehicle may become trapped in *local minima* (e.g., an obstacle is directly between the vehicle and the goal); this can be corrected using various techniques, including adding a dither force to get the vehicle out of these false minima. The potential field approach can be combined with Lyapunov analysis techniques to integrate the path planning and trajectory following servocontrol functions of a mobile robot [Jagannathan et al. 1994].

In fact, Lyapunov functions and potential fields may simply be added in an overall controls design technique.

71.8.4.5.1 Emergent Behaviors

The responses to individual potential fields can be interpreted as *behaviors* such as seek goal, avoid obstacle, etc. Potential fields can be selected to achieve specialized behaviors such as *docking* (i.e., attaining a goal position with a prescribed angle of approach) and remaining in the center of a corridor (simply define repulsive fields from each wall). The sum of all of the potential fields yields an *emergent behavior* that has not been preprogrammed (e.g., seek goal while avoiding obstacle and remaining in the center of the hallway). This makes the robot exhibit behaviors that could be called intelligent or self-determined.

FIGURE 71.28 Potential field approach to navigation: (a) attractive field for goal at lower left corner, (b) repulsive fields for obstacles, (c) sum of potential fields, and (d) contour plot showing motion trajectory. (Courtesy of Zhou, C. 1996. Planning and intelligent control. In *CRC Handbook of Mechanical Engineering*. F. Kreith, Ed. CRC Press, Boca Raton, FL.)

71.9 Job and Activity Coordination

Coordination of workcell activities occurs on two distinct planes. On the *discrete event* (DE) or discrete activity plane, *job coordination* and sequencing, along with resource handling, is required. Digital input/output signals, or sequencing *interlocks*, are used between the workcell agents to signal job completion, resource availability, errors and exceptions, and so on. On a lower plane, servo-level motion/force coordination between multiple interacting robots is sometimes needed in special-purpose applications; this specialized topic is relegated to the end of this section.

71.9.1 Matrix Rule-Based Job Coordination Controller

The workcell DE coordinators must sequence the jobs according to the task plan, coordinating the agents and activities of the workcell. Discrete event workcell coordination occurs at two levels in [Figure 71.7](#): coordination of *interagent* activities occurs within the job coordinator and coordination of *intra-agent* activities occurs within the virtual agent at the machine coordinator level. The latter might be considered as *reflex actions* of the virtual agent.

71.9.1.1 Rule-Based Matrix DE Coordinator

The workcell DE coordinators are easily produced using the four task plan matrices constructed by the task planner designed in the section on Petri net from task plan matrices. Given the job sequencing matrix F_v , the job start matrix S_v , the resource requirements matrix F_r , and the resource release matrix S_r , the

DE coordinator is given by

$$\bar{\mathbf{x}} = F_v \bar{\mathbf{v}}_c + F_r \bar{\mathbf{r}}_c + F_u \bar{\mathbf{u}} + F_D \bar{\mathbf{u}}_D \quad (71.29)$$

$$\mathbf{v}_s = S_v \mathbf{x} \quad (71.30)$$

$$\mathbf{r}_s = S_r \mathbf{x} \quad (71.31)$$

where Eq. (71.29) is the *controller state equation*, Eq. (71.30) is the *job start equation*, and Eq. (71.31) is the *resource release equation*. This is a set of *logical equations* where all matrix operations are carried out in the matrix or/and algebra; addition of elements is replaced by OR, and multiplication of elements is replaced by AND. Overbars denote logical negation, so that Equation 71.29 is a rule base composed of AND statements (e.g., if job b is completed and job c is completed and resource $R1$ is available, then set state component \mathbf{x}_4 high), and Equation 71.30 and Equation 71.31 are rule bases composed of OR statements (e.g., if state component \mathbf{x}_4 is high or state component \mathbf{x}_7 is high, then release resource $M1$).

For complex tasks with many jobs, the matrices in the DE controller can be large. However, they are sparse. Moreover, for special manufacturing structures such as the re-entrant flow line, the matrices in Equation (71.29) are *lower block triangular*, and this special structure gets around problems associated with the NP-hard nature of general manufacturing job shops. Finally, as rule bases, the DE controller equations may be fired using standard efficient techniques for forward chaining, backward chaining (Rete algorithm), and so on.

The structure of the DE job coordination controller is given in [Figure 71.29](#). This shows that the job coordinator is simply a *closed-loop feedback control system* operating at the DE level. At each time increment, workcell status signals are measured including the job complete status vector \mathbf{v}_c (where entries of 1 denote jobs complete), the resource availability vector \mathbf{r}_c (where entries of 1 denote resources available), and the part input vector \mathbf{u} (where entries of 1 denote parts coming into the workcell). These signals are determined using workcell digital interlocks and digital input/output between the agents. Based on this workcell status information, the DE controller computes which jobs to start next and which resources to release. These commands are passed to the workcell in the job start vector \mathbf{v}_s (where entries of 1 denote jobs to be started) and the resource release vector \mathbf{r}_s (where entries of 1 denote resources to be released).

71.9.1.2 Deadlocks and Resource Dispatching Commands

Outer feedback loops are required to compute the *dispatching input* u_D . A separate dispatching input is required whenever a column of F_r contains multiple ones, indicating that the corresponding resource is a *shared resource* required for more than one job. In a manufacturing workcell, if care is not taken to assign shared resources correctly, *system deadlock* may occur. In deadlock, operation of a subsystem ceases as a *circular blocking* of resources has developed [Wysk et al. 1991]. In a circular blocking, each resource is waiting for each other resource, but none will ever again become available. In the example of [Figure 71.24](#), a circular blocking occurs if machine $M1$ is waiting at b to be unloaded by $R1$, but $R1$ already has a part at d and the buffer $B2$ is full at e . On the other hand, buffer $B2$ cannot be unloaded at e since $M1$ already has a part at b .

There are well-established algorithms in industrial engineering for job dispatching [Panwalker and Iskander 1977], including first-in–first-out, earliest due date, last buffer first serve, etc. *Kanban systems* are pull systems where no job can be started unless a kanban card is received from a downstream job (possibly indicating buffer space or resource availability, or part requirements). A generalized kanban system that guarantees deadlock avoidance can be detailed in terms of the DE controller matrices, for it can be shown that all the *circular waits* of the workcell for a particular task are given in terms of the graph defined by $S_r F_r$, with S_r the resource release matrix and F_r the resource requirements matrix. Only circular waits can develop into circular blockings. Based on this, in Lewis and Huang [1995] a procedure known as maximum work-in-process (MAXWIP) is given that guarantees dispatching with no deadlock.

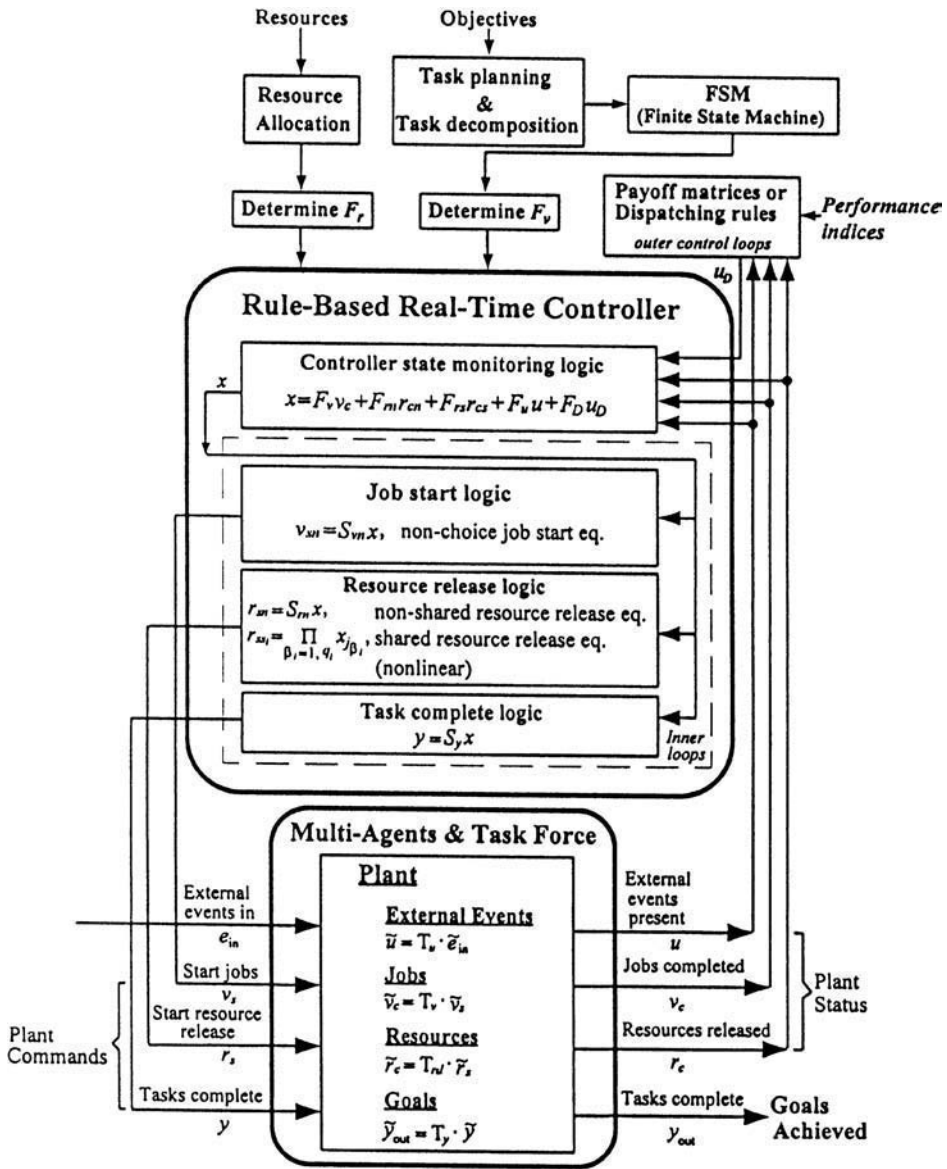

FIGURE 71.29 Matrix-based DE feedback controller for job sequencing and resource allocation.

71.9.2 Process Integration, Digital I/O, and Job Coordination Controller Implementation

Information integration is the process by which the activities and status of the various workcell agents interact. Subcategories of information integration include *sensor integration* and *sensor/actuator integration*. Motion/process integration involves coordinating manipulator motion with process sensor or process controller devices. The most primitive process integration is through discrete digital I/O, or sequencing interlocks. For example a machine controller external to the robot controller might send a 1-b signal indicating that it is ready to be loaded by the robot. The DE matrix-based job coordination controller provides an ideal technique for information integration. The workcell status signals required in Figure 71.29, the job completion vector and resource availability vector, are given by digital output signals provided by

sensors in the workcell (e.g., gripper open, part inserted in machine). The workcell command signals in Figure 71.29, the job start vector and resource release vector, are given by digital *discrete input* signals to the workcell agents (e.g., move robot to next via point, pick up part, load machine).

The DE job coordination controller is nothing but a rule base, and so may be implemented either on commercial programmable logic controllers (PLC) or on commercial robot controllers. In many cases, the DE controller matrices are block triangular, so that portions of the controller can be implemented hierarchically in separate subsystems (e.g., coordination between a single robot and a camera for some jobs). If this occurs, portions of the controller may be implemented in the machine coordinator in Figure 71.7, which often resides within the robot arm controller. Many robot controllers now support information integration functions by employing integrated PC interfaces through the communications ports, or in some through direct connections to the robot controller data bus. Higher level interactive portions of the DE controller should be implemented at the job coordination level, which is often realized on a dedicated PLC. Vision-guided high-precision pick and place and assembly are major applications in the electronics and semiconductor industries. Experience has shown that the best integrated vision/robot performance has come from running both the robot and the vision system internal to the same computing platform, since data communication is much more efficient due to data bus access, and computing operations are coordinated by one operating system.

71.9.3 Coordination of Multiple Robots

Coordination of multiple robots can be accomplished either at the discrete event level or the servocontrol level. In both cases it is necessary to avoid collisions and other interactions that impede task completion. If the arms are not interacting, it is convenient to coordinate them at the DE level, where collision avoidance may be confronted by assigning any intersecting workspace where two robots could collide as a *shared resource*, accessible by only a single robot at any given time. Then, techniques such as those in the section on the task matrix approach to workcell planning may be used (where $M1$ was a shared resource). Such approaches are commonly used in coordination control of automated guided vehicles (AGV) [Gruver et al. 1984].

71.9.3.1 Two-Arm Motion/Force Coordination

In specialized robotic applications requiring two-arm interaction, such as coordinated lifting or process applications, it may be necessary to coordinate the motion and force exertion of the arms on the joint servocontrol level [Hayati et al. 1989]. In such cases, the two robot arms may be considered in Figure 71.7 as a *single virtual agent* having specific behaviors as defined by the feedback servocontroller.

There are two basic approaches to two-arm servocontrol. In one approach, one arm is considered as the *master*, whose commanded trajectory is in terms of motion. The other, *slave*, arm is commanded to maintain prescribed forces and torques across a payload mass, which effectively constrains its relative motion with respect to the master arm. By this technique, the motion control and force/torque control problems are relegated to different arms, so that the control objectives are easily accomplished by servo-level feedback controller design. Another approach to two-arm coordination is to treat both arms as equals, coordinating to maintain prescribed linear and angular motions of the center-of-gravity (c.g.) of a payload mass, as well as prescribed internal forces and torques across the payload. This approach involves complex analyses to decompose the payload c.g. motion and internal forces into the required motion of each arm; kinematic transformations and Jacobians are needed.

71.10 Error Detection and Recovery

The material in this section is modified from Zhou [1996]. In the execution of a task, errors can occur. The errors can be classified into several categories: hardware error, software error, and operational error. The hardware errors include errors in mechanical and electrical mechanisms of the robot, such as failure in the drive system or sensing system. Software errors can be bugs in the application program or control software. Timing with cooperative devices can also be called software error. Operational errors are errors

in the robot environment that are external to the robot system such as jamming of parts or collision with obstacles.

During this discussion one should keep in mind the PC&C structure in [Figure 71.7](#). Error handling can be classified into two activities, *error detection* and *error recovery*. Error detection is composed of error sensing, interpretation, and classification. Error recovery is composed of decision making and corrective job assignment. While corrective jobs are being performed, the assigned task may be interrupted, or may continue to run at a reduced capability (e.g., one of two drilling machines may be down).

71.10.1 Error Detection

The sensors used in error detection can include all those discussed in [Section 71.7](#) including tactile sensors for sensing contact errors, proximity sensors for sensing location or possible collision, force/torque sensors for sensing collision and jamming, and vision for sensing location, orientation and error existence. Once an error is sensed, it must be interpreted and classified. This may be accomplished by servo-level state observers, logical rule-based means, or using advanced techniques such as neural networks.

71.10.2 Error Recovery

The occurrence of an error usually causes interruption of the normal task execution. Error recovery can be done at three levels, where errors can be called *exceptions*, *faults*, and *failures*. At the lowest level the exception will be corrected automatically, generally in the real-time servocontrol loops, and the task execution continued. An example is jamming in the pin insertion problem, where a force/torque wrist sensor can indicate jamming as well as provide the information needed to resolve the problem. At the second level, the error is a fault that has been foreseen by the task planner and included in the task plan passed to the job coordinator.

The vector x in Equation 71.29 contains *fault states*, and logic is built into the task plan matrices to allow corrective job assignment. Upon detection of an error, jobs can be assigned to correct the fault, with the task subsequently continued from the point where the error occurred. At this level, the error detection/recovery logic can reside either in the machine coordinator or in the job coordinator.

At the highest level of recovery, the error was not foreseen by the task planner and there is no error state in the task plan. This results in a failure, where the task is interrupted. Signals are sent to the planner, who must correct the failure, sometimes with external resources, and replan the task, passing another plan to the coordinator. In the worst case, manual operator intervention is needed. It can be seen that the flow of error signals proceeds upwards and of commands proceeds downwards, exactly as in the NASREM architecture in [Figure 71.4](#).

At the lowest servocontrol level, additional sensory information is generally required for error recovery, as in the requirement for a wrist force/torque sensor in pin insertion. At the mid-level, additional logic is needed for error recovery. At the highest level, task replanning capabilities are needed.

71.11 Human Operator Interfaces

Human operator integration is critical to the expeditious setup, programming, maintenance, and sometimes operation of the robotic workcell. Especially important for effective human integration are the available human I/O devices, including the information available to the operator in graphical form and the modes of real-time control operation available for human interaction. Teaching, programming, and operational efforts are dramatically influenced by the type of user interface I/O devices available.

71.11.1 Levels of User Interface

Discounting workcell design and layout, operator interfaces occur at several levels in [Figure 71.7](#) and may be classified into off-line and on-line activities. Off-line interfaces occur in task definition and setup, often

consisting of teaching activities. In workcell management, user inputs include assignment of tasks, due dates, and so on. At the workcell planning level, user functions might be required in task planning, both in task decomposition/job sequencing and in resource assignment. Off-line CAD programs are often useful at this level. In path planning, the user might be required to teach a robot specific path via points for job accomplishment. Finally, if failures occur, a human might be required to clear the failure, reset the workcell, and restart the job sequence.

On-line user interfaces may occur at the discrete event level and the servocontrol level. In the former case, a human might perform some of the jobs requested by the job coordinator, or may be required to perform corrective jobs in handling foreseen faults. At the servocontrol level, a human might perform teleoperator functions, or may be placed in the inner feedback control loop with a machine or robotic device.

71.11.2 Mechanisms for User Interface

71.11.2.1 Interactive 3-D CAD

Computer integrated manufacturing operations require off-line programming and simulation in order to layout production facilities, model and evaluate design concepts, optimize motion of devices, avoid interference and collisions, minimize process cycle times, maximize productivity, and ensure maximum return on investment. Graphical interfaces, available on some industrial robots, are very effective for conveying information to the operator quickly and efficiently. A graphical interface is most important for design and simulation functions in applications which require frequent reprogramming and setup changes. Several very useful off-line programming software systems are available from third party suppliers (CimStation [SILMA 1992], ROBCAD, IGRIP). These systems use CAD and/or dynamics computer models of commercially available robots to simulate job execution, path motion, and process activities, providing rapid programming and virtual prototyping functions. Interactive off-line CAD is useful for assigning tasks at the management level and for task decomposition, job sequencing, and resource assignment at the task planning level.

71.11.2.2 Off-Line Robot Teaching and Workcell Programming

Commercial robot or machine tool controllers may have several operator interface mechanisms. These are generally useful at the level of off-line definition or teaching of jobs, which can then be sequenced by the job coordinator or machine coordinator to accomplish assigned tasks. At the lowest level one may program the robot in its operating language, specifying path via points, gripper open/close commands, and so on. Machine tools may require programming in CNC code. These are very tedious functions, which can be avoided by object-oriented and open architecture approaches in well-designed workcells, where such functions should be performed automatically, leaving the user free to deal with other higher level supervisory issues. In such approaches, macros or subroutines are written in machine code which *encapsulate the machine behaviors* (e.g., set speed, open gripper, go to prescribed point). Then, higher level software passes specific parameters to these routines to execute behaviors with specific location and motion details as directed by the job coordinator.

Many robots have a teach pendant, which is a low-level teleoperation device with push buttons for moving individual axes and other buttons to press commanding that certain positions should be memorized. On job execution, a playback mode is switched in, wherein the robot passes through the taught positions to sweep out a desired path. This approach is often useful for teaching multiple complex poses and Cartesian paths.

The job coordinator may be implemented on a programmable logic controller (PLC). PLC programming can be a tedious and time-consuming affair, and in well-designed flexible reconfigurable workcells an object-oriented approach is used to avoid reprogramming of PLCs. This might involve a programming scheme that takes the task plan matrices in [Section 71.9](#) as inputs and automatically implements the coordinator using rule-based techniques (e.g., forward chaining, Rete algorithm).

71.11.2.3 Teleoperation and Man-in-the-Loop Control

Operator interaction at the servocontrol level can basically consist of two modes. In man-in-the-loop control, a human provides or modifies the feedback signals that control a device, actually operating a machine tool or robotic device. In teleoperation, an inner feedback loop is closed around the robot, and a human provides motion trajectory and force commands to the robot in a master/slave relationship. In such applications, there may be problems if extended communications distances are involved, since delays in the communications channel can destabilize a teleoperation system having force feedback unless careful attention is paid to designing the feedback loops to maintain *passivity*. See Lewis [1996] for more details.

71.12 Robot Workcell Programming

The robotic workcell requires programming at several levels [Leu 1985]. At the lower levels one generally uses commercial programming languages peculiar to device manufacturers of robots and CNC machine tools. At the machine coordination level, robot controllers are also often used with discrete I/O signals and decision making commands. At the job coordination level programmable logic controllers (PLCs) are often used in medium complexity workcells, so that a knowledge of PLC programming techniques is required. In modern manufacturing and process workcells, coordination may be accomplished using general purpose computers with programs written, for instance, in C.

71.12.1 Robot Programming Languages

Subsequent material in this section is modified from Bailey [1996]. Each robot manufacturer has its own proprietary programming language. The variety of motion and position command types in a programming language is usually a good indication of the robot's motion generation capability. Program commands which produce complex motion should be available to support the manipulation needs of the application. If palletizing is the application, then simple methods of creating position commands for arrays of positions are essential. If continuous path motion is needed, an associated set of continuous motion commands should be available. The range of motion generation capabilities of commercial industrial robots is wide. Suitability for a particular application can be determined by writing test code.

The earliest industrial robots were simple sequential machines controlled by a combination of servomotors, adjustable mechanical stops, limit switches, and PLCs. These machines were generally programmed by a record and play-back method with the operator using a teach pendant to move the robot through the desired path. MHI, the first robot programming language, was developed at Massachusetts Institute of Technology (MIT) during the early 1960s. MINI, developed at MIT during the mid-1970s was an expandable language based on LISP. It allowed programming in Cartesian coordinates with independent control of multiple joints. VAL and VAL II [Shimano et al. 1984], developed by Unimation, Inc., were interpreted languages designed to support the PUMA series of industrial robots. **A manufacturing language (AML)** was a completely new programming language developed by IBM to support the R/S 1 assembly robot. It was a subroutine-oriented, interpreted language which ran on the Series/1 minicomputer. Later versions were compiled to run on IBM compatible personal computers to support the 7535 series of SCARA robots. Several additional languages [Gruver et al. 1984, Lozano-Perez 1983] were introduced during the late 1980s to support a wide range of new robot applications which were developed during this period.

71.12.2 V+, A Representative Robot Language

V+, developed by Adept Technologies, Inc., is a representative modern robot programming language with several hundred program instructions and reserved keywords. V+ will be used to demonstrate important features of robot programming. Robot program commands fall into several categories, as detailed in the following subsections.

71.12.2.1 Robot Control

Program instructions required to control robot motion specify location, trajectory, speed, acceleration, and obstacle avoidance. Examples of V+ robot control commands are as follows:

MOVE:	Move the robot to a new location.
DELAY:	Stop the motion for a specified period of time.
SPEED:	Set the speed for subsequent motions.
ACCEL:	Set the acceleration and deceleration for subsequent motions.
OPEN:	Open the hand.
CLOSE:	Close the hand.

71.12.2.2 System Control

In addition to controlling robot motion, the system must support program editing and debugging, program and data manipulation, program and data storage, program control, system definitions and control, system status, and control/monitoring of external sensors. Examples of V+ control instructions are as follows:

EDIT:	Initiate line-oriented editing.
STORE:	Store information from memory onto a disk file.
COPY:	Copy an existing disk file into a new program.
EXECUTE:	Initiate execution of a program.
ABORT:	Stop program execution.
DO:	Execute a single program instruction.
WATCH:	Set and clear breakpoints for diagnostic execution.
TEACH:	Define a series of robot location variables.
CALIBRATE:	Initiate the robot positioning system.
STATUS:	Display the status of the system.
ENABLE:	Turn on one or more system switches.
DISABLE:	Turn off one or more system switches.

71.12.2.3 Structures and Logic

Program instructions are needed to organize and control execution of the robot program and interaction with the user. Examples include familiar commands such as FOR, WHILE, IF as well as commands like the following:

WRITE:	Output a message to the manual control pendant.
PENDANT:	Receive input from the manual control pendant.
PARAMETER:	Set the value of a system parameter.

71.12.2.4 Special Functions

Various special functions are required to facilitate robot programming. These include mathematical expressions such as COS, ABS, and SQRT, as well as instructions for data conversion and manipulation, and kinematic transformations such as the following:

BCD:	Convert from real to binary coded decimal.
FRAME:	Compute the reference frame based on given locations.
TRANS:	Compose a transformation from individual components.
INVERSE:	Return the inverse of the specified transformation.

71.12.2.5 Program Execution

Organization of a program into a sequence of executable instructions requires scheduling of tasks, control of subroutines, and error trapping/recovery. Examples include the following:

PCEXECUTE: Initiate the execution of a process control program.
PCABORT: Stop execution of a process control program.
PCPROCEED: Resume execution of a process control program.
PCRETRY: After an error, resume execution at the last step tried.
PCEND: Stop execution of the program at the end of the current execution cycle.

71.12.2.6 Example Program

This program demonstrates a simple pick and place operation. The values of position variables *pick* and *place* are specified by a higher level executive that then initiates this subroutine:

```
1 .PROGRAM move.parts()
2 ; Pick up parts at location "pick" and put them down at "place"
3 parts = 100 ; Number of parts to be processed
4 height1 = 25 ; Approach/depart height at "pick"
5 height2 = 50 ; Approach/depart height at "place"
6 PARAMETER.HAND.TIME = 16 ; Setup for slow hand
7 OPEN ; Make sure hand is open
8 MOVE start ; Move to safe starting location
9 For i = 1 TO parts ; Process the parts
10 APPRO pick, height1 ; Go toward the pick-up
11 MOVES pick ; Move to the part
12 CLOSEI ; Close the hand
13 DEPARTS height1 ; Back away
14 APPRO place, height2 ; Go toward the put-down
15 MOVES place ; Move to the destination
16 OPENI ; Release the part
17 DEPARTS height2 ; Back away
18 END ; Loop for the next part
19 TYPE "ALL done.," /I3, parts, "parts processed"
20 STOP ; End of the program
21 .END
```

71.12.2.7 Off-Line Programming and Simulation

Commercially available software packages (discussed in [Section 71.11](#)) provide support for off-line design and simulation of 3-D workcell layouts including robots, end effectors, fixtures, conveyors, part positioners, and automatic guided vehicles. Dynamic simulation allows off-line creation, animation, and verification of robot motion programs. However, these techniques are limited to verification of overall system layout and preliminary robot program development. With support for data exchange standards [e.g., **International Graphics Exchange Specification (IGES)**, **Virtual Data Acquisition and File Specification (VDAFS)**, **Specification for Exchange of Text (SET)**], these software tools can pass location and trajectory data to a robot control program, which in turn can provide the additional functions required for full operation (operator guidance, logic, error recovery, sensor monitoring/control, system management, etc.).

71.13 Mobile Robots and Automated Guided Vehicles

A topic which has always intrigued computer scientists is that of **mobile robots** [Zheng 1993]. These machines move in generally unstructured environments and so require enhanced decision making and sensors; they seem to exhibit various anthropomorphic aspects since vision is often the sensor, decision

making mimics brain functions, and mobility is similar to humans, particularly if there is an onboard robot arm attached. Here are discussed mobile robot research and factory automated guided vehicle (AGV) systems, two widely disparate topics.

71.13.1 Mobile Robots

Unfortunately, in order to focus on higher functions such as decision making and high-level vision processing, many researchers treat the mobile robot as a dynamical system obeying Newton's laws $F = ma$ (e.g., in the potential field approach to motion control, discussed earlier). This simplified dynamical representation does not correspond to the reality of moving machinery which has nonholonomic constraints, unknown masses, frictions, Coriolis forces, drive train **compliance**, wheel slippage, and backlash effects. In this subsection we provide a framework that brings together three camps: computer science results based on the $F = ma$ assumption, nonholonomic control results that deal with a kinematic steering system, and full servo-level feedback control that takes into account all of the vehicle dynamics and uncertainties.

71.13.1.1 Mobile Robot Dynamics

The full dynamical model of a rigid mobile robot (e.g., no flexible modes) is given by

$$M(\mathbf{q})\ddot{\mathbf{q}} + V_m(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + F(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{G}(\mathbf{q}) + \boldsymbol{\tau}_d = B(\mathbf{q})\boldsymbol{\tau} - A^T(\mathbf{q})\boldsymbol{\lambda} \quad (71.32)$$

which should be compared to Equation 71.7 and Equation 71.14. In this equation, M is an inertia matrix, V_m is a matrix of Coriolis and centripetal terms, F is a friction vector, \mathbf{G} is a gravity vector, and $\boldsymbol{\tau}_d$ is a vector of disturbances. The n -vector $\boldsymbol{\tau}(t)$ is the control input. The dynamics of the driving and steering motors should be included in the robot dynamics, along with any gearing. Then, $\boldsymbol{\tau}$ might be, for example, a vector of voltage inputs to the drive actuator motors.

The vehicle variable $\mathbf{q}(t)$ is composed of Cartesian position (x, y) in the plane plus orientation θ . If a robot arm is attached, it can also contain the vector of robot arm joint variables. A typical mobile robot with no onboard arm has $\mathbf{q} = [x \ y \ \theta]^T$, where there are three variables to control, but only two inputs, namely, the voltages into the left and right driving wheels (or, equivalently, vehicle speed and heading angle).

The major problems in control of mobile robots are the fact that there are more degrees of freedom than control inputs, and the existence of nonholonomic constraints.

71.13.1.2 Nonholonomic Constraints and the Steering System

In Equation 71.12 the vector of constraint forces is $\boldsymbol{\lambda}$ and matrix $A(\mathbf{q})$ is associated with the constraints. These may include nonslippage of wheels and other *holonomic* effects, as well as the *nonholonomic constraints*, which pose one of the major problems in mobile robot control. Nonholonomic constraints are those which are nonintegrable, and include effects such as the impossibility of sideways motion (think of an automobile). In research laboratories, it is common to deal with omnidirectional robots that have no nonholonomic constraints, but can rotate and translate with full degrees of freedom; such devices do not correspond to the reality of existing shop floor or cross-terrain vehicles which have nonzero turn radius.

A general case is where all kinematic equality constraints are independent of time and can be expressed as

$$A(\mathbf{q})\dot{\mathbf{q}} = 0 \quad (71.33)$$

Let $S(\mathbf{q})$ be a full-rank basis for the nullspace of $A(\mathbf{q})$ so that $AS = 0$. Then one sees that the linear and angular velocities are given by

$$\dot{\mathbf{q}} = S(\mathbf{q})\mathbf{v}(\mathbf{t}) \quad (71.34)$$

where $\mathbf{v}(\mathbf{t})$ is an auxiliary vector. In fact, $\mathbf{v}(\mathbf{t})$ often has physical meaning, consisting of two components: the commanded vehicle speed and the heading angle. Matrix $S(\mathbf{q})$ is easily determined independently of

the dynamics 71.32 from the wheel configuration of the mobile robot. Thus, Equation 71.34 is a *kinematic* equation that expresses some simplified relations between motion $\mathbf{q}(t)$ and a fictitious *ideal speed and heading* vector \mathbf{v} . It does not include dynamical effects, and is known in the nonholonomic literature as the *steering system*. In the case of omnidirectional vehicles $S(\mathbf{q})$ is 3×3 and Equation 71.34 corresponds to the Newton's law model $F = ma$ used in, e.g., potential field approaches.

There is a large literature on selecting the command $\mathbf{v}(t)$ to produce desired motion $\mathbf{q}(t)$ in nonholonomic systems; the problem is that \mathbf{v} has two components and \mathbf{q} has three. Illustrative references include the chapters by Yamamoto and Yun and by Canudas de Wit et al. in Zheng [1993], as well as Samson and Ait-Abderrahim [1991]. There are basically three problems considered in this work: following a prescribed path, tracking a prescribed trajectory (e.g., a path with prescribed transit times), and stabilization at a prescribed final docking position (x, y) and orientation θ . Single vehicle systems as well as multi-body systems (truck with multiple trailers) are treated. The results obtained are truly remarkable and are in the vein of a path including the forward/backward motions necessary to park a vehicle at a given docking position and orientation. All of the speed reversals and steering commands are automatically obtained by solving certain coupled nonlinear equations. This is truly the meaning of intelligence and autonomy.

71.13.1.3 Conversion of Steering System Commands to Actual Vehicle Motor Commands

The steering system command vector obtained from the nonholonomic literature may be called $\mathbf{v}_c(t)$, the ideal desired value of the speed/heading vector $\mathbf{v}(t)$. Under the so-called perfect velocity assumption the actual vehicle velocity $\mathbf{v}(t)$ follows the command vector $\mathbf{v}_c(t)$, and can be directly given as control input to the vehicle. Unfortunately, in real life this assumption does not hold. One is therefore faced with the problem of obtaining drive wheel and steering commands for an actual vehicle from the steering system command $\mathbf{v}_c(t)$.

To accomplish this, premultiply Equation 71.32 by $S^T(\mathbf{q})$ and use Equation 71.34 to obtain

$$\overline{M}(\mathbf{q})\dot{\mathbf{v}} + \overline{V}_m(\mathbf{q}, \dot{\mathbf{q}})\mathbf{v} + \overline{F}(\mathbf{v}) + \overline{\tau}_d = \overline{B}(\mathbf{q})\tau \quad (71.35)$$

where gravity plays no role and so has been ignored, the constraint term drops out due to the fact that $AS = 0$, and the overbar terms are easily computed in terms of original quantities. The true model of the vehicle is thus given by combining both Equation 71.34 and Equation 71.35. However, in the latter equation it turns out that $(\overline{B})(\mathbf{q})$ is square and invertible, so that standard computed torque techniques (see section on robot servo-level motion control) can be used to compute the required vehicle control τ from the steering system command $\mathbf{v}_c(t)$. In practice, correction terms are needed due to the fact that $\mathbf{v} \neq \mathbf{v}_c$; they are computed using a technique known as *integrator backstepping* [Fierro and Lewis 1995].

The overall controller for the mobile robot is similar in structure to the multiloop controller in Figure 71.13, with an inner nonlinear **feedback linearization** loop (e.g., computed torque) and an outer tracking loop that computes the steering system command. The robustifying term is computed using backstepping. Adaptive control and neural net control inner loops can be used instead of computed torque to reject uncertainties and provide additional dynamics learning capabilities. Using this multiloop control scheme, the idealized control inputs provided, e.g., by potential field approaches, can also be converted to actual control inputs for any given vehicle. A major criticism of potential field approaches has been that they do not take into account the vehicle nonholonomic constraints.

71.13.2 Automated Guided Vehicle Systems

Though research in mobile robots is intriguing, with remarkable results exhibiting intelligence at the potential field planning level, the nonholonomic control level, and elsewhere, few of these results make their way into the factory or other unstructured environments. There, reliability and repeatability are the main issue of concern.

71.13.2.1 Navigation and Job Coordination

If the environment is unstructured one may either provide sophisticated planning, decision making, and control schemes or one may force structure onto the environment. Thus, in most AGV systems the vehicles are guided by wires buried in the floor or stripes painted on the floor. Antennas buried periodically in the floor provide check points for the vehicle as well as transmitted updates to its commanded job sequence.

A single computer may perform scheduling and routing of multiple vehicles. Design of this coordinating controller is often contorted and complex in actual installed systems, which may be the product of several engineers working in an ad hoc fashion over several years of evolution of the system. To simplify and unify design, the discrete event techniques in the task matrix approach section may be used for planning. Track intersections should be treated as shared resources only accessible by a single vehicle at a time, so that on-line dispatching decisions are needed. The sequencing controller is then implemented using the approach in [Section 71.9](#).

71.13.2.2 Sensors, Machine Coordination, and Servo-level Control

Autonomous vehicles often require extensive sensor suites. There is usually a desire to avoid vision systems and use more reliable sensors including contact switches, proximity detectors, laser rangefinders, sonar, etc. Optical bar codes are sometimes placed on the walls; these are scanned by the robot so it can update its absolute position. Integrating this multitude of sensors and performing coordinated activities based on their readings may be accomplished using simple decision logic on low-level microprocessor boards. Servo-level control consists of simple PD loops that cause the vehicle to follow commanded speeds and turn commands. Distance sensors may provide information needed to maintain minimum safe intervehicular spacing.

Defining Terms

Accuracy: The degree to which the actual and commanded position (of, e.g., a robot manipulator) correspond.

Adaptive control: A large class of control algorithms where the controller has its own internal dynamics and so is capable of learning the unknown dynamics of the robot arm, thus improving performance over time.

A manufacturing language (AML): A robot programming language.

Automatic programming of tools (APT): A robot programming language.

Cell decomposition: An approach to path planning where the obstacles are modeled as polygons and the free space is decomposed into cells such that a straight line path can be generated between any two points in a cell.

Compliance: The inverse of stiffness, useful in end effectors and tooling whenever a robot must interact with rigid constraints in the environment.

Computed torque control: An important and large class of robot arm controller algorithms that relies on subtracting out some or most of the dynamical nonlinearities using feedforward compensation terms including, e.g., gravity, friction, Coriolis, and desired acceleration feedforward.

End effector: Portion of robot (typically at end of chain of links) designed to contact the external world.

Feedback linearization: A modern approach to robot arm control that formalizes computed torque control mathematically, allowing formal proofs of stability and design of advanced algorithms using Lyapunov and other techniques.

Force control: A class of algorithms allowing control over the force applied by a robot arm, often in a direction normal to a prescribed surface while the position trajectory is controlled in the plane of the surface.

Forward kinematics: Identification of Cartesian task coordinates given robot joint configuration.

International Graphics Exchange Specification (IGES): A data exchange standard.

Inverse kinematics: Identification of possible robot joint configurations given desired Cartesian task coordinates.

Joint variables: Scalars specifying position of each joint, one for each degree of freedom. The joint variable for a revolute joint is an angle in degrees; the joint variable for a prismatic joint is an extension in units of length.

Learning control: A class of control algorithms for repetitive motion applications (e.g., spray painting) where information on the errors during one run is used to improve performance during the next run.

Linearity in the parameters: A property of the robot arm dynamics, important in adaptive controller design, where the nonlinearities are linear in the unknown parameters such as unknown masses and friction coefficients.

Manipulator Jacobian: A configuration-dependent matrix relating joint velocities to Cartesian coordinate velocities.

Mechanical part feeders: Mechanical devices for feeding parts to a robot with a specified frequency and orientation. They are classified as vibratory bowl feeders, vibratory belt feeders, and programmable belt feeders.

Mobile robot: A special type of manipulator which is not bolted to the floor but can move. Based on different driving mechanisms, mobile robots can be further classified as wheeled mobile robots, legged mobile robots, treaded mobile robots, underwater mobile robots, and aerial vehicles.

Path planning: The process of finding a continuous path from an initial robot configuration to a goal configuration without collision.

Prismatic joint: Sliding or telescoping robot joint that produces relative translation of the connected links.

Proportional-integral-derivative (PID) control: A classical servocontrol feedback algorithm where the actual system output is subtracted from the desired output to obtain a tracking error. Then, a weighted linear combination of the tracking error, its derivative, and its integral are used as the control input to the system.

Remote-center-of-compliance (RCC): A compliant wrist or end effector designed so that task-related forces and moments produce deflections with a one-to-one correspondence (i.e., without side effects). This property simplifies programming of assembly and related tasks.

Repeatability: The degree to which the actual positions resulting from two repeated commands to the same position (of, e.g., a robot manipulator) correspond.

Revolute joint: Rotary robot joint producing relative rotation of the connected links.

Robot axis: A direction of travel or rotation usually associated with a degree of freedom of motion.

Robot joint: A mechanism that connects the structural links of a robot manipulator together while allowing relative motion.

Robot link: The rigid structural elements of a robot manipulator that are joined to form an arm.

Robust control: A large class of control algorithms where the controller is generally nondynamic, but contains information on the maximum possible modeling uncertainties so that the tracking errors are kept small, often at the expense of large control effort. The tracking performance does not improve over time so the errors never go to zero.

SCARA: Selectively compliant assembly robot arm.

Singularity: Configuration for which the manipulator Jacobian has less than full rank.

Skew symmetry: A property of the dynamics of rigid-link robot arms, important in controller design, stating that $\dot{M} - \frac{1}{2}V_m$ is skew symmetric, with M the inertia matrix and V_m the Coriolis/centripetal matrix. This is equivalent to stating that the internal forces do no work.

Specification for Exchange of Text (SET): A data exchange standard.

Task coordinates: Variables in a frame most suited to describing the task to be performed by manipulator. They are generally taken as Cartesian coordinates relative to a base frame.

Virtual Data Acquisition and File Specification (VDAFS): A data exchange standard.

Visibility graph: A road map approach to path planning where the obstacles are modeled as polygons. The visibility graph has nodes given by the vertices of the polygons, the initial point, and the goal point. The links are straight line segments connecting the nodes without intersecting any obstacles.

Voronoi diagram: A road map approach to path planning where the obstacles are modeled as polygons. The Voronoi diagram consists of line as having an equal distance from adjacent obstacles; it is composed of straight lines and parabolas.

VIII

Net-Centric Computing

The rapid evolution of the World Wide Web in the last decade has had enormous impact on the priorities for computer science research and application development. NSF's recent initiatives in this area are labeled "cyberinfrastructure," which has provided major support for research on the design and performance of the Web and its various uses. The chapters in this section encapsulate fundamental aspects of network organization, routing, security, and privacy concerns. They also cover contemporary issues and applications such as data mining, data compression, and malicious software (viruses and worms) and its detection.

72.1 Transmission Control Protocol/Internet Protocol and Open Systems Interconnection

In this chapter, we examine the communications software needed to interconnect computers, workstations, servers, and other devices across networks. Then we look at some of the networks in contemporary use. When communication is desired among computers from different vendors, the software development effort can be a nightmare. Different vendors use different data formats and data exchange protocols. Even within one vendor's product line, different model computers may communicate in unique ways.

As the use of computer communications and computer networking proliferates, a one at a time special-purpose approach to communications software development is too costly to be acceptable. The only alternative is for computer vendors to adopt and implement a common set of conventions. For this to happen, standards are needed. Such standards would have two benefits:

- Vendors feel encouraged to implement the standards because of an expectation that, because of wide usage of the standards, their products will be more marketable.
- Customers are in a position to require that the standards be implemented by any vendor wishing to propose equipment to them.

It should become clear from the ensuing discussion that no single standard will suffice. Any distributed application, such as electronic mail or client/server interaction, requires a complex set of communications functions for proper operation. Many of these functions, such as reliability mechanisms, are common across many or even all applications. Thus, the communications task is best viewed as consisting of a modular architecture, in which the various elements of the architecture perform the various required functions. Hence, before one can develop standards, there should be a structure, or *protocol architecture*, that defines the communications tasks.

Two protocol architectures have served as the basis for the development of interoperable communications standards: the transmission control protocol/Internet protocol (TCP/IP) protocol suite and the **open**

systems interconnection (OSI) reference model. TCP/IP is the most widely used interoperable architecture, especially in the context of **local-area networks (LANs)**. In this section, we provide a brief overview of the two architectures.

72.1.1 The Transmission Control Protocol/Internet Protocol Architecture

This architecture is a result of protocol research and development conducted on the experimental packet-switched network, ARPANET, funded by the Defense Advanced Research Projects Agency (DARPA), and is generally referred to as the TCP/IP protocol suite.

72.1.1.1 The Transmission Control Protocol/Internet Protocol Layers

In general terms, communications can be said to involve three agents: applications, computers, and networks. Examples of applications include file transfer and electronic mail. The applications that we are concerned with here are distributed applications that involve the exchange of data between two computer systems. These applications, and others, execute on computers that can often support multiple simultaneous applications. Computers are connected to networks, and the data to be exchanged are transferred by the network from one computer to another. Thus, the transfer of data from one application to another involves first getting the data to the computer in which the application resides and then getting it to the intended application within the computer.

With these concepts in mind, it appears natural to organize the communication task into four relatively independent layers:

- Network access layer
- Internet layer
- Host-to-host layer
- Process layer

The network access layer is concerned with the exchange of data between an end system (server, workstation, etc.) and the network to which it is attached. The sending computer must provide the network with the address of the destination computer, so that the network may route the data to the appropriate destination. The sending computer may wish to invoke certain services, such as priority, that might be provided by the network. The specific software used at this layer depends on the type of network to be used; different standards have been developed for **circuit switching**, **packet switching** (e.g., X.25), local-area networks (e.g., Ethernet), and others. Thus, it makes sense to separate those functions having to do with network access into a separate layer. By doing this, the remainder of the communications software, above the network access layer, need not be concerned about the specifics of the network to be used. The same higher layer software should function properly regardless of the particular network to which the computer is attached.

The network access layer is concerned with access to and routing data across a network for two end systems attached to the same network. In those cases where two devices are attached to different networks, procedures are needed to allow data to traverse multiple interconnected networks. This is the function of the Internet layer. The Internet protocol is used at this layer to provide the routing function across multiple networks. This protocol is implemented not only in the end systems but also in routers. A router is a processor that connects two networks and whose primary function is to relay data from one network to the other on its route from the source to the destination end system.

Regardless of the nature of the applications that are exchanging data, there is usually a requirement that data be exchanged reliably. That is, we would like to be assured that all of the data arrive at the destination application and that the data arrive in the order in which they were sent. As we shall see, the mechanisms for providing reliability are essentially independent of the nature of the applications. Thus, it makes sense to collect those mechanisms in a common layer shared by all applications; this is referred to as the host-to-host layer. The transmission control protocol provides this functionality.

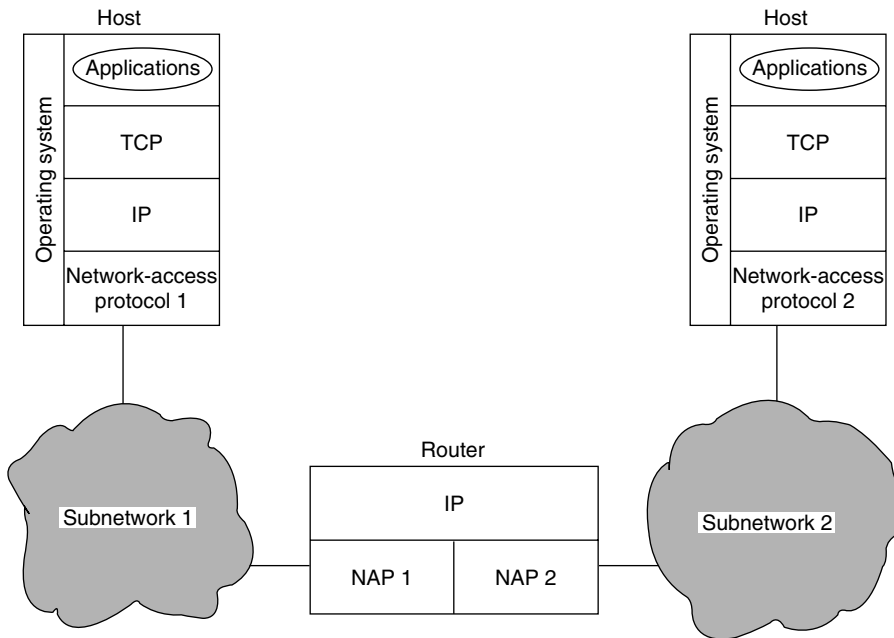

FIGURE 72.1 Communications using the TCP/IP protocol architecture.

Finally, the process layer contains the logic needed to support the various user applications. For each different type of application, such as file transfer, a separate module is needed that is peculiar to that application.

72.1.1.2 Operation of Transmission Control Protocol and Internet Protocol

Figure 72.1 indicates how these protocols are configured for communications. To make clear that the total communications facility may consist of multiple networks, the constituent networks are usually referred to as *subnetworks*. Some sort of network access protocol, such as the Ethernet logic, is used to connect a computer to a subnetwork. This protocol enables the host to send data across the subnetwork to another host or, in the case of a host on another subnetwork, to a router. IP is implemented in all of the end systems and the routers. It acts as a relay to move a block of data from one host, through one or more routers, to another host. TCP is implemented only in the end systems; it keeps track of the blocks of data to ensure that all are delivered reliably to the appropriate application.

For successful communication, every entity in the overall system must have a unique address. Actually, two levels of addressing are needed. Each host on a subnetwork must have a unique global Internet address; this allows the data to be delivered to the proper host. Each process with a host must have an address that is unique within the host; this allows the host-to-host protocol (TCP) to deliver data to the proper process. These latter addresses are known as ports.

Let us trace a simple operation. Suppose that a process, associated with port 1 at host *A*, wishes to send a message to another process, associated with port 2 at host *B*. The process at *A* hands the message down to TCP with instructions to send it to host *B*, port 2. TCP hands the message down to IP with instructions to send it to host *B*. Note that IP need not be told the identity of the destination port. All that it needs to know is that the data are intended for host *B*. Next, IP hands the message down to the network access layer (e.g., Ethernet logic) with instructions to send it to router *X* (the first hop on the way to *B*).

To control this operation, control information as well as user data must be transmitted, as suggested in [Figure 72.2](#). Let us say that the sending process generates a block of data and passes this to TCP. TCP may break this block into smaller pieces to make it more manageable. To each of these pieces, TCP appends control information known as the TCP header, forming a *TCP segment*. The control information is to be

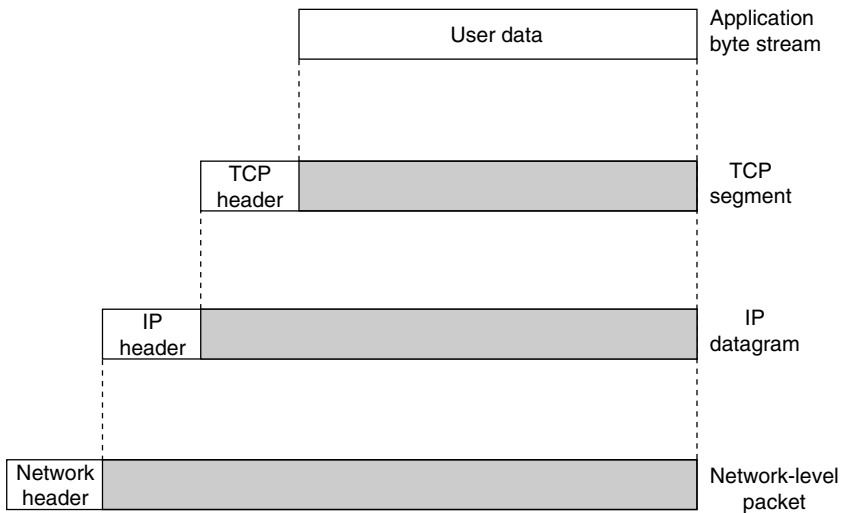

FIGURE 72.2 Protocol data units in the TCP/IP architecture.

used by the peer TCP protocol entity at host *B*. Examples of items that are included in this header include the following:

- *Destination port*: When the TCP entity at *B* receives the segment, it must know to whom the data are to be delivered.
- *Sequence number*: TCP numbers the segments that it sends to a particular destination port sequentially, so that if they arrive out of order, the TCP entity at *B* can reorder them.
- *Checksum*: The sending TCP includes a code that is a function of the contents of the remainder of the segment. The receiving TCP performs the same calculation and compares the result with the incoming code. A discrepancy results if there has been some error in transmission.

Next, TCP hands each segment over to IP, with instructions to transmit it to *B*. These segments must be transmitted across one or more subnetworks and relayed through one or more intermediate routers. This operation, too, requires the use of control information. Thus, IP appends a header of control information to each segment to form an *IP datagram*. An example of an item stored in the IP header is the destination host address (in this example, *B*).

Finally, each IP datagram is presented to the network access layer for transmission across the first subnetwork in its journey to the destination. The network access layer appends its own header, creating a packet, or frame. The packet is transmitted across the subnetwork to router *X*. The packet header contains the information that the subnetwork needs to transfer the data across the subnetwork. Examples of items that may be contained in this header include the following:

- *Destination subnetwork address*: The subnetwork must know to which attached device the packet is to be delivered.
- *Facilities requests*: The network access protocol might request the use of certain subnetwork facilities, such as priority.

At router *X*, the packet header is stripped off and the IP header is examined. On the basis of the destination address information in the IP header, the IP module in the router directs the datagram out across subnetwork 2 to *B*. To do this, the datagram is again augmented with a network access header.

When the data are received at *B*, the reverse process occurs. At each layer, the corresponding header is removed, and the remainder is passed on the next higher layer, until the original user data are delivered to the destination process.

72.1.1.3 Transmission Control Protocol/Internet Protocol Applications

A number of applications have been standardized to operate on top of TCP. We mention three of the most common here.

The simple mail transfer protocol (SMTP) provides a basic electronic mail facility. It provides a mechanism for transferring messages among separate hosts. Features of SMTP include mailing lists, return receipts, and forwarding. The SMTP protocol does not specify the way in which messages are to be created; some local editing or native electronic mail facility is required. Once a message is created, SMTP accepts the message, and makes use of TCP to send it to an SMTP module on another host. The target SMTP module will make use of a local electronic mail package to store the incoming message in a user's mailbox.

The file transfer protocol (FTP) is used to send files from one system to another under user command. Both text and binary files are accommodated, and the protocol provides features for controlling user access. When a user wishes to engage in file transfer, FTP sets up a TCP connection to the target system for the exchange of control messages. These allow user identifier (ID) and password to be transmitted and allow the user to specify the file and file actions desired. Once a file transfer is approved, a second TCP connection is set up for the data transfer. The file is transferred over the data connection, without the overhead of any headers or control information at the application level. When the transfer is complete, the control connection is used to signal the completion and to accept new file transfer commands.

TELNET provides a remote log-on capability, which enables a user at a terminal or personal computer to log on to a remote computer and function as if directly connected to that computer. The protocol was designed to work with simple scroll-mode terminals. TELNET is actually implemented in two modules: User TELNET interacts with the terminal input/output (I/O) module to communicate with a local terminal. It converts the characteristics of real terminals to the network standard and vice versa. Server TELNET interacts with an application, acting as a surrogate terminal handler so that remote terminals appear as local to the application. Terminal traffic between user and server TELNET is carried on a TCP connection.

72.1.2 The Open Systems Interconnection Model

The open systems interconnection (OSI) reference model was developed by the International Organization for Standardization (ISO) to serve as a framework for the development of communications protocol standards.

72.1.2.1 Overall Architecture

A widely accepted structuring technique, and the one chosen by ISO, is layering. The communications functions are partitioned into a hierarchical set of layers. Each layer performs a related subset of the functions required to communicate with another system. It relies on the next lower layer to perform more primitive functions and to conceal the details of those functions. It provides services to the next higher layer. Ideally, the layers should be defined so that changes in one layer do not require changes in the other layers. Thus, we have decomposed one problem into a number of more manageable subproblems.

The task of ISO was to define a set of layers and the services performed by each layer. The partitioning should group functions logically and should have enough layers to make each layer manageably small, but it should not have so many layers that the processing overhead imposed by the collection of layers is burdensome.

The resulting OSI architecture has seven layers, which are illustrated in [Figure 72.3](#). Each computer contains the seven layers. Communication is between applications in the two computers, labeled application *X* and application *Y* in the figure. If application *X* wishes to send a message to application *Y*, it invokes the application layer (layer 7). Layer 7 establishes a peer relationship with layer 7 of the target computer, using a layer-7 protocol (application protocol). This protocol requires services from layer 6, so the two layer-6 entities use a protocol of their own, and so on down to the physical layer, which actually transmits bits over a transmission medium.

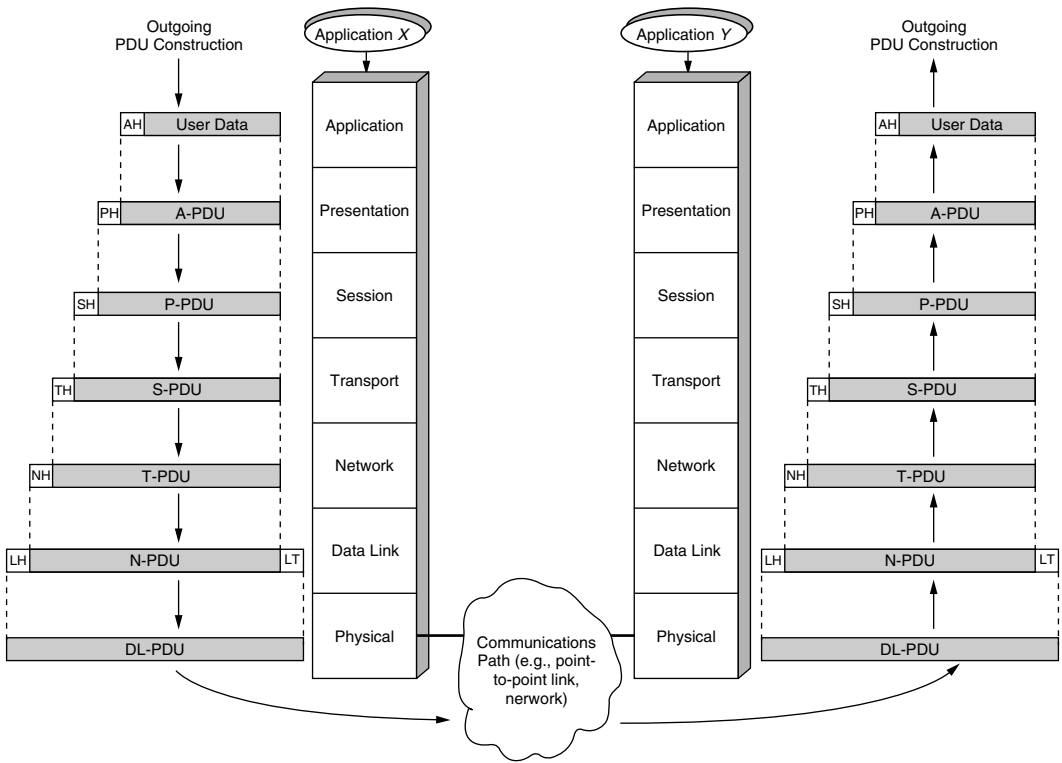

FIGURE 72.3 The OSI environment.

The figure also illustrates the way in which the protocols at each layer are realized. When application X has a message to send to application Y, it transfers those data to an application layer module. That module appends an application header to the data; the header contains the control information needed by the peer layer on the other side. The original data plus the header, referred to as an application protocol data unit (PDU), are passed as a unit to layer 6. The presentation module treats the whole unit as data and appends its own header. This process continues down through layer 2, which generally adds both a header and a trailer. This layer-2 protocol data unit, usually called a *frame*, is then transmitted by the physical layer onto the transmission medium. When the frame is received by the target computer, the reverse process occurs. As we ascend the layers, each layer strips off the outermost header, acts on the protocol information contained therein, and passes the remainder up to the next layer.

The principal motivation for development of the OSI model was to provide a framework for standardization. Within the model, one or more protocol standards can be developed at each layer. The model defines in general terms the functions to be performed at that layer and facilitates the standards-making process in two ways:

- Because the functions of each layer are well defined, standards can be developed independently and simultaneously for each layer. This speeds up the standards-making process.
- Because the boundaries between layers are well defined, changes in standards in one layer need not affect already existing software in another layer. This makes it easier to introduce new standards.

We now turn to a brief description of each layer and discuss some of the standards that have been developed for each layer.

72.1.2.2 Physical Layer

The physical layer covers the physical interface between a data transmission device and a transmission medium and the rules by which bits are passed from one to another. A well-known physical layer standard is RS-232-C.

72.1.2.3 Data Link Layer

The physical layer provides only a raw bit stream service. The data link layer attempts to make the physical link reliable and provides the means to activate, maintain, and deactivate the link. The principal service provided by the data link layer to higher layers is that of error detection and control. Thus, with a fully functional data link layer protocol, the next higher layer may assume error-free transmission over the link.

A well-known data link layer standard is high-level data link control (HDLC). For local area networks, the functionality of the data link layer is generally split into two sublayers: logical link control (LLC) and medium access control (MAC).

72.1.2.4 Network Layer

The network layer provides for the transfer of information between computers across some sort of communications network. It relieves higher layers of the need to know anything about the underlying data transmission and switching technologies used to connect systems. The network service is responsible for establishing, maintaining, and terminating connections across the intervening network. At this layer, the computer system engages in a dialogue with the network to specify the destination address and to request certain network facilities, such as priority.

There is a spectrum of possibilities for intervening communications facilities to be managed by the network layer. At one extreme, there is a direct point-to-point link between stations. In this case, there may be no need for a network layer because the data link layer can perform the necessary function of managing the link.

Next, the systems could be connected across a single network, such as a circuit-switching or packet-switching network. The lower three layers are concerned with attaching to and communicating with the network; a well-known example is the X.25 standard. The packets that are created by the end system pass through one or more network nodes that act as relays between the two end systems. The network nodes implement layers 1–3 of the architecture. The upper four layers are end-to-end protocols between the attached computers.

At the other extreme, two stations might wish to communicate but are not even connected to the same network. Rather, they are connected to networks that, directly or indirectly, are connected to each other. This case requires the use of some sort of internetworking technique, such as the use of IP.

72.1.2.5 Transport Layer

The transport layer provides a reliable mechanism for the exchange of data between computers. It ensures that data are delivered error free, in sequence, and with no losses or duplications. The transport layer also may be concerned with optimizing the use of network services and providing a requested quality of service. For example, the session layer may specify acceptable error rates, maximum delay, priority, and security features.

The mechanisms used by the transport protocol to provide reliability are very similar to those used by data link control protocols such as HDLC: the use of sequence numbers, error detecting codes, and retransmission after timeout. The reason for this apparent duplication of effort is that the data link layer deals only with a single, direct link, whereas the transport layer deals with a chain of network nodes and links. Although each link in that chain is reliable because of the use of HDLC, a node along that chain may fail at a critical time. Such a failure will affect data delivery, and it is the transport protocol that addresses this problem.

The size and complexity of a transport protocol depend on how reliable or unreliable the underlying network and network layer services are. Accordingly, ISO had developed a family of five transport protocol standards, each oriented toward a different underlying service.

72.1.2.6 Session Layer

The session layer provides the mechanism for controlling the dialogue between the two end systems. In many cases, there will be little or no need for session-layer services, but for some applications, such services are used. The key services provided by the session layer include the following:

- *Dialogue discipline*: This can be two-way simultaneous (full duplex) or two-way alternate (half-duplex).
- *Grouping*: The flow of data can be marked to define groups of data. For example, if a retail store is transmitting sales data to a regional office, the data can be marked to indicate the end of the sales data for each department. This would signal the host computer to finalize running totals for that department and start new running counts for the next department.
- *Recovery*: The session layer can provide a checkpointing mechanism, so that if a failure of some sort occurs between checkpoints, the session entity can retransmit all data since the last checkpoint.

ISO has issued a standard for the session layer that includes as options services such as those just described.

72.1.2.7 Presentation Layer

The presentation layer defines the format of the data to be exchanged between applications and offers application programs a set of data transformation services. For example, data compression or data encryption could occur at this level.

72.1.2.8 Application Layer

The application layer provides a means for application programs to access the OSI environment. This layer contains management functions and generally useful mechanisms to support distributed applications. In addition, general-purpose applications such as file transfer, electronic mail, and terminal access to remote computers are considered to reside at this layer.

72.2 Network Organization

Traditionally, data networks have been classified as either **wide-area network** (WAN) or local-area network. Although there has been some blurring of this distinction, it is still a useful one. We look first at traditional WANs and then at the more recently introduced higher speed WANs. The discussion then turns to traditional and high-speed LANs.

WANs are used to connect stations over a large area: anything from a metropolitan area to worldwide. LANs are used within a single building or a cluster of buildings. Usually, LANs are owned by the organization that uses them. A WAN may be owned by the organization that uses it (private network) or provided by a third party (public network); in the latter case, the network is shared by a number of organizations.

72.2.1 Traditional Wide-Area Networks

Traditional WANs are switched communications networks, consisting of an interconnected collection of nodes, in which information is transmitted from source station to destination station by being routed through the network of nodes. [Figure 72.4](#) is a simplified illustration of the concept. The nodes are connected by transmission paths. Signals entering the network from a station are routed to the destination by being switched from node to node. Two quite different technologies are used in wide-area switched networks: circuit switching and packet switching. These two technologies differ in the way the nodes switch information from one link to another on the way from source to destination.

72.2.1.1 Circuit Switching

Circuit switching is the dominant technology for both voice and data communications today and will remain so for the foreseeable future. Communication via circuit switching implies that there is a dedicated

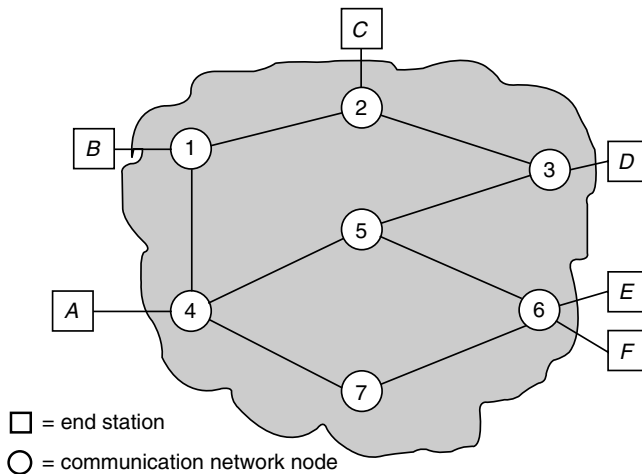

FIGURE 72.4 Simple switching network.

communication path between two stations. That path is a connected sequence of links between network nodes. On each physical link, a channel is dedicated to the connection. The most common example of circuit switching is the telephone network.

Communication via circuit switching involves three phases, which can be explained with reference to Figure 72.4. The three phases are as follows:

1. *Circuit establishment:* Before any signals can be transmitted, an end-to-end (station-to-station) circuit must be established. For example, station *A* sends a request to node 4 requesting a connection to station *E*. Typically, the link from *A* to 4 is a dedicated line, so that part of the connection already exists. Node 4 must find the next leg in a route leading to node 6. Based on routing information and measures of availability and perhaps cost, node 4 selects the link to node 5, allocates a free channel [using frequency-division multiplexing (FDM) or time-division multiplexing (TDM)] on that link and sends a message requesting connection to *E*. So far, a dedicated path has been established from *A* through 4 to 5. Because a number of stations may attach to 4, it must be able to establish internal paths from multiple stations to multiple nodes. The remainder of the process proceeds similarly. Node 5 dedicates a channel to node 6 and internally ties that channel to the channel from node 4. Node 6 completes the connection to *E*. In completing the connection, a test is made to determine if *E* is busy or is prepared to accept the connection.
2. *Information transfer:* Information can now be transmitted from *A* through the network to *E*. The transmission may be analog voice, digitized voice, or binary data, depending on the nature of the network. As the carriers evolve to fully integrated digital networks, the use of digital (binary) transmission for both voice and data is becoming the dominant method. The path is: *A*-4 link, internal switching through 4, 4-5 channel, internal switching through 5, 5-6 channel, internal switching through 6, 6-*E* link. Generally, the connection is full duplex, and signals may be transmitted in both directions simultaneously.
3. *Circuit disconnect:* After some period of information transfer, the connection is terminated, usually by the action of one of the two stations. Signals must be propagated to nodes 4, 5, and 6 to deallocate the dedicated resources.

Note that the connection path is established before data transmission begins. Thus, channel capacity must be reserved between each pair of nodes in the path and each node must have available internal switching capacity to handle the requested connection. The switches must have the intelligence to make these allocations and to devise a route through the network.

Circuit switching can be rather inefficient. Channel capacity is dedicated for the duration of a connection, even if no data are being transferred. For a voice connection, utilization may be rather high, but it still does not approach 100%. For a terminal-to-computer connection, the capacity may be idle during most of the time of the connection. In terms of performance, there is a delay prior to signal transfer for call establishment. However, once the circuit is established, the network is effectively transparent to the users. Information is transmitted at a fixed data rate with no delay other than the propagation delay through the transmission links. The delay at each node is negligible.

Circuit-switching technology has been driven by those applications that handle voice traffic. One of the key requirements for voice traffic is that there must be virtually no transmission delay and certainly no variation in delay. A constant signal transmission rate must be maintained, because transmission and reception occur at the same signal rate. These requirements are necessary to allow normal human conversation. Further, the quality of the received signal must be sufficiently high to provide, at a minimum, intelligibility.

72.2.1.2 Packet Switching

A packet-switching network is a switched communications network that transmits data in short blocks called packets. The network consists of a set of interconnected packet-switching nodes. A device attaches to the network at one of these nodes and presents data for transmission in the form of a stream of packets. Each packet is routed through the network. As each node along the route is encountered, the packet is received, stored briefly, and then transmitted along a link to the next node in the route. Two approaches are used to manage the transfer and routing of these streams of packets: datagram and virtual circuit.

In the datagram approach, each packet is treated independently, with no reference to packets that have gone before. This approach is illustrated in [Figure 72.5a](#). Each node chooses the next node on a packet's path, taking into account information received from neighboring nodes on traffic, line failures, and so on. So the packets, each with the same destination address, do not all follow the same route, and they may arrive out of sequence at the exit point. In some networks, the exit node restores the packets to their original order before delivering them to the destination. In other datagram networks, it is up to the destination rather than the exit node to do the reordering. Also, it is possible for a packet to be destroyed in the network. For example, if a packet-switching node crashes momentarily, all of its queued packets may be lost. Again, it is up to either the exit node or the destination to detect the loss of a packet and decide how to recover it. In this technique, each packet, treated independently, is referred to as a datagram.

In the virtual circuit approach, a preplanned route is established before any packets are sent. Once the route is established, all of the packets between a pair of communicating parties follow this same route through the network. This is illustrated in [Figure 72.5b](#). Because the route is fixed for the duration of the logical connection, it is somewhat similar to a circuit in a circuit-switching network and is referred to as a virtual circuit. Each packet now contains a virtual circuit identifier as well as data. Each node on the pre-established route knows where to direct such packets; no routing decisions are required. At any time, each station can have more than one virtual circuit to any other station and can have virtual circuits to more than one station.

If two stations wish to exchange data over an extended period of time, there are certain advantages to virtual circuits. First, the network may provide services related to the virtual circuit, including sequencing and error control. *Sequencing* refers to the fact that, because all packets follow the same route, they arrive in the original order. Error control is a service that ensures not only that packets arrive in proper sequence but also that all packets arrive correctly. For example, if a packet in a sequence from node 4 to node 6 fails to arrive at node 6, or arrives with an error, node 6 can request a retransmission of that packet from node 4. Another advantage is that packets should transit the network more rapidly with a virtual circuit; it is not necessary to make a routing decision for each packet at each node.

One advantage of the datagram approach is that the call setup phase is avoided. Thus, if a station wishes to send only one or a few packets, datagram delivery will be quicker. Another advantage of the datagram service is that, because it is more primitive, it is more flexible. For example, if congestion develops in

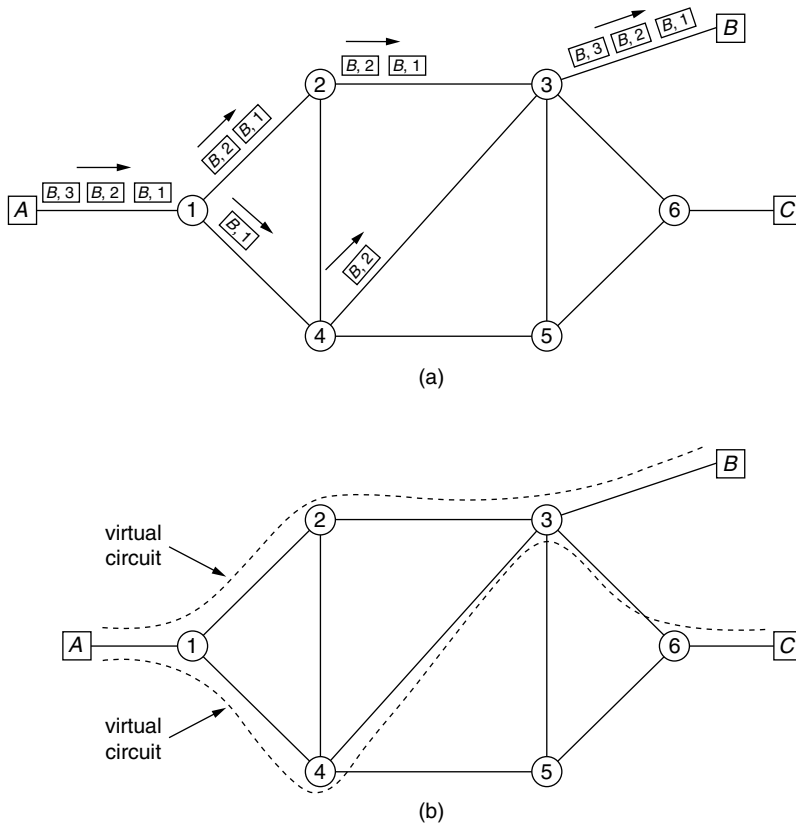

FIGURE 72.5 Virtual circuit and datagram operation: (a) datagram approach and (b) virtual circuit approach.

one part of the network, incoming datagrams can be routed away from the congestion. With the use of virtual circuits, packets follow a predefined route, and thus it is more difficult for the network to adapt to congestion. A third advantage is that datagram delivery is inherently more reliable. With the use of virtual circuits, if a node fails, all virtual circuits that pass through that node are lost. With datagram delivery, if a node fails, subsequent packets may find an alternative route that bypasses that node.

72.2.2 High-Speed Wide-Area Networks

As the speed and number of local-area networks continue their relentless growth, increasing demand is placed on wide-area packet-switching networks to support the tremendous throughput generated by these LANs. In the early days of wide-area networking, X.25 was designed to support direct connection of terminals and computers over long distances. At speeds up to 64 kb/s or so, X.25 copes well with these demands. As LANs have come to play an increasing role in the local environment, X.25, with its substantial overhead, is being recognized as an inadequate tool for wide-area networking. Fortunately, several new generations of high-speed switched services for wide-area networking are moving rapidly from the research laboratory and the draft standard stage to the commercially available, standardized-product stage. The two most important such technologies are **frame relay** and **asynchronous transfer mode (ATM)**.

72.2.2.1 Frame Relay

Frame relay provides a streamlined technique for wide-area packet switching, compared to X.25 [Black 1994b, Smith 1993]. It provides superior performance by eliminating as much as possible of the overhead

of X.25. The key differences of frame relaying from a conventional X.25 packet-switching service are as follows:

- Call control signaling (e.g., requesting that a connection be set up) is carried on a logical connection that is separate from the connections used to carry user data. Thus, intermediate nodes need not maintain state tables or process messages relating to call control on an individual per-connection basis.
- There are only physical and link layers of processing for frame relay, compared to physical, link, and packet layers for X.25. Thus, one entire layer of processing is eliminated with frame relay.
- There is no hop-by-hop flow control and error control. End-to-end flow control and error control is the responsibility of a higher layer, if it is employed at all.

Frame relay takes advantage of the reliability and fidelity of modern digital facilities to provide faster packet switching than X.25. Whereas X.25 typically operates only up to speeds of about 64 kb/s, frame relay is designed to work at access speeds up to 2 Mb/s.

Transmission of data by X.25 packets involves considerable overhead. At each hop through the network, the data link control protocol involves the exchange of a data frame and an acknowledgment frame. Furthermore, at each intermediate node, state tables must be maintained for each virtual circuit to deal with the call management and flow control/error control aspects of the X.25 protocol. In contrast, with frame relay a single user data frame is sent from source to destination, and an acknowledgment, generated at a higher layer, is carried back in a frame.

Let us consider the advantages and disadvantages of this approach. The principal potential disadvantage of frame relaying, compared to X.25, is that we have lost the ability to do link-by-link flow and error control. (Although frame relay does not provide end-to-end flow and error control, this is easily provided at a higher layer.) In X.25, multiple virtual circuits are carried on a single physical link, and link access procedure to frame mode bearer service (LAPB) is available at the link level for providing reliable transmission from the source to the packet-switching network and from the packet-switching network to the destination. In addition, at each hop through the network, the link control protocol can be used for reliability. With the use of frame relaying, this hop-by-hop link control is lost. However, with the increasing reliability of transmission and switching facilities, this is not a major disadvantage.

The advantage of frame relaying is that we have streamlined the communications process. The protocol functionality required at the user-network interface is reduced, as is the internal network processing. As a result, lower delay and higher throughput can be expected. Preliminary results indicate a reduction in frame processing time of an order of magnitude.

The frame relay data transfer protocol consists of the following functions:

- Frame delimiting, alignment, and transparency
- Frame multiplexing/demultiplexing using the address field
- Inspection of the frame to ensure that it consists of an integer number of octets (8-b bytes) prior to zero-bit insertion or following zero-bit extraction
- Inspection of the frame to ensure that it is neither too long nor too short
- Detection of transmission errors
- Congestion control functions

This architecture reduces to the bare minimum the amount of work accomplished by the network. User data are transmitted in frames with virtually no processing by the intermediate network nodes other than to check for errors and to route based on connection number. A frame in error is simply discarded, leaving error recovery to higher layers.

The operation of frame relay for user data transfer is best explained by beginning with the frame format, illustrated in [Figure 72.6](#). The format is similar to that of other data link control protocols, such as HDLC

FIGURE 72.6 Frame relay formats: (a) frame format; (b) address field, 2 octets (default); (c) address field, 3 octets; and (d) address field, 4 octets.

and LAPB, with one omission: there is no control field. In traditional data link control protocols, the control field is used for the following functions:

- Part of the control field identifies the frame type. In addition to a frame for carrying user data, there are various control frames. These carry no user data but are used for various protocol control functions, such as setting up and tearing down logical connections.
- The control field for user data frames includes send and receive sequence numbers. The send sequence number is used to sequentially number each transmitted frame. The receive sequence number is used to provide a positive or negative acknowledgment to incoming frames. The use of sequence numbers allows the receiver to control the rate of incoming frames (flow control) and to report missing or damaged frames, which can then be retransmitted (error control).

The lack of a control field in the frame relay format means that the process of setting up and tearing down connections must be carried out on a separate channel at a higher layer of software. It also means that it is not possible to perform flow control and error control.

The flag and frame check sequence (FCS) fields function as in HDLC and other traditional data link control protocols. The flag field is a unique pattern that delimits the start and end of the frame. The FCS field is used for error detection. On transmission, the FCS checksum is calculated and stored in the FCS field. On reception, the checksum is again calculated and compared to the value stored in the incoming FCS field. If there is a mismatch, then the frame is assumed to be in error and is discarded.

The information field carries higher layer data. The higher layer data may be either user data or call control messages, as explained subsequently.

The address field has a default length of 2 octets and may be extended to 3 or 4 octets. It carries a data link connection identifier (DLCI) of 10, 17, or 24 b. The DLCI serves the same function as the virtual circuit number in X.25: it allows multiple logical frame relay connections to be multiplexed over a single channel. As in X.25, the connection identifier has only local significance: each end of the logical connection assigns its own DLCI from the pool of locally unused numbers, and the network must map from one to the other. The alternative, using the same DLCI on both ends, would require some sort of global management of DLCI values.

The length of the address field, and hence of the DLCI, is determined by the address field extension (EA) bits. The C/R bit is application specific and not used by the standard frame relay protocol. The remaining bits in the address field have to do with congestion control.

72.2.2.2 Asynchronous Transfer Mode

As the speed and number of local-area networks continue their relentless growth, increasing demand is placed on wide-area packet-switching networks to support the tremendous throughput generated by these LANs. In the early days of wide-area networking, X.25 was designed to support direct connection of terminals and computers over long distances. At speeds up to 64 kb/s or so, X.25 copes well with these demands. As LANs have come to play an increasing role in the local environment, X.25, with its substantial overhead, is being recognized as an inadequate tool for wide-area networking. This has led to increasing interest in frame relay, which is designed to support access speeds up to 2 Mb/s. But, as we look to the not-too-distant future, even the streamlined design of frame relay will falter in the face of a requirement for wide-area access speeds in the tens and hundreds of megabits per second. To accommodate these gargantuan requirements, a new technology is emerging: asynchronous transfer mode (ATM), also known as cell relay [Boudec 1992, Prycker 1993].

Cell relay is similar in concept to frame relay. Both frame relay and cell relay take advantage of the reliability and fidelity of modern digital facilities to provide faster packet switching than X.25. Cell relay is even more streamlined than frame relay in its functionality and can support data rates several orders of magnitude greater than frame relay.

ATM is a packet-oriented transfer mode. Like frame relay and X.25, it allows multiple logical connections to be multiplexed over a single physical interface. The information flow on each logical connection is organized into fixed-size packets, called cells. As with frame relay, there is no link-by-link error control or flow control.

Logical connections in ATM are referred to as virtual channels. A virtual channel is analogous to a virtual circuit in X.25 or a frame-relay logical connection. A virtual channel is set up between two end users through the network and a variable-rate, full-duplex flow of fixed-size cells is exchanged over the connection. Virtual channels are also used for user–network exchange (control signaling) and network–network exchange (network management and routing).

For ATM, a second sublayer of processing has been introduced that deals with the concept of virtual path. A virtual path is a bundle of virtual channels that have the same endpoints. Thus, all of the cells flowing over all of the virtual channels in a single virtual path are switched together.

Several advantages can be listed for the use of virtual paths:

- *Simplified network architecture:* Network transport functions can be separated into those related to an individual logical connection (virtual channel) and those related to a group of logical connections (virtual path).
- *Increased network performance and reliability:* The network deals with fewer, aggregated entities.
- *Reduced processing and short connection setup time:* Much of the work is done when the virtual path is set up. The addition of new virtual channels to an existing virtual path involves minimal processing.
- *Enhanced network services:* The virtual path is internal to the network but is also visible to the end user. Thus, the user may define closed user groups or closed networks of virtual channel bundles.

International Telecommunications Union–Telecommunications Standardization Sector (ITU-T) Recommendation I.150 lists the following as characteristics of virtual channel connections:

- *Quality of service:* A user of a virtual channel is provided with a quality of service specified by parameters such as cell loss ratio (ratio of cells lost to cells transmitted) and cell delay variation.
- *Switched and semipermanent virtual channel connections:* Both switched connections, which require call-control signaling, and dedicated channels can be provided.

- *Cell sequence integrity*: The sequence of transmitted cells within a virtual channel is preserved.
- *Traffic parameter negotiation and usage monitoring*: Traffic parameters can be negotiated between a user and the network for each virtual channel. The input of cells to the virtual channel is monitored by the network to ensure that the negotiated parameters are not violated.

The types of traffic parameters that can be negotiated would include average rate, peak rate, burstiness, and peak duration. The network may need a number of strategies to deal with congestion and to manage existing and requested virtual channels. At the crudest level, the network may simply deny new requests for virtual channels to prevent congestion. Additionally, cells may be discarded if negotiated parameters are violated or if congestion becomes severe. In an extreme situation, existing connections might be terminated.

Recommendation I.150 also lists characteristics of virtual paths. The first four characteristics listed are identical to those for virtual channels. That is, quality of service, switched and semipermanent virtual paths, cell sequence integrity, and traffic parameter negotiation and usage monitoring are all also characteristics of a virtual path. There are a number of reasons for this duplication. First, this provides some flexibility in how the network manages the requirements placed on it. Second, the network must be concerned with the overall requirements for a virtual path and, within a virtual path, may negotiate the establishment of virtual circuits with given characteristics. Finally, once a virtual path is set up, it is possible for the end users to negotiate the creation of new virtual channels. The virtual path characteristics impose a discipline on the choices that the end users may make.

In addition, a fifth characteristic is listed for virtual paths:

- *Virtual channel identifier restriction within a virtual path*: One or more virtual channel identifiers, or numbers, may not be available to the user of the virtual path but may be reserved for network use. Examples would be virtual channels used for network management.

The asynchronous transfer mode makes use of fixed-size cells, consisting of a 5-octet header and a 48-octet information field (Figure 72.7). There are several advantages to the use of small, fixed-size cells. First, the use of small cells may reduce queuing delay for high-priority cells, because it waits less if it arrives slightly behind a lower priority cell that has gained access to a resource (e.g., the transmitter). Second, it appears that fixed-size cells can be switched more efficiently, which is important for the very high data rates of ATM.

Figure 72.7a shows the header format at the user–network interface. Multiple terminals may share a single access link to the network. The generic flow control field is to be used for end-to-end flow control. The details of its application are for further study. The field could be used to assist the customer in controlling the flow of traffic for different qualities of service. One candidate for the use of this field is a multiple-priority level indicator to control the flow of information in a service-dependent manner.

The virtual path identifier and virtual channel identifier fields constitute a routing field for the network. The virtual path identifier indicates a user-to-user or user-to-network virtual path. The virtual channel identifier indicates a user-to-user or user-to-network virtual channel. These identifiers have local significance (as with X.25 and frame relay) and may change as the cell traverses the network.

The payload type field indicates the type of information in the information field. A value of 00 indicates user information; that is, information from the next higher layer. Other values are for further study. Presumably, network management and maintenance values will be assigned. This field allows the insertion of network-management cells onto a user's virtual channel without impacting user's data. Thus, it could provide in-band control information.

The cell loss priority is used to provide guidance to the network in the event of congestion. A value of 0 indicates a cell of relatively higher priority, which should not be discarded unless no other alternative is available. A value of 1 indicates that this cell is subject to discard within the network. The user might employ this field so that extra information may be inserted into the network, with a CLP of 1, and delivered to the destination if the network is not congested. The network sets this field to 1 for any data cell that is in violation of a traffic agreement. In this case, the switch that does the setting realizes that the cell exceeds

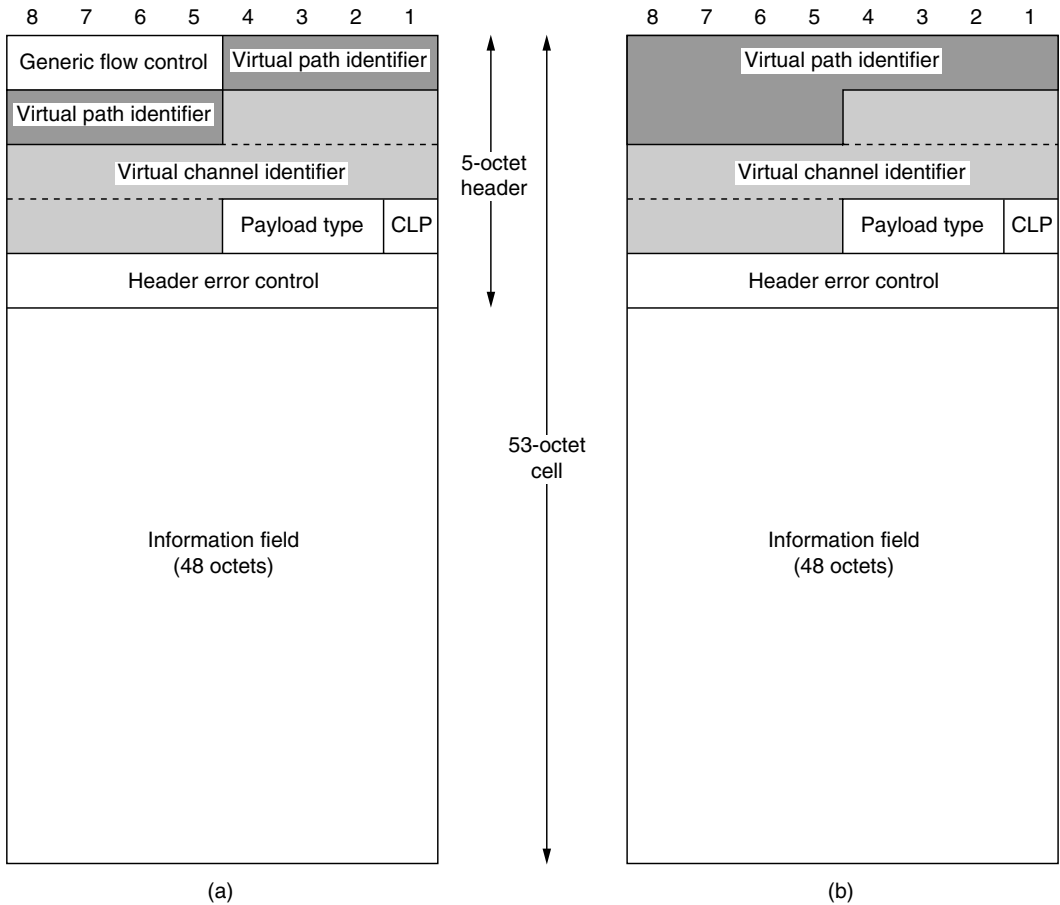

FIGURE 72.7 ATM cell format: (a) user-network interface and (b) network-network interface.

the agreed traffic parameters but that the switch is capable of handling the cell. At a later point in the network, if congestion is encountered, this cell has been marked for discard in preference to cells that fall within agreed traffic limits.

The header error control (HEC) field is an 8-b error code that can be used to correct single-bit errors in the header and to detect double-bit errors.

Figure 72.7b shows the cell header format internal to the network. The generic flow control field, which performs end-to-end functions, is not retained. Instead, the virtual path identifier field is expanded from 8 to 12 b. This allows support for an expanded number of virtual paths internal to the network to include those supporting subscribers and those required for network management.

72.2.3 Traditional Local-Area Networks

The two most widely used traditional LANs are carrier-sense multiple access/collision detection (CSMA/CD) (Ethernet) and token ring.

72.2.3.1 Carrier-Sense Multiple Access/Collision Detection (Ethernet)

The Ethernet LAN standards was originally designed to work over a bus LAN topology. With the bus topology, all stations attach, through appropriate interfacing hardware, directly to a linear transmission

medium, or bus. A transmission from any station propagates the length of the medium in both directions and can be received by all other stations.

Transmission is in the form of frames containing addresses and user data. Each station monitors the medium and copies frames addressed to itself. Because all stations share a common transmission link, only one station can successfully transmit at a time, and some form of medium access control technique is needed to regulate access.

More recently, a star topology has been used. In the star LAN topology, each station attaches to a central node, referred to as the star coupler, via two point-to-point links, one for transmission in each direction. A transmission from any one station enters the central node and is retransmitted on all of the outgoing links. Thus, although the arrangement is physically a star, it is logically a bus: a transmission from any station is received by all other stations, and only one station at a time may successfully transmit. Thus, the medium access control techniques used for the star topology are the same as for bus and tree.

With CSMA/CD, a station wishing to transmit first listens to the medium to determine if another transmission is in progress (carrier sense). If the medium is idle, the station may transmit. It may happen that two or more stations attempt to transmit at about the same time. If this happens, there will be a collision; the data from both transmissions will be garbled and not received successfully. Thus, a procedure is needed that specifies what a station should do if the medium is found busy and what it should do if a collision occurs:

1. If the medium is idle, transmit
2. If the medium is busy, continue to listen until the channel is idle, then transmit immediately
3. If a collision is detected during transmission, immediately cease transmitting
4. After a collision, wait a random amount of time and then attempt to transmit again (repeat from step 1)

Figure 72.8 illustrates the technique. At time t_0 , station *A* begins transmitting a packet addressed to *D*. At t_1 , both *B* and *C* are ready to transmit. *B* senses a transmission and so defers. *C*, however, is still unaware of *A*'s transmission and begins its own transmission. When *A*'s transmission reaches *C*, at t_2 , *C* detects the collision and ceases transmission. The effect of the collision propagates back to *A*, where it is detected some time later, t_3 , at which time *A* ceases transmission.

FIGURE 72.8 CSMA/CD operation.

The Institute of Electrical and Electronics Engineers (IEEE) LAN standards committee has developed a number of versions of the CSMA/CD standard, all under the designation IEEE 802.3. The following options are defined:

- 10-Mb/s bus topology using coaxial cable
- 10-Mb/s star topology using unshielded twisted pair
- 100-Mb/s star topology using unshielded twisted pair
- 100-Mb/s star topology using optical fiber

The last two elements in the list, both known as fast Ethernet, are the newest addition to the IEEE 802.3 standard. Both provide a higher data rate over shorter distances than traditional Ethernet. The token ring LAN standards operates over a ring topology LAN. In the ring topology, the LAN or metropolitan-area network (MAN) consists of a set of *repeaters* joined by point-to-point links in a closed loop. The repeater is a comparatively simple device, capable of receiving data on one link and transmitting it, bit by bit, on the other link as fast as it is received, with no buffering at the repeater. The links are unidirectional; that is, data are transmitted in one direction only and all oriented in the same way. Thus, data circulate around the ring in one direction (clockwise or counterclockwise).

72.2.3.2 Token Ring

Each station attaches to the network at a repeater and can transmit data onto the network through the repeater. As with the bus topology, data are transmitted in frames. As a frame circulates past all of the other stations, the destination station recognizes its address and copies the frame into a local buffer as it goes by. The frame continues to circulate until it returns to the source station, where it is removed.

Because multiple stations share the ring, medium access control is needed to determine at what time each station may insert frames.

The token ring technique is based on the use of a token packet that circulates when all stations are idle. A station wishing to transmit must wait until it detects a token passing by. It then seizes the token by changing 1 b in the token, which transforms it from a token to a start-of-packet sequence for a data packet. The station then appends and transmits the remainder of the fields (e.g., destination address) needed to construct a data packet.

There is now no token on the ring, so other stations wishing to transmit must wait. The packet on the ring will make a round trip and be purged by the transmitting station. The transmitting station will insert a new token on the ring after it has completed transmission of its packet. Once the new token has been inserted on the ring, the next station downstream with data to send will be able to seize the token and transmit. [Figure 72.9](#) illustrates the technique. In the example, *A* sends a packet to *C*, which receives it and then sends its own packets to *A* and *D*.

The IEEE 802.5 subcommittee of IEEE 802 has developed a token ring standard with the following alternative configurations:

- Unshielded twisted pair at 4 Mb/s
- Shielded twisted pair at 4 or 16 Mb/s

72.2.4 High-Speed Local-Area Networks

In recent years, the increasing traffic demands placed on LANs has led to the development of a number of high-speed LAN alternatives. The three most important are fiber distributed data interface (FDDI), Fibre Channel, and ATM LANs.

72.2.4.1 Fiber Distributed Data Interface

One of the newest LAN standards is the fiber distributed data interface [Mills 1995]. The topology of FDDI is ring. The medium access control technique employed is token ring, with only minor differences from the

FIGURE 72.9 Token ring operation.

IEEE token ring specification. The medium specified is 100-Mb/s optical fiber. The medium specification specifically incorporates measures designed to ensure high availability.

72.2.4.2 Fibre Channel

As the speed and memory capacity of personal computers, workstations, and servers have grown, and as applications have become ever more complex with greater reliance on graphics and video, the requirement for greater speed in delivering data to the processor has grown. This requirement affects two methods of data communications with the processor: I/O channel and network communications.

An I/O channel is a direct point-to-point or multipoint communications link, predominantly hardware based and designed for high speed over very short distances. The I/O channel transfers data between a buffer at the source device and a buffer at the destination device, moving only the user contents from one device to another, without regard to the format or meaning of the data. The logic associated with the channel typically provides the minimum control necessary to manage the transfer plus simple error detection. I/O channels typically manage transfers between processors and peripheral devices, such as disks, graphics equipment, compact disc-read-only memories (CD-ROMs), and video I/O devices.

A network is a collection of interconnected access points with a software protocol structure that enables communication. The network typically allows many different types of data transfer, using software to implement the networking protocols and to provide flow control, error detection, and error recovery.

Fibre Channel is designed to combine the best features of both technologies: the simplicity and speed of channel communications with the flexibility and interconnectivity that characterize protocol-based network communications [Stephens and Dedek 1995]. This fusion of approaches allows system designers to combine traditional peripheral connection, host-to-host internetworking, loosely coupled processor

clustering, and multimedia applications in a single multiprotocol interface. The types of channel-oriented facilities incorporated into the Fibre Channel protocol architecture include:

- Data-type qualifiers for routing frame payload into particular interface buffers
- Link-level constructs associated with individual I/O operations
- Protocol interface specifications to allow support of existing I/O channel architectures, such as the small computer system interface (SCSI)

The types of network-oriented facilities incorporated into the Fibre Channel protocol architecture include:

- Full multiplexing of traffic between multiple destinations
- Peer-to-peer connectivity between any pair of ports on a Fiber Channel network
- Capabilities for internetworking to other connection technologies

Depending on the needs of the application, either channel or networking approaches can be used for any data transfer.

Fibre Channel is based on a simple generic transport mechanism based on point-to-point links and a switching network. This underlying infrastructure supports a simple encoding and framing scheme that in turn supports a variety of channel and network protocols.

The key elements of a Fibre Channel network are the end systems, called *nodes*, and the network itself, which consists of one or more switching elements. The collection of switching elements is referred to as a *fabric*. These elements are interconnected by point-to-point links between ports on the individual nodes and switches. Communication consists of the transmission of frames across the point-to-point links.

Figure 72.10 illustrates these basic elements. Each node includes one or more ports, called N_Ports, for interconnection. Similarly, each fabric switching element includes one or more ports, called F_ports. Interconnection is by means of bidirectional links between ports. Any node can communicate with any other node connected to the same fabric using the services of the fabric. All routing of frames between N_Ports is done by the fabric. Frames are buffered within the fabric, making it possible for different nodes to connect to the fabric at different data rates.

A fabric can be implemented as a single fabric element, as depicted in Figure 72.10, or as a more general network of fabric elements. In either case, the fabric is responsible for buffering and routing frames between source and destination nodes.

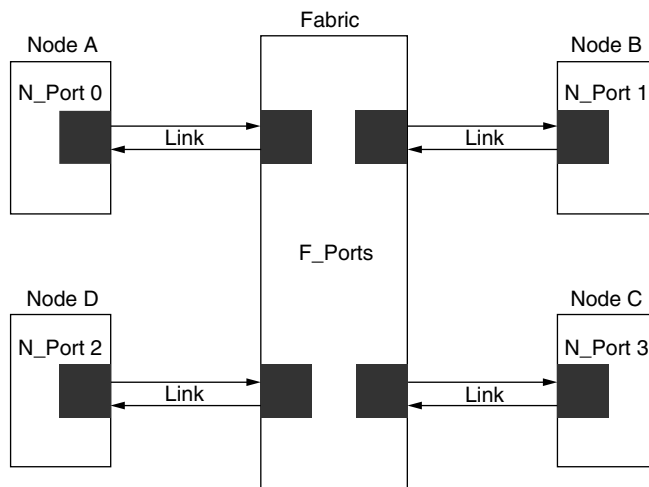

FIGURE 72.10 Fibre Channel port types.

The Fibre Channel network is quite different from the other LANs that we have examined so far. Fibre Channel is more like a traditional circuit-switching or packet-switching network in contrast to the typical shared-medium LAN. Thus, Fibre Channel need not be concerned with medium access control (MAC) issues. Because it is based on a switching network, the Fibre Channel scales easily in terms of both data rate and distance covered. This approach provides great flexibility. Fibre Channel can readily accommodate new transmission media and data rates by adding new switches and nodes to an existing fabric. Thus, an existing investment is not lost with an upgrade to new technologies and equipment. Further, as we shall see, the layered protocol architecture accommodates existing I/O interface and networking protocols, preserving the pre-existing investment.

72.2.4.3 Asynchronous Transfer Mode Local-Area Networks

High-speed LANs such as FDDI and Fiber Channel, provide a means for implementing a backbone LAN to tie together numerous small LANs in an office environment. However, there is another solution, known as the ATM LAN, that seems likely to become a major factor in local-area networking [Biagioni et al. 1993, Newman 1994]. The ATM LAN is based on the asynchronous ATM technology used in wide-area networks. The ATM LAN approach has several important strengths, two of which are as follows:

1. The ATM technology provides an open-ended growth path for supporting attached devices. ATM is not constrained to a particular physical medium or data rate. A dedicated data rate between workstations of 155 Mb/s is practical today. As demand increases and prices continue to drop, ATM LANs will be able to support devices at dedicated speeds, which are standardized for ATM, of 622 Mb/s, 2.5 Gb/s, and above.
2. ATM is becoming the technology of choice for wide-area networking. ATM can therefore be used effectively to integrate LAN and WAN configurations.

To understand the role of the ATM LAN, consider the following classification of LANs into three generations:

- *First generation:* Typified by the CSMA/CD and token ring LANs, the first generation provided terminal-to-host connectivity and supported client/server architectures at moderate data rates.
- *Second generation:* Typified by FDDI, the second generation responds to the need for backbone LANs and for support of high-performance workstations.
- *Third generation:* Typified by ATM LANs, the third generation is designed to provide the aggregate throughputs and real-time transport guarantees that are needed for multimedia applications.

Typical requirements for a third-generation LAN include the following:

1. They must support multiple, guaranteed classes of service. A live video application, for example, may require a guaranteed 2-Mb/s connection for acceptable performance, whereas a file transfer program can utilize a *background* class of service.
2. They must provide scalable throughput that is capable of growing both per-host capacity (to enable applications that require large volumes of data in and out of a single host) and aggregate capacity (to enable installations to grow from a few to several hundred high-performance hosts).
3. They must facilitate the interworking between LAN and WAN technology.

ATM is ideally suited to these requirements. Using virtual paths and virtual channels, multiple classes of service are easily accommodated, either in a preconfigured fashion (permanent connections) or on demand (switched connections). ATM is easily scalable by adding more ATM switching nodes and using higher data rates for attached devices. Finally, with the increasing acceptance of cell-based transport for wide-area networking, the use of ATM for a premises network enables seamless integration of LANs and WANs.

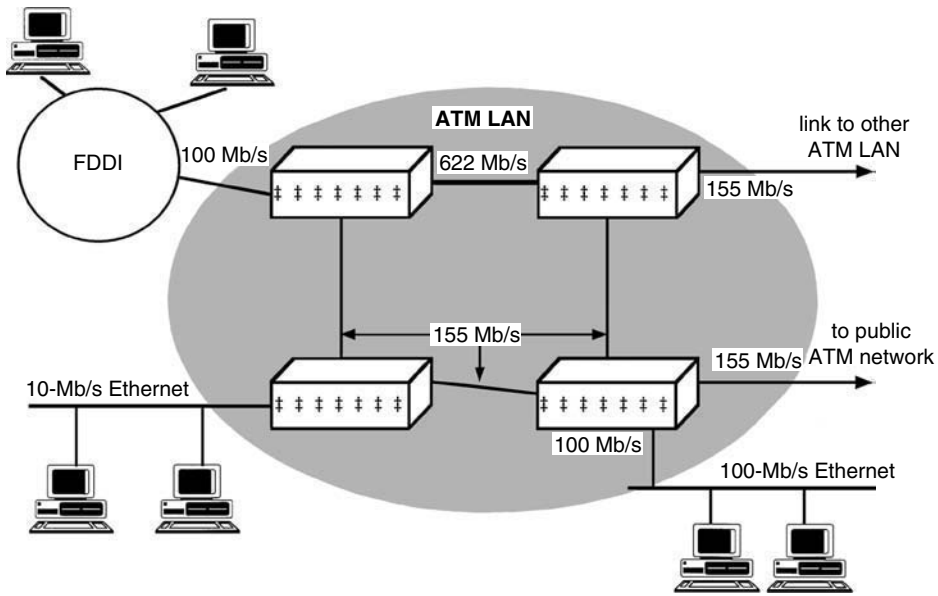

FIGURE 72.11 Example of ATM LAN configuration.

The term ATM LAN has been used by vendors and researchers to apply to a variety of configurations. At the very least, ATM LAN implies the use of ATM as a data transport protocol somewhere within the local premises. Among the possible types of ATM LANs are the following:

- *Gateway to ATM WAN:* An ATM switch acts as a router and traffic concentrator for linking a premises network complex to an ATM WAN.
- *Backbone ATM switch:* Either a single ATM switch or a local network of ATM switches interconnect other LANs.
- *Workgroup ATM:* High-performance multimedia workstations and other end systems connect directly to an ATM switch.

These are all pure configurations. In practice, a mixture of two or all three of these types of networks is used to create ATM LAN.

Figure 72.11 shows an example of a backbone ATM LAN that includes links to the outside world. In this example, the local ATM network consists of four switches interconnected with high-speed point-to-point links running at the standardized ATM rates of 155 and 622 Mb/s. On the premises, there are three other LANs, each of which has a direct connection to one of the ATM switches. The data rate from an ATM switch to an attached LAN conforms to the native data rate of that LAN. For example, the connection to the FDDI network is at 100 Mb/s. Thus, the switch must include some buffering and speed conversion capability to map the data rate from the attached LAN to an ATM data rate. The ATM switch must also perform some sort of protocol conversion from the MAC protocol used on the attached LAN to the ATM cell stream used on the ATM network. A simple approach is for each ATM switch that attaches to a LAN to function as a bridge or router.

An ATM LAN configuration such as that shown in Figure 72.11 provides a relatively painless method for inserting a high-speed backbone into a local environment. As the on-site demand rises, it is a simple matter to increase the capacity of the backbone by adding more switches, increasing the throughput of each switch, and increasing the data rate of the trunks between switches. With this strategy, the load on individual LANs within the premises can be increased and the number of LANs can grow.

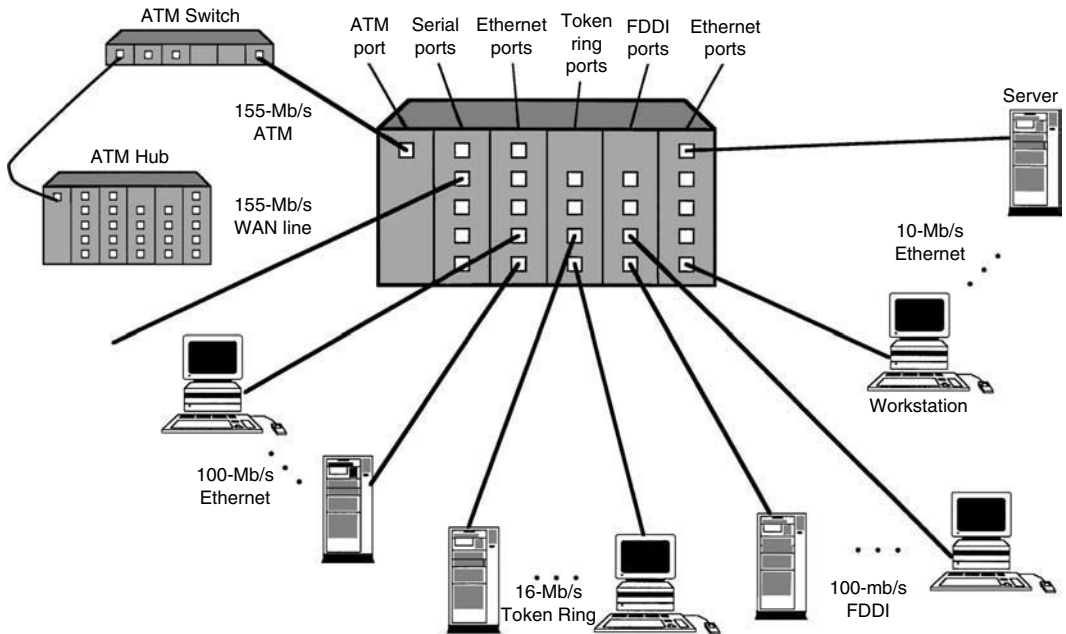

FIGURE 72.12 ATM LAN hub configuration.

However, this simple backbone ATM LAN does not address all of the needs for local communications. In particular, in the simple backbone configuration, the end systems (workstations, servers, etc.) remain attached to shared-media LANs with the limitations on data rate imposed by the shared medium.

A more advanced, and more powerful, approach is to use ATM technology in a hub. Figure 72.12 suggests the capabilities that can be provided with this approach. Each ATM hub includes a number of ports that operate at different data rates and use different protocols. Typically, such a hub consists of a number of rack-mounted modules, with each module containing ports of a given data rate and protocol.

The key difference between the ATM hub shown in Figure 72.12 and the ATM nodes depicted in Figure 72.11 is the way in which individual end systems are handled. Notice that in the ATM hub, each end system has a dedicated point-to-point link to the hub. Each end system includes the communications hardware and software to interface to a particular type of LAN, but in each case the LAN contains only two devices: the end system and the hub! For example, each device attached to a 10-Mb/s Ethernet port operates using the CSMA/CD protocol at 10 Mb/s. However, because each end system has its own dedicated line, the effect is that each system has its own dedicated 10-Mb/s Ethernet. Therefore, each end system can operate at close to the maximum 10-Mb/s data rate.

The use of a configuration such as that of either Figure 72.11 or Figure 72.12 has the advantage that existing LAN installations and LAN hardware, so-called legacy LANs, can continue to be used while ATM technology is introduced. The disadvantage is that the use of such a mixed-protocol environment requires the implementation of some sort of protocol conversion capability. A simpler approach, but one that requires that end systems be equipped with ATM capability, is to implement a pure ATM LAN.

Defining Terms

Asynchronous transfer mode (ATM): A form of packet transmission using fixed-size packets, called cells. ATM is the data transfer interface for broadband-integrated services digital network (B-ISDN). Unlike X.25, ATM does not provide error control and flow control mechanisms.

Circuit switching: A method of communicating in which a dedicated communications path is established between two devices through one or more intermediate switching nodes. Unlike packet switching, digital data are sent as a continuous stream of bits. Bandwidth is guaranteed, and delay is essentially limited to propagation time. The telephone system uses circuit switching.

Frame relay: A form of packet switching based on the use of variable-length link-layer frames. There is no network layer and many of the basic functions have been streamlined or eliminated to provide for greater throughput.

Local-area network (LAN): A communication network that provides interconnection of a variety of data communicating devices within a small area.

Open systems interconnection (OSI) reference model: A model of communications between cooperating devices. It defines a seven-layer architecture of communication functions.

Packet switching: A method of transmitting messages through a communication network, in which long messages are subdivided into short packets. The packets are then transmitted as in message switching.

Wide-area network (WAN): A communication network that provides interconnection of a variety of communicating devices over a large area, such as a metropolitan area or larger.

73.1 Introduction

Computer networking can be a very confusing field. Terms such as network, subnetwork, domain, **local area network (LAN)**, internetwork, **bridge**, **router**, and **switch** are often ill-defined. Taking the simplest view, we know that the **data-link layer** of a network delivers a packet of information to a neighboring machine, the **network layer** routes through a series of packet switches to deliver a packet from source to destination, and the transport layer recovers from lost, duplicated, and out-of-order packets. But the bridge standards choose to place routing in the data-link layer, and the X.25 network layer puts the onus on the network layer to prevent packet loss, duplication, or misordering.

In this chapter we discuss routing protocols, attempting to avoid philosophical questions such as which layer something is, or whether something is an internetwork or a network. For a more complete treatment of these and other questions, see Perlman [1999] and other chapters in this section of this Handbook.

A network consists of several computers interconnected with various types of links. One type is a *point-to-point link*, which connects exactly two machines. It can either be a dedicated link (e.g., a wire connecting the two machines) or a dial-on-demand link, which can be connected when needed (e.g., when there is traffic to send over the link). Another category of link is a **multiaccess link**. Examples are LANs, asynchronous transfer mode (ATM), and X.25. Indeed, any network can be considered a link. When one protocol uses a network as a link, it is referred to as a **tunnel**. A multiaccess link presents special challenges to the routing protocol because it has two headers with addressing information. One header (which for simplicity we call the network layer header) gives the addresses of the ultimate source and destination. The other header (which for simplicity we call the data-link header) gives the addresses of the transmitter and receiver on that particular link. (See [Figure 73.1](#), which shows a path incorporating a multiaccess link and a packet with two headers.) The terminology cannot be taken too seriously. It is not uncommon to tunnel IP over IP, for example, for an employee to connect to the corporate firewall across the Internet, using an encrypted connection. Although the “data link” in that case is an entire network, from the point of view of the protocols using it as a link, it can be considered just a data link.

We start by describing the routing protocols used by devices called bridges or switches, and then describe the routing protocols used by routers. Although the purpose of this chapter is to discuss the algorithms

FIGURE 73.1 A multiaccess link and a packet with two headers.

generically, the ones we have chosen are ones that are in widespread use. In many cases we state timer values and field lengths chosen by the implementation, but it should be understood that these are general-purpose algorithms. The purpose of this chapter is not as a reference on the details of particular implementations, but to understand the variety of routing algorithms and the trade-offs between them.

73.2 Bridges/Switches

The term **switch** is generally a synonym for a bridge, although the term “switch” is sometimes used to refer to any forwarding box, including routers. So we use the term “bridge” to avoid ambiguity. The characteristic of a bridge that differentiates it from a router is that a bridge does its routing in the data-link layer, whereas a router does it in the network layer. But that becomes a matter of philosophy and history in which a standards body defined a particular algorithm rather than any property of the protocol itself. If the protocol was defined by a data-link layer standards body, the box implementing it becomes a bridge. If the same protocol were defined by a network layer standards body, the box implementing it would become a router. The algorithm itself could, in theory, be implemented in either layer.

There were routers before there were bridges. What happened was the invention of the so-called local area network, which is a multiaccess link. Unfortunately, the world did not think of a LAN as a multiaccess link, which would be a component in some larger network. Instead, perhaps because the inclusion of the word “network” into the name local area network, many systems were designed with the assumption that the LAN itself was the entire network, and the systems were designed without a network layer, making these protocols unroutable, at least through the existing network layer protocols.

There are two types of bridging technologies specified in the standards. One is known as the transparent bridge. This technology had as a goal complete backward compatibility with existing LAN-only systems. The other technique is known as source route bridging, which can only be considered different from a network layer protocol because the standards committee that adopted it was empowered to define data-link protocols, and because the fields necessary for running this protocol were stuck into a header that was defined as a data-link header. Source route bridges are becoming rare in practice, although they are still defined by the standards.

73.2.1 Transparent Bridging

The goal of transparent bridging was to invent a box that would interconnect LANs even though the stations were designed with protocols that only worked on a LAN; that is, they lacked a network layer able to cooperate with routers, devices that were designed for forwarding packets.

The basic idea of a transparent bridge is something that is attached to two or more LANs. On each LAN, the bridge listens promiscuously to all packets, stores them, and forwards each packet onto each other LAN when given permission by the LAN protocol on that LAN. An enhancement is to have the bridge learn, based on addresses in the LAN header, of packets received by the bridge, where the stations reside, so that the bridge does not unnecessarily forward packets. (See [Figure 73.2](#), where a bridge has learned some of

FIGURE 73.2 A bridge learning station addresses.

the station addresses.) The bridge learns from the source field in the LAN header, and forwards based on the destination address. For example, in Figure 73.2, when S transmits a packet with destination address D, the bridge learns which interface S resides on, and then looks to see if it has already learned where D resides. If the bridge does not know where D is, then the bridge forwards the packet onto all interfaces (except the one from which the packet was received). If the bridge does know where D is, then the bridge forwards it only onto the interface where D resides, or if the packet arrived from that interface, the bridge discards the packet.

This simple idea only works in a loop-free topology. Loops create problems:

- Packets that will not die: there is no **hop** count in the header, as there would be in a reasonable network layer protocol, to eliminate a packet that is traversing a loop.
- Packets that proliferate uncontrollably: network layer forwarding does not, in general, create duplicate packets, because each router forwards the packet in exactly one direction, and specifies the next recipient. With bridges, a bridge might forward a packet in multiple directions, and many bridges on the LAN might forward a packet. Each time a bridge forwards in multiple directions, or more than one bridge picks up a packet for forwarding, the number of copies of the packet grows.
- If there is more than one path from a bridge to a given station, that bridge cannot learn the location of the station, because packets from that source will arrive on multiple interfaces.

One possibility was to simply declare that bridged topologies must be physically loop-free. But that was considered unacceptable for the following reasons:

- The consequences of accidental misconfiguration could be disastrous; any loop in some remote section of the bridged network might spawn such an enormous number of copies of packets that it would bring down the entire bridged network. It would also be very difficult to diagnose and to fix.
- Loops are good because a loop indicates an alternate path in case of failure.

The solution was the spanning tree algorithm, which is constantly run by bridges to determine a loop-free subset of the current topology. Data packets are only transmitted along the tree found by the spanning tree algorithm. If a bridge or link fails, or if bridges or links start working, the spanning tree algorithm will compute a new tree. The spanning tree algorithm is described in the next section.

73.2.2 Spanning Tree Algorithm

The basic idea behind the spanning tree algorithm is that the bridges agree upon one bridge to be the root of the spanning tree. The tree of shortest paths from that root bridge to each LAN is the calculated spanning tree.

How do the bridges decide on the root? Each bridge comes, at manufacture time, with a globally unique 48-bit **IEEE 802 address**, usually one per interface. A bridge chooses one of the 48-bit addresses that it owns as its identifier (ID). Because each bridge has a unique number, it is a simple matter to choose the one with the smallest number. However, because some network managers like to easily influence which bridge will be chosen, there is a configurable priority value that acts as a more significant field tacked onto the ID. The concatenated number consisting of priority and ID is used in the election, and the bridge

with the smallest value is chosen as the root. The way in which the election proceeds is that each bridge assumes itself to be the root unless it hears, through spanning tree configuration messages, of a bridge with a smaller value for priority-ID. News of other bridges is learned through receipt of spanning tree configuration messages, which we describe shortly.

The next step is for a bridge to determine its best path to the root bridge and its own cost to the root. This information is also discovered through receipt of spanning tree configuration messages.

A spanning tree configuration message contains the following, among other information:

- Priority-ID of best known root
- Cost from transmitting bridge to root
- Priority-ID of transmitting bridge

A bridge keeps the best configuration message received on each of its interfaces. The fields in the message are concatenated together, from most significant to least significant, as root's priority-ID to cost to root to priority-ID of transmitting bridge. This concatenated quantity is used to compare messages. The one with the smaller quantity is considered better. In other words, only information about the best-known root is relevant. Then, information from the bridge closest to that root is considered, and then the priority-ID of the transmitting bridge is used to break ties.

Given a best received message on each interface, B chooses the root as follows:

- Itself, if its own priority-ID beats any of the received value, else
- The smallest received priority-ID value

B chooses its path to the root as follows:

- Itself, if it considers itself to be the root, else
- The minimum cost through each of its interfaces to the best-known root

Each interface has a cost associated with it, either as a default or configured. The bridge adds the interface cost to the cost in the received configuration message to determine its cost through that interface.

B chooses its own cost to the root as follows:

- 0, if it considers itself to be the root, else
- The cost of the minimum cost path chosen in the previous step

B now knows what it would transmit as a configuration message, because it knows the root's priority-ID, its own cost to that root, and its own priority-ID. If B's configuration message is better than any of the received configuration messages on an interface, then B considers itself the *designated bridge* on that interface, and transmits configuration messages on that interface. If B is not the designated bridge on an interface, then B will not transmit configuration messages on that interface.

Each bridge determines which of its interfaces are in the spanning tree. The interfaces in the spanning tree are as follows:

- The bridge's path to the root: if more than one interface gives the same minimal cost, then exactly one is chosen. Also, if this bridge is the root, then there is no such interface.
- Any interfaces for which the bridge is designated bridge are in the spanning tree.

If an interface is not in the spanning tree, the bridge continues running the spanning tree algorithm but does not transmit any data messages (messages other than spanning tree protocol messages) to that interface, and ignores any data messages received on that interface.

If the topology is considered a graph with two types of nodes, bridges and LANs, the following is the reasoning behind why this yields a tree:

- The root bridge is the root of the tree.
- The unique parent of a LAN is the designated bridge.
- The unique parent of a bridge is the interface that is the best path from that bridge to the root.

73.2.3 Dealing with Failures

The root bridge periodically transmits configuration messages (with a configurable timer on the order of 1 s). Each bridge transmits a configuration message on each interface for which it is designated, after receiving one on the interface which is that bridge's path to the root. If some time elapses (a configurable value with default on the order of 15 s) in which a bridge does not receive a configuration message on an interface, the configuration message learned on that interface is discarded.

In this way, roughly 15 s after the root or the path to the root has failed, a bridge will discard all information about that root, assume itself to be the root, and the spanning algorithm will compute a new tree.

73.2.3.1 Eliminating Temporary Loops

In a routing algorithm, the nodes learn information at different times. During the time after a topology change and before all nodes have adapted to the new topology, there are temporary loops or temporary partitions (no way to get from some place to some other place). Because temporary loops are so disastrous with bridges (because of the packet proliferation problem), bridges are conservative about bringing an interface into the spanning tree. There is a timer (on the order of 30 s, but configurable). If an interface was not in the spanning tree, but new events convince the bridge that the interface should be in the spanning tree, the bridge waits for this timer to expire before forwarding data messages to and from the interface.

73.2.3.2 Properties of Transparent Bridges

Transparent bridges have some good properties:

- They are plug-and-play; that is, no configuration is required.
- They fulfill the goal of making no demands on end stations to interact with the bridges in any way.

They have some disadvantages:

- The topology is confined to a spanning tree, which means that some paths are not optimal.
- The spanning tree algorithm is purposely slow about starting to forward on an interface (to prevent temporary loops).

The overhead of the spanning tree algorithm is insignificant. The memory required for a bridge that has k interfaces is about $k * 50$ bytes, regardless of how large the actual network is. The bandwidth consumed per LAN (once the algorithm settles down) is a constant, regardless of the size of the network (because only the designated bridge periodically issues a spanning tree message, on the order of once a second). At worst, for the few seconds while the algorithm is settling down after a topology change, the bandwidth on a LAN is at most multiplied by the number of bridges on that LAN (because for a while more than one bridge on that LAN will think it is the designated bridge). The central processing unit (CPU) consumed by a bridge to run the spanning tree algorithm is also a constant, regardless of the size of the network.

73.2.4 Source Route Bridging

Source route bridging was a competing proposal in the IEEE 802 committee. Initially, 802.1, the committee standardizing bridges, chose transparent bridges, but the source routing proposal resurfaced in the 802.5 (Token Ring) committee as a method of interconnecting token rings.

Source route bridging did not have as a goal the ability to work with existing stations. As such, there is really no technical property of source route bridging that makes it natural for it to appear in the data-link layer. It places as much burden on a station as a network layer protocol (e.g., IP, IPX, Appletalk, DECnet). The only reason it is considered a bridging protocol rather than a routing protocol is that it was done within IEEE 802, a committee whose charter was LANs, rather than a network layer committee. The fields to support source route bridging also appear in the LAN header (because it was defined by a data-link layer committee), but the actual algorithm could, in theory, have been done in the network layer.

The idea behind source route bridging is that the data-link header is expanded to include a route. The stations are responsible for discovering routes and maintaining route caches. Discovery of a route to station D is done by source S launching a special type of packet, an *all-paths explorer* packet, which spawns copies every time there is a choice of path (multiple bridges on a LAN or a bridge with more than two ports). Each copy of the explorer packet keeps a history of the route it has taken. This process, although it might be alarmingly prolific in richly connected topologies, does not spawn infinite copies of the explorer packet for two reasons:

- The maximum length route is 14 hops; and so after 14 hops, the packet is no longer forwarded.
- A bridge examines the route before forwarding it onto a LAN, and will not forward onto that LAN if that LAN already appears in the route.

When D receives the (many) copies of the packet, it can choose a path based on criteria such as when it arrived (perhaps indicating the path is faster), or on length of path, or on maximum packet size along the route, which is calculated along with the route.

A route consists of an alternating list of LAN numbers and bridge numbers: 12 bits are allocated for the LAN number, and 4 bits for the bridge number. The bridge number at 4 bits will obviously not distinguish between all the bridges. Instead, the bridge number only distinguishes bridges that interconnect the same pair of LANs. For example, if the route is LAN A, bridge 3, LAN B, bridge 7, LAN C, and it is received by a bridge on the port that bridge considers to be LAN A, then the bridge looks forward in the route, finds the next LAN number (B), and then looks up the bridge number it has been assigned with respect to the LAN pair (A, B). If it has been assigned 3 for that pair, then it will forward the packet onto the port it has configured to be B.

There are three types of source route bridge packets:

1. Specifically routed: the route is in the header and the packet follows the specified route.
2. All-paths explorer: the packet spawns copies of itself at each route choice, and each copy keeps track of the route it has traversed so far.
3. Single copy broadcast: this acts as an all-paths explorer except that this type of packet is only accepted from ports in the spanning tree and only forwarded to ports in the spanning tree. A single copy will be delivered to the destination, and the accumulated route at the destination will be the path through the spanning tree.

To support the third type of packet, source route bridges run the same spanning tree algorithm as described in the transparent bridge section.

A source route bridge is configured with a 12-bit LAN number for each of its ports, along with a 4-bit bridge number for each possible pair of ports. In cases where a bridge has too many ports to make it feasible to configure a bridge number for each port pair, many implementations pretend there is an additional LAN inside the bridge, which must be configured with a LAN number, say, n . Paths through the bridge from LAN j to LAN k (where j and k are real LANs) look like they go from j to n to k . Each time a packet goes through such a bridge, it uses up another available hop in the route, but the advantage of this scheme is that because no other bridge connects to LAN n , the bridge does not need to be configured with any bridge numbers; it can always use 1.

The algorithm the source route bridge follows for each type of packet is as follows:

- A specifically routed packet is received on the port that the bridge considers LAN j : do a scan through the route to find j . If j is not found, drop the packet. If j is found, scan to the next LAN in the route. If the LAN is k , and this bridge has a port configured as k , then find the bridge number specified between j and k , say, b . If this bridge is configured to be b with respect to the pair (j, k) , then forward the packet onto LAN k . Otherwise, drop the packet.
- An all-paths explorer packet is received on the port that the bridge considers LAN j : if j is not the last hop in the route, drop the packet. Otherwise, for each other port, forward the packet onto that port unless the destination port's LAN number is already in the accumulated route. If the destination LAN number, say, k , is not in the route, then append (b, k) to the route, where k is the

destination LAN number and b is the bridge's number with respect to (j, k) . If the route is already full, then drop the packet.

- A single copy broadcast is received on the port that the bridge considers LAN j : if the port from which it was received is not in the spanning tree, drop the packet; otherwise, treat it as an all-paths explorer except do not forward onto ports in the spanning tree.

The standard was written from the point of view of the bridge and did not specify end-station operation. For example, there are several strategies end stations might use to maintain their route cache. If S wants to talk to D , and does not have D in its cache, S might send an all-paths explorer. Then D might at that point choose a route from the received explorers, or it might return each one to the source so that the source could make the choice. Or it might choose a route but send an explorer back to the source so that the source could independently make a route choice. Or maybe S , instead of sending an all-paths explorer, might send a single copy explorer, and D might respond with an all-paths explorer.

73.2.5 Properties of Source Route Bridging

Relative to transparent bridges, source route bridges have the following advantages:

- It is possible to get an optimal route from source to destination.
- It is possible to spread traffic load around the network rather than concentrating it into the spanning tree.
- It computes a maximum packet size on the path.
- A bridge that goes down will not disrupt conversations that have computed paths that do not go through that bridge.

Relative to transparent bridges, source route bridges have the following disadvantages:

- In a topology that is not physically a tree, the exponential proliferation of explorer packets is a serious bandwidth drain.
- It requires a lot of configuration.
- It makes end stations more complicated because they have to maintain a route cache.

Because source route bridging is a routing protocol that requires end-station cooperation, it must in fairness be compared as well against network layer protocols. Against a network layer protocol such as IP, IPX, DECnet, Appletalk, CLNP, etc., source route bridging has the following advantages:

- It computes the maximum packet size on the path.
- Although it requires significant configuration of bridges, it does not require configuration of endnodes (as in IP, although IPX, DECnet Phase V, and Appletalk also avoid configuration of endnodes).

However, relative to network layer protocols, source route bridging has the following disadvantages:

- The exponential overhead of the all-paths explorer packets.
- The delay before routes are established and data can be exchanged, unless data are carried as an all-paths explorer or single copy broadcast.

73.3 Routers

In this section we discuss network layer protocols and routing algorithms generically. Network layer protocols can be connection oriented or connectionless. A connection-oriented protocol sets up a path, and the routers along the path of a conversation keep state about the information. A connectionless protocol just puts a source and destination address on the packet and launches it. Each packet is self-contained and

is routed independently of other packets from the same conversation. Different packets from the same source to the same destination might take different paths.

Another dimension in which network layer protocols can differ is whether they provide reliable or datagram service. Datagram is best-effort service. With a reliable service, the network layer makes sure that every packet is delivered and refuses to deliver packet n until it manages to deliver $n - 1$.

Examples of datagram connectionless network layers are IPv4, IPv6, IPX, DECnet, CLNP, and Appletalk. An example of a datagram connection-oriented network layer is ATM. An example of a reliable connection-oriented network layer is X.25. The last possibility, a reliable connectionless network layer, is not possible, and fortunately there are no examples of standards attempting to accomplish this.

The distinction between connection-oriented and connectionless network layers is blurring. In a connectionless network, routers often keep caches of recently seen addresses, and forward much more efficiently when the destination is in the cache. Usually all but the first packet of a conversation are routed very quickly because the destination is in the router's cache. As such, the first packet of the conversation acts as a route setup, and the routers along the path are keeping state, in some sense. Also, there is talk of adding lightweight connections to connectionless network layer protocols for bandwidth reservation or other reasons. In the header would be a field called something like *flow identifier*, which identifies the conversation, and the routers along the path would keep state about the conversation. Another connection-like feature sometimes implemented in routers is header compression, whereby neighbor routers agree on a shorthand for the header of recently seen packets. The first packet of a conversation alerts neighbors to negotiate a shorthand for packets for that conversation.

Whether the network layer is connection oriented or not (even if it is possible to categorize network layers definitively as one or the other) has no relevance to the fact that the network layer needs a routing protocol. Sometimes people think of a connection-oriented network as one in which all of the connections are already established, with a table of input port/connection ID mapping to output port/connection ID, and the only thing the router needs to do is a table lookup of input port/connection ID. If this were the case, then a router in a connection-oriented network would not need a routing protocol, but it is not the case. For the mapping table to be created, a route setup packet traverses the path to the destination, and a router has to make the same sort of routing decision as to how to reach the destination as it would on a per-packet basis in a connectionless network. Thus, whether the network is connectionless or not does not affect the type of routing protocol needed. Connectionless network layer protocols differ only in packet format and type of addressing. The type of routing protocol is not affected by the format of data packets and so for the purpose of discussing routing algorithms, it is not necessary for us to pick a specific network layer protocol.

73.3.1 Types of Routing Protocols

One categorization of routing protocols is distance vector vs. link state. Another categorization is intradomain vs. interdomain. We discuss these issues, but first we discuss the basic concepts of addressing and hierarchy in routing and addressing.

73.3.1.1 Hierarchy

A routing protocol can handle up to some sized network. Beyond that, many factors might make the routing protocol overburdened, including:

- Memory to hold the routing database
- CPU to compute the routing database
- Bandwidth to transmit the routing information
- The volatility of the information

It takes a routing protocol some amount of time to stabilize to new routes after a topology change. If the topology changes more frequently than the time it takes for the algorithm to settle, things will not work very well.

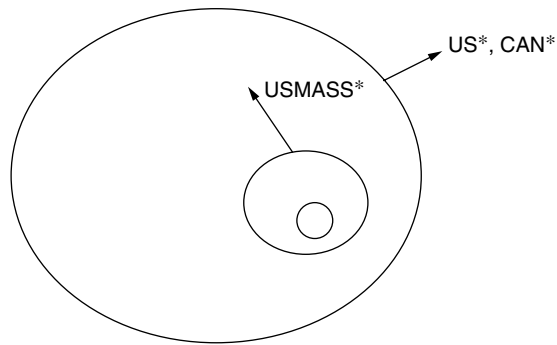

FIGURE 73.3 Network topology with addresses.

To support a larger network, portions of the network can be summarized to the outside world. This is similar to breaking the world up into countries, and within a country into states, and within a state into cities. It would be too difficult for the post office to know how to reach every street in the world (assuming that all of the streets had globally unique names); and so within a city, the post office knows all of the streets. But if it does not belong in your city, your post office just forwards it to the appropriate city, unless the letter belongs in a different state (or country). Then the post office just forwards it to the appropriate state (or country). It is routed to the appropriate state, then city, then street, and then finally to the destination.

With a network, assuming addresses are handed out sensibly, a logical circle can be drawn around a portion of the network, and all of the contents of the circle can be summarized with a small amount of information. For example, assuming postal addresses again, all of the U.S. could be summarized as: any addresses that start with the string US. All of Massachusetts, U.S., could be summarized as: any addresses that start with the string USMass'. Assuming North America was the logical place to draw a logical circle, then what would be advertised is: any addresses that start with the string US' or Canada' (see Figure 73.3).

A packet is routed according to the longest matching prefix that has been advertised. For instance, if the packet is addressed to: USMassLittletownMainStRadiaPerlman, and there are prefixes that have been advertised for US*, USMass*, then the packet will be routed toward USMass*. If the packet originated outside the U.S., then most likely the longest prefix seen by the routing protocol outside the U.S. would be US*. Once it reached the U.S., the advertisement USMass' would be visible.

73.3.1.2 Hierarchical Addressing

To support hierarchical routing, addresses must be handed out so there is some mechanism for conveniently summarizing addresses in a region. The typical method is to give an organization a block of addresses that all start with the same prefix. The organization might then hand out blocks of the addresses it owns to suborganizations. For example, suppose there are three major backbone Internet providers, and each is given a block of addresses. Say the blocks are xyz*, a*, and b* (there is no reason why the prefix has to be the same length for each provider). The provider that has the block a* has some subscribing regional providers, and gives each of them a block of addresses to give to their customers. Say there are five regional providers, and the blocks given out are axyc*, an*, ak*, and adkfjlk*. The regional provider with the block axye* might give out blocks to each subscribing customer network that look like axyc1*, axyc2*, axyc3*, etc. One of those customers with a large network might be careful to assign addresses within the network so that the network can be broken again into pieces that are summarizable (see Figure 73.4).

With this assignment of addresses, provider 1 merely has to advertise: I can reach all addresses of the form xyz*. Typically, the network closer to the backbone advertises * outward, and a network advertises the block summarizing its own addresses toward the backbone. Thus, in Figure 73.4, R1 would most likely advertise * to R2, and R2 would advertise axye* to R1.

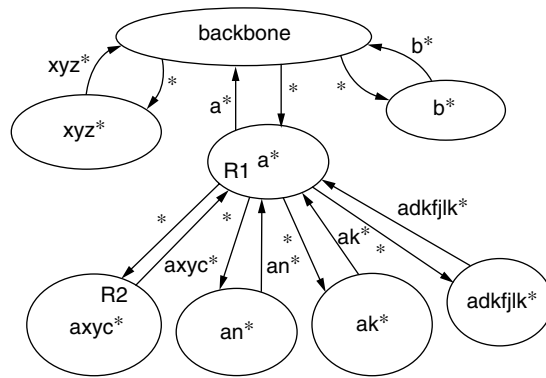

FIGURE 73.4 Block address assignment example.

73.3.1.3 Domains

What is a domain? It is a portion of a network in which the routing protocol that is running is called an intradomain routing protocol. Between domains one runs an interdomain routing protocol. Well, what is an intradomain protocol? It is something run within a domain. This probably does not help our intuition any.

Originally, the concept of a domain arose around the superstition that routing protocols were so complex that it would be impossible to get the routers from two different organizations to cooperate in a routing protocol, because the routers might have been bought from different vendors, and the metrics assigned to the links might have been assigned according to different strategies. It was thought that a routing protocol could not work under these circumstances. Yet it was important to have reachability between domains.

One possibility was to statically configure reachable addresses from other domains. But a protocol of sorts was devised, known as EGP, which was like a distance vector protocol but without exchanging metrics. It only specified what addresses were reachable, and only worked if the topology of domains was a tree (loop-free). EGP placed such severe restraints on the topology, and was itself such an inefficient protocol, that it was clear it needed to be replaced.

In the meantime, intradomain routing protocols were being specified well enough that multivendor operation was considered not only possible but mandatory. There was no particular reason why a different type of protocol needed to run between domains, except for the possible issue of policy-based routing.

The notion of policy-based routing is that it no longer suffices to find a path that physically works, or to find the minimum cost path, but that paths had to obey fairly arbitrary, complex, and eternally changing rules such as a particular country would not want its packets routed via some other particular country. The notion that there should be different types of routing protocols within a domain and between domains makes sense if we agree with all of the following assumptions:

- Within a domain, policy-based routing is not an issue; all paths are legal.
- Between domains, policy-based routing is mandatory, and the world would not be able to live without it.
- Providing for complex policies is such a burden on the routing protocol that a protocol that did policy-based routing would be too cumbersome to be deployed within a domain.

I happen not to agree with any of these assumptions, but these are beliefs, and not something subject to proof either way. Because enough of the world believes these assumptions, different protocols are being devised for interdomain vs. intradomain. At the end of this chapter we discuss some of the interdomain protocols.

73.3.1.4 Forwarding

In a connectionless protocol (such as IP, etc.), data is sent in chunks known as packets, together with information that specifies the source and destination. Each packet is individually addressed and two packets between the same pair of nodes might take different paths. Each router makes an independent decision as to where to forward the packet. The forwarding table consists of (destination, forwarding decision) pairs.

In contrast, in a connection-oriented protocol such as ATM, X.25, or MPLS, an initial packet sets up the path and assigns a connection identifier (also known as a label). Data packets only contain the connection identifier, rather than a source and destination address. Typically the connection identifier is shorter, and easier to parse (because it is looked up based on exact match rather than on longest prefix match). It would be very difficult to assign a connection identifier that was guaranteed not to be in use on any link in the path, so instead the connection identifier is only link-local, and is replaced at each hop.

In a connection-oriented protocol, the forwarding decision is based on the (input port, connection identifier) and the forwarding table will tell the router not only the outgoing port, but also what value the connection identifier on the outgoing packet should be.

A connection-oriented protocol still needs a routing protocol, and the initial path setup packet is routed similarly to packets in connectionless protocols.

Originally, connection-oriented forwarding was assumed preferable because it allowed for faster forwarding decisions. But today, connection-oriented forwarding is gaining popularity because it allows different traffic to be assigned to different paths. This is known as **traffic engineering**.

73.3.1.5 Routing Protocols

The purpose of a routing protocol is to compute a *forwarding database*, which consists of a table listing (destination, neighbor) pairs. When a packet needs to be forwarded, the destination address is found in the forwarding table, and the packet is forwarded to the indicated neighbor.

In the case of hierarchical addressing and routing, destinations are not exact addresses, but are rather address prefixes. The longest prefix matching the destination address is selected and routed forward.

The result of the routing computation, the forwarding database, should be the same whether the protocol used is distance vector or link state.

73.3.1.6 Distance Vector Routing Protocols

One class of routing protocol is known as distance vector. The idea behind this class of algorithm is that each router is responsible for keeping a table (known as a distance vector) of distances from itself to each destination. It computes this table based on receipt of distance vectors from its neighbors. For each destination D, router R computes its distance to D as follows:

- 0, if $R = D$
- The configured cost, if D is directly connected to R
- The minimum cost through each of the reported paths through the neighbors

For example, suppose R has four ports, a, b, c, and d. Suppose also that the cost of each of the links is, respectively, 2, 4, 3, and 5. On port a, R has received the report that D is reachable at a cost of 7. The other (port, cost) pairs R has heard are (b, 6), (c, 10), and (d, 2). Then the cost to D through port a will be 2 (cost to traverse that link) + 7, or 9. The cost through b will be 4 + 6, or 10. The cost through c will be 3 + 10, or 13. The cost through d will be 5 + 2, or 7. So the best path to D is through port d, and R will report that it can reach D at a cost of 7 (see [Figure 73.5](#)).

The spanning tree algorithm is similar to a distance vector protocol in which each bridge is only computing its cost and path to a single destination, the root. But the spanning tree algorithm does not suffer from the count-to-infinity behavior that distance vector protocols are prone to (see next section).

FIGURE 73.5 Example: distance vector protocol.

FIGURE 73.6 Example: the count-to-infinity problem.

73.3.1.7 Count-to-Infinity

One of the problems with distance vector protocols is known as the count-to-infinity problem. Imagine a network with three nodes, A, B, and C (see Figure 73.6).

Let us discuss everyone's distance to C. C will be 0 from itself, B will be 1 from C, and A will be 2 from C. When C crashes, B unfortunately does not conclude that C is unreachable, but instead goes to its next best path, which is via neighbor A, who claims to be able to reach C at a cost of 2. So now B concludes it is 3 from C, and that it should forward packets for C through A. When B tells A its new distance vector, A does not get too upset. It merely concludes its path (still through B) has gotten a little worse, and now A is 4 from C. A will report this to B, which will update its cost to C as 5, and A and B will continue this until they count to infinity. Infinity in this case is mercifully not the mathematical definition of infinity, but is instead a parameter (with a definite finite value such as 16). Routers conclude if the cost to something is greater than this parameter, that something must be unreachable.

A common enhancement that makes the behavior a little better is known as *split horizon*. The split horizon rule as usually implemented says that if router R uses neighbor N as its best path to destination D, R should not tell N that R can reach D. This eliminates loops of two routers. For instance, in Figure 73.6, A would not have told B that A could reach C. Thus, when C crashed, B would conclude B could not reach C at all; and when B reported infinity to A, A would conclude that A could not reach C either, and everything would work as we would hope it would.

Unfortunately, split horizon does not fix loops of three or more routers. Referring to Figure 73.7, and looking at distances to D, when D crashes, C will conclude C cannot reach D. (Because of the split horizon rule, A and B are not reporting to C that they can reach D.)

C will inform A and B that C can no longer reach D. Unfortunately, each of them thinks they have a next-best path through the other. Say A acts first, decides its best path is through B, and that A is now 3 from D. A will report infinity to B (because of split horizon), and report 3 to C. B will now (for a moment) think it cannot reach D. It will report infinity to A, but it is too late; A has already reported a finite cost to C. C will now report 4 to B, which will now conclude it is 5 from D.

Although split horizon does not solve the problem, it is a simple enhancement, never does any harm, does not add overhead, and helps in many cases.

Most of the distance vector protocols in use [router information protocol (RIP) for IP and IPX, and RTMP for Appletalk] are remarkably similar, and we call them the RIP-family of distance vector protocols. These protocols are simple to implement, but are very slow to converge after a topology change. The idea is

FIGURE 73.7 Example: loops with three or more routers.

that routing information is periodically transmitted, quite frequently (on the order of 30 s). Information is discarded if it has not been heard recently (on the order of 2 min). Most implementations only store the best path, and when that path fails they need to wait for their neighbors' periodic transmissions in order to hear about the second best path. Some implementations query their neighbors ("do you know how to reach D?") when the path to D is discarded. In some implementations when R discards its route to D (for instance, it times out), R lets its neighbors know that R has discarded the route, by telling the neighbors R's cost to D is now infinity. In other implementations, after R times out the route, R will merely stop advertising the route, so R's neighbors will need to time out the route (starting from when R timed out the route).

Distance vector protocols need not be periodic. The distance vector protocol in use for DECnet Phases 3 and 4 transmits routing information reliably, and only sends information that has changed. Information on a LAN is sent periodically (rather than collecting acknowledgments from all router neighbors), but the purpose of sending it periodically is solely as an alternative to sending acknowledgments. Distance vector information is not timed out in DECnet, as it is in a RIP-like protocol. Instead, there is a separate protocol in which Hello messages are broadcast on the LAN to detect a dead router. If a Hello is not received in time, the neighbor router is assumed dead and its distance vector is discarded.

Another variation from the RIP-family of distance vectors is to store the entire received distance vector from each neighbor, rather than only keeping the best report for each destination. Then, when information must be discarded (e.g., due to having that neighbor report infinity for some destination, or due to that neighbor being declared dead) information for finding an alternative path is available immediately.

There are variations proposed to solve the count-to-infinity behavior. One variation has been implemented in Border Gateway Protocol (BGP). Instead of just reporting a cost to destination D, a router reports the entire path from itself to D. This eliminates loops but has high overhead. Another variation proposed by Garcia-Luna [1989] and implemented in the proprietary protocol EIGRP involves sending a message in the opposite direction of D, when the path to D gets worse, and not switching over to a next-best path until acknowledgments are received indicating that the information has been received by the downstream subtree. These variations may improve convergence to be comparable to link state protocols, but they also erode the chief advantage of distance vector protocols, which is their simplicity.

73.3.1.8 Link State Protocols

The idea behind a link state protocol is that each router R is responsible for the following:

- Identifying its neighbors
- Constructing a special packet known as a *link state packet* (LSP) that identifies R and lists R's neighbors (and the cost to each neighbor)
- Cooperating with all of the routers to reliably broadcast LSPs to all the routers
- Keeping a database of the most recently generated LSP from each other router
- Using the LSP database to calculate routes

Identifying neighbors and constructing an LSP is straightforward. Calculating routes using the LSP database is also straightforward. Most implementations use a variation of an algorithm attributed to Dijkstra. The tricky part is reliably broadcasting the LSP. The original link state algorithm was implemented in the ARPANET. Its LSP distribution mechanism had the unfortunate property that if LSPs from the same source, but with three different sequence numbers, were injected into the network, these LSPs would turn into a virus. Every time a router processed one of them, it would generate more copies, and so the harder the routers worked, the more copies of the LSP would exist in the system. The problem was analyzed and a stable distribution scheme was proposed in Perlman [1983]. The protocol was further refined for the IS-IS routing protocol and copied in OSPF. (See next section.)

One advantage of link state protocols is that they converge quickly. As soon as a router notices one of its links has changed (going up or down), it broadcasts an updated LSP which propagates in a straight line outwards (in contrast to a distance vector protocol where information might sometimes be ping-ponged back and forth before proceeding further, or where propagation of the information is delayed waiting for news from downstream nodes that the current path's demise has been received by all nodes.)

Link state protocols have other advantages as well. The LSP database gives complete information, which is useful for managing the network, mapping the network, or constructing custom routes for complex policy reasons [Clark, 1989] or for sabotage-proof routing [Perlman, 1988].

73.3.1.9 Reliable Distribution of Link State Packets

Each LSP contains:

- Identity of the node that generated the LSP
- A sequence number, large enough to never wrap around except if errors occur (for example, 64 bits)
- An age field, estimating time since source generated the LSP
- Other information

Each router keeps a database of the LSP with the largest sequence number seen thus far from each source. The purpose of the age field is to eventually eliminate an LSP from a source that does not exist any more, or that has been down for a very long time. It also serves to get rid of an LSP that is corrupted, or for which the sequence number has reached the largest value.

For each LSP, a router R has a table, for each of R's neighbors, as to whether R and the neighbor N are *in sync* with respect to that LSP. The possibilities are as follows:

- R and N are in sync. R does not need to send anything to N about this LSP.
- R thinks N has not yet seen this LSP. R needs to periodically retransmit this LSP to N until N acknowledges it.
- R thinks N does not know R has the LSP. R needs to send N an acknowledgment (ack) for this LSP.

R goes through the list of LSPs round-robin, for each link, and transmits LSPs or acks as indicated. If R sends an ack to N, R changes the state of that LSP for N to be in sync.

The state of an LSP gets set as follows:

- If R receives a new LSP from neighbor N, R overwrites the one in memory (if any) with smaller sequence number, sets send ack for N, and sets send LSP for each of R's other neighbors.
- If R receives an ack for an LSP from neighbor N, R sets the flag for that LSP to be in sync.
- If R receives a duplicate LSP or older LSP from neighbor N, R sets the flag for the LSP in memory (the one with higher sequence number) to send LSP.
- After R transmits an ack for an LSP to N, R changes the state of that LSP to in sync.

If an LSP's age expires, it is important that all of the routers purge the LSP at about the same time. The age is a field that is set to some value by the source, and is counted down. In this way, the source can control how long it will last. If R decides that an LSP's age has expired, R reflows it to R's neighbors (by setting the

state to send LSP). If R receives an LSP with the same sequence number as one stored, but the received one has zero age, R sets the LSP's age to 0 and floods it to its neighbors. If R does not have an LSP in memory, and receives one with zero age, R acks it but does not store it or reflood it.

73.3.2 Calculating Routes

Given an LSP database, the most popular method of computing routes is to use some variant of an algorithm attributed to Dijkstra. The algorithm involves having each router compute a tree of shortest paths from itself to each destination. Each node on the tree has a value associated with it which is the cost from the root to that node. The algorithm is as follows:

- Step 0: put yourself, with cost 0, on the tree as root.
- Step 1: examine the LSP of the node X just put on the tree. For each neighbor N listed in X's LSP, add X's cost in the LSP to the cost to X to get some number c. If c is smaller than any path to N found so far, place N tentatively in the tree, with cost c.
- Step 2: find the node tentatively in the tree with smallest associated cost c. Place that node permanently in the tree. Go to step 1.

73.3.3 Interdomain Routing

As stated previously, the only plausible technical difference between a routing protocol designed for inter- vs. intra-domain is support of policy-based routing. Policy-based routing is the ability to route according to exotic constraints, such as that one country does not want to see its traffic routed through some other country, some network might be willing to serve as a route-through carrier for only certain classes of traffic, or even that one backbone carrier has special rates at certain times of day and during those times someone would like to see all possible traffic routed via that carrier.

One method of accommodating all these policies is to have the source compute its own route, perhaps by being given the LSP database. Once the source computes the desired route that meets its constraints, it sets up the path by launching a special path setup packet that specifies the path, travels along the path, and has the router along the path keep track of the route. This is the basic approach taken by IDPR when the route that would be computed by the network would not be appropriate for whatever reason [Steenstrup, 1993].

The approach taken by BGP/IDRP [Lougheed, 1991] is to use a distance vector protocol in which the entire path is specified (the sequence of domains, not the sequence of routers because the path through a domain is assumed not to be of interest in terms of policy issues). Each router is configured with information that helps it evaluate choices of path to determine how it would like to route to the destination. For instance, if one neighbor says it can reach destination D through path XYZ, and another through path XQV, the router will use its configured information to decide which path it prefers. It chooses one, and that is the path it tells its neighbors. There are also policies that can be configured about which destinations can be reported to which neighbors. The assumption is that if you do not tell a neighbor you can get to a particular destination, that neighbor will not choose to route packets to that destination through you.

A link state approach makes support for many more different types of policies possible than a distance vector approach. With a distance vector approach, either a router chooses one path to the destination and only advertises that (as in BGP/IDRP), or the algorithm has exponential overhead (if every router advertises every possible path to the destination). If the router chooses one path, then it greatly limits the possible paths. For instance, suppose router R can reach destination D through A, B, X, or through A, Q, V. Suppose two sources that must get to D through R have different policies. One does not want to route through domain B. The other wants to avoid domain Q. Because R makes the choice, it makes the same choice for all sources. The ability for each source to have a custom route is supposedly one of the primary motivations behind policy-based routing.

BGP has a problem with convergence as described by Griffin and Wilfong [1999]. BGP makes forwarding decisions based on configured “policy,” such as “do not use domain B” or “do not use domain B when going to destination D” or “only use domain B if there is no other choice.” In contrast, other protocols using hop-by-hop forwarding base decisions on minimizing a metric. Minimizing a number is well-defined, and all routers will be making compatible decisions, once the routing information has propagated. However, with BGP, the routing decisions might be incompatible. A router R1, seeing the choices its neighbors have made for reaching D, bases its decision on those choices and advertises its chosen path. Once R1 does so, it is possible for that to affect the decision of another router R2, which will change what it advertises, which can cause R1 to change its mind, and so forth.

Defining Terms

Bridge: A box that forwards information from one link to another but only looks at information in the data link header.

Cloud: An informal representation of a multiaccess link. The purpose of representing it as a cloud is that what goes on inside is irrelevant to what is being discussed. When a system is connected to the cloud, it can communicate with any other system attached to the cloud.

Data-link layer: The layer that gets information from one machine to a neighbor machine (a machine on the same link).

IEEE 802 address: The 48-bit address defined by the IEEE 802 committee as the standard address on 802 LANs.

Hops: The number of times a packet is forwarded by a router.

Local area network (LAN): A multiaccess link with multicast capability.

MAC address: Synonym for IEEE 802 address.

Medium access control (MAC): The layer defined by the IEEE 802 committee that deals with the specifics of each type of LAN (for instance, token passing protocols on token passing LANs).

Multiaccess link: A link on which more than two nodes can reside.

Multicast: The ability to transmit a single packet that is received by multiple recipients.

Network layer: The layer that forms a path by concatenation of several links.

74.1 Introduction

Why is network security so hard, whereas stand-alone computers remain relatively secure? The problem of network security is hard because of the complex and open nature of the networks themselves.

There are a number of reasons for this. First and foremost, a network is designed to accept requests from outside. It is easier for an isolated computer to protect itself from outsiders because it can demand authentication — a successful log-in — first. By contrast, a networked computer expects to receive unauthenticated requests, if for no other reason than to receive electronic mail. This lack of authentication introduces some additional risk, simply because the receiving machine needs to talk to potentially hostile parties.

Even services that should, in principle, be authenticated often are not. The reasons range from technical difficulty (see the subsequent discussion of routing) to cost to design choices: the architects of that service were either unaware of, or chose to discount, the threats that can arise when a system intended for use in a friendly environment is suddenly exposed to a wide-open network such as the Internet.

More generally, a networked computer offers many different services; a stand-alone computer offers just one: log-in. Whatever the inherent difficulty of implementing any single service, it is obvious that

adding more services will increase the threat at least linearly. In reality, the problem is compounded by the fact that different services can interact. For example, an attacker may use a file transfer protocol to upload some malicious software and then trick some other network service into executing it.

Additional problems arise because of the unbounded nature of a network. A typical local area network may be viewed as an implementation of a loosely coupled, distributed operating system. But in single-computer operating systems, the kernel can **trust** its own data. That is, one component can create a control block for another to act on. Similarly, the path to the disk is trustable, in that a read request will retrieve the proper data, and a write request will have been vetted by the operating system.

Those assumptions do not hold on a network. A request to a file server may carry fraudulent user credentials, resulting in access violations. The data returned may have been inserted by an intruder or by an authorized user who is nevertheless trying to gain more privileges. In short, the distributed operating system can not believe anything, even transmissions from the kernel talking to itself.

In principle, many of these problems can be overcome. In practice, the problem seems to be intractable. Networked computers are far more vulnerable than standalone computers.

74.2 General Threats

Network security flaws fall into two main categories. Some services do inadequate authentication of incoming requests. Others try to do the right thing; however, buggy code lets the intruder in. Strong authentication and **cryptology** can do nothing against this second threat; it allows the target computer to establish a well-authenticated, absolutely private connection to a hacker who is capable of doing harm.

74.2.1 Authentication Failures

Some machines grant access based on the network address of the caller. This is acceptable if and only if two conditions are met. First, the trusted network and its attached machines must both be adequately secure, both physically and logically. On a typical local area network (LAN), anyone who controls a machine attached to the LAN can reconfigure it to impersonate any other machine on that cable. Depending on the exact situation, this may or may not be easily detectable. Additionally, it is often possible to turn such machines into eavesdropping stations, capable of listening to all other traffic on the LAN. This specifically includes passwords or even encrypted data if the encryption key is derived from a user-specified password [Gong et al. 1993].

Network-based authentication is also suspect if the network cannot be trusted to tell the truth. However, such a level of trust is not tautological; on typical packet networks, such as the Internet, each transmitting host is responsible for putting its own reply address in each and every packet. Obviously, an attacker's machine can lie — and this often happens.

In many instances, a **topological defense** will suffice. For example, a router at a network border can reject incoming packets that purport to be from the inside network. In the general case, though, this is inadequate; the interconnections of the networks can be too complex to permit delineation of a simple border, or a site may wish to grant privileges — that is, trust — to some machine that really is outside the physical boundaries of the network.

Although **address spoofing** is commonly associated with packet networks, it can happen with circuit networks as well. The difference is in who can lie about addresses; in a circuit net, a misconfigured or malconfigured switch can announce incorrect source addresses. Although not often a threat in simple topologies, in networks where different switches are run by different parties address errors present a real danger. The best-known example is probably the phone system, where many different companies and organizations around the world run different pieces of it. Again, topological defenses sometimes work, but you are still limited by the actual interconnection patterns.

Even if the network address itself can be trusted, there still may be vulnerabilities. Many systems rely not on the network address but on the network *name* of the calling party. Depending on how addresses are

mapped to names, an enemy can attack the translation process and thereby spoof the target. See Bellovin [1995] for one such example.

74.2.2 User Authentication

User authentication is generally based on any of three categories of information: something you know, something you have, and something you are. All three have their disadvantages.

The something you know is generally a password or personal identification number (PIN). In today's threat environment, passwords are an obsolete form of authentication. They can be guessed [Klein 1990, Morris and Thompson 1979, Spafford 1989a], picked up by network wiretappers, or simply *social engineered* from users. If possible, avoid using passwords for authentication over a network.

Something you have is a token of some sort, generally cryptographic. These tokens can be used to implement cryptographically strong challenge/response schemes. But users do not like token devices; they are expensive and inconvenient to carry and use. Nevertheless, for many environments they represent the best compromise between security and usability.

Biometrics, or something you are, are useful in high-threat environments. But the necessary hardware is scarce and expensive. Furthermore, biometric authentication systems can be disrupted by biological factors; a user with laryngitis may have trouble with a voice recognition system. Finally, cryptography must be used in conjunction with biometrics across computer networks; otherwise, a recording of an old fingerprint scan may be used to trick the authentication system.

74.2.3 Buggy Code

The Internet has been plagued by buggy network servers. In and of itself, this is not surprising; most large computer programs are buggy. But to the extent that outsiders should be denied access to a system, every network server is a privileged program.

The two most common problems are buffer overflows and shell escapes. In the former case, the attacker sends an input string that overwrites a buffer. In the worst case, the stack can be overwritten as well, letting the attacker inject code. Despite the publicity this failure mode has attracted — the Internet Worm used this technique [Spafford 1989a, 1989b, Eichen and Rochlis 1989, Rochlis and Eichen 1989] — new instances of it are legion. Too many programmers are careless or lazy.

More generally, network programs should check *all* inputs for validity. The second failure mode is simply another example of this: input arguments can contain shell metacharacters, but the strings are passed, unchecked, to the shell in the course of executing some other command. The result is that two commands will be run, the one desired and the one requested by the attacker.

Just as no general solution to the program correctness problem seems feasible, there is no cure for buggy network servers. Nor will the best cryptography in the world help; you end up with a secure, protected communication between a hacker and a program that holds the **back door** wide open.

74.3 Routing

In most modern networks of any significant size, host computers cannot talk directly to all other machines they may wish to contact. Instead, intermediate nodes — switches or routers of some sort — are used to route the data to their ultimate destination. The security and integrity of the network depends very heavily on the security and integrity of this process.

The switches in turn need to know the next hop for any given network address; whereas this can be configured manually on small networks, in general the switches talk to each other by means of **routing protocols**. Collectively, these routing protocols allow the switches to learn the topology of the network. Furthermore, they are dynamic, in the sense that they rapidly and automatically learn of new network nodes, failures of nodes, and the existence of alternative paths to a destination.

Most routing protocols work by having switches talk to their neighbors. Each tells the other of the hosts it can reach, along with associated cost metrics. Furthermore, the information is transitive; a switch will not only announce its directly connected hosts but also destinations of which it has learned by talking to other routers. These latter announcements have their costs adjusted to account for the extra hop.

An enemy who controls the routing protocols is in an ideal position to monitor, intercept, and modify most of the traffic on a network. Suppose, for example, that some enemy node *X* is announcing a very low-cost route to hosts *A* and *B*. Traffic from *A* to *B* will flow through *X*, as will traffic from *B* to *A*. Although the diversion will be obvious to anyone who checks the path, such checks are rarely done unless there is some suspicion of trouble.

A more subtle routing issue concerns the return data flow. Such a flow almost always exists, if for no other reason than to provide flow control and error correction feedback. On packet-switched networks, the return path is independent of the forward path and is controlled by the same routing protocols. Machines that rely on network addresses for authentication and authorization are implicitly trusting the integrity of the return path; if this has been subverted, the network addresses cannot be trusted either. For example, in the previous situation, *X* could easily impersonate *B* when talking to *A* or vice versa.

That is somewhat less of a threat on circuit-switched networks, where the call is typically set up in both directions at once. But often, the trust point is simply moved to the switch; a subverted or corrupt switch can still issue false routing advertisements.

Securing routing protocols is hard because of the transitive nature of the announcements. That is, a switch cannot simply secure its link to its neighbors, because it can be deceived by messages really sent by its legitimate and uncorrupted peer. That switch, in turn, might have been deceived by its peers, ad infinitum. It is necessary to have an authenticated chain of responses back to the source to protect routing protocols from this sort of attack.

Another class of defense is topological. If a switch has a priori knowledge that a certain destination is reachable only via a certain wire, routing advertisements that indicate otherwise are patently false. Although not necessarily indicative of malice — link or node failures can cause temporary confusion of the network-wide routing tables — such announcements can and should be dismissed out of hand. The problem, of course, is that adequate topological information is rarely available. On the Internet, most sites are *out there* somewhere; the false hop, if any, is likely located far beyond an individual site's borders. Additionally, the prevalence of redundant links, whether for performance or reliability, means that more than one path may be valid. In general, then, topological defenses are best used at **choke points: firewalls** (Section 74.7) and the other end of the link from a site to a network service provider. The latter allows the service provider to be a good network citizen and prevent its customers from claiming routes to other networks.

Some networks permit hosts to override the routing protocols. This process, sometimes called source routing, is often used by network management systems to bypass network outages and as such is seen as very necessary by some network operators.

The danger, though, arises because source-routed packets bypass the implicit authentication provided by use of the return path, as previously outlined. A host that does network address-based authentication can easily be spoofed by such messages. Accordingly, if source routing is to be used, address-based authentication must not be used.

74.4 The Transmission Control Protocol/Internet Protocol (TCP/IP) Protocol Suite

The **transmission control protocol** (TCP) suite is the basis for the Internet. Although the general features of the protocols are beyond the scope of this chapter (see Stevens [1995] and Wright and Stevens [1994] for more detail), the security problems of it are less well known.

The most important thing to realize about TCP/IP security is that since IP is a datagram protocol, one cannot trust the source addresses in packets. This threat is not just hypothetical. One of the most famous

security incidents — the penetration of Tsutomu Shimomura's machines [Shimomura 1996, Littman 1996] — involved IP address spoofing in conjunction with a TCP sequence number guessing attack.

74.4.1 Sequence Number Attacks

TCP **sequence number attacks** were described in the literature many years before they were actually employed [Morris 1985, Bellovin 1989]. They exploit the predictability of the sequence number field in TCP in such a way that it is not necessary to see the return data path. To be sure, the intruder cannot get any output from the session, but if you can execute a few commands, it does not matter much if you see their output.

Every byte transmitted in a TCP session has a sequence number; the number for the first byte in a segment is carried in the header. Furthermore, the control bits for opening and closing a connection are included in the sequence number space. All transmitted bytes must be acknowledged explicitly by the recipient; this is done by sending back the sequence number of the next byte expected.

Connection establishment requires three messages. The first, from the client to the server, announces the client's initial sequence number. The second, from the server to the client, acknowledges the first message's sequence number and announces the server's initial sequence number. The third message acknowledges the second.

In theory, it is not possible to send the third message without having seen the second, since it must contain an explicit acknowledgment for a random-seeming number. But if two connections are opened in a short time, many TCP stacks pick the initial sequence number for the second connection by adding some constant to the sequence number used for the first.

The mechanism for the attack is now clear. The attacker first opens a legitimate connection to the target machine and notes its initial sequence number. Next, a spoofed connection is opened by the attacker, using the IP address of some machine trusted by the target. The sequence number learned in the first step is used to send the third message of the TCP open sequence, without ever having seen the second. The attacker can now send arbitrary data to the target; generally, this is a set of commands designed to open up the machine even further.

74.4.2 Connection Hijacking

Although a defense against classic sequence number attacks has now been found [Bellovin 1996], a more serious threat looms on the horizon: **connection hijacking** [Joncheray 1995]. An attacker who observes the current sequence number state of a connection can inject phony packets.

Again, the network in general will believe the source address claimed in the packet. If the sequence number is correct, it will be accepted by the destination machine as coming from the real source. Thus, an eavesdropper can do far worse than simply steal passwords; he or she can take over a session after log in. Even the use of a high-security log-in mechanism, such as a one-time password system [Haller 1994], will not protect against this attack. The only defense is full-scale encryption.

Session hijacking is detectable, since the acknowledgment packet sent by the target cites data the sender never sent. Arguably, this should cause the connection to be reset; instead, the system assumes that sequence numbers have wrapped around and resends its current sequence number and acknowledgment number state.

74.4.3 The r-Commands

The so-called **r-commands** — `rsh` and `rlogin` — use address-based authentication. As such, they are not secure. But too often, the alternative is sending a password in the clear over an insecure net. Neither alternative is attractive; the right choice is cryptography. But that is used all too infrequently.

In many situations, where insiders are considered reasonably trustworthy, use of these commands without cryptography is an acceptable risk. If so, a low-grade fire wall such as a simple **packet filter** *must* be used.

74.4.4 The X Window System

The paradigm for the X window system [Stubblebine and Gligor 1992] is simple: a server runs the physical screen, keyboard, and mouse; applications connect to it and are allocated use of those resources. Put another way, when an application connects to the server, it gains control of the screen, keyboard, and mouse. Whereas this is good when the application is legitimate, it poses a serious security risk if uncontrolled applications can connect. For example, a rogue application can monitor all keystrokes, even those destined for other applications, dump the screen, inject synthetic events, and so on.

There are several modes of access control available. A common default is no restriction; the dangers of this are obvious. A more common option is control by IP address; apart from the usual dangers of this strategy, it allows anyone to gain access on the trusted machine. The so-called **magic cookie** mechanism uses (in effect) a clear-text password; this is vulnerable to anyone monitoring the wire, anyone with privileged access to the client machines, and — often — anyone with network file system access to that machine. Finally, there are some cryptographic options; these, although far better than the other options, are more vulnerable than they might appear at first glance, as any privileged user on the application's machine can steal the secret cryptographic key.

There have been some attempts to improve the security of the X window system [Epstein et al. 1992, Kahn 1995]. The principal risk is the complexity of the protocol: are you sure that all of the holes have been closed? The analysis in Kahn [1995] provides a case in point; the author had to rely on various heuristics to permit operations that seemed dangerous but were sometimes used safely by common applications.

74.4.5 User Datagram Protocol (UDP)

The **user datagram protocol (UDP)** [Postel 1980] poses its own set of risks. Unlike TCP, it is not connection oriented; thus, there is no implied authentication from use of the return path. Source addresses cannot be trusted at all. If an application wishes to rely on address-based authentication, it must do its own checking, and if it is going to go to that much trouble, it may as well use a more secure mechanism.

74.4.6 Remote Procedure Call (RPC), Network Information Service (NIS), and Network File System (NFS)

The most important UDP-based protocol is **remote procedure call (RPC)** [Sun 1988, 1990]. Many other services, such as network information service (NIS) and **network file system (NFS)** [Sun 1989, 1990] are built on top of RPC. Unfortunately, these services inherit all of the weaknesses of UDP and add some of their own. For example, although RPC has an authentication field, in the normal case it simply contains the calling machine's assertion of the user's identity. Worse yet, given the ease of forging UDP packets, the server does not even have any strong knowledge of the actual source machine. Accordingly, no serious action should be taken based on such a packet.

There is a cryptographic authentication option for RPC. Unfortunately, it is poorly integrated and rarely used. In fact, on most systems only NFS can use it. Furthermore, the key exchange mechanism used is cryptographically weak [LaMacchia and Odlyzko 1991].

NIS has its own set of problems; these, however, relate more to the information it serves up. In particular, NIS is often used to distribute password files, which are very sensitive. Password guessing is very easy [Klein 1990, Morris and Thompson 1979, Spafford 1992]; letting a hacker have a password file is tantamount to omitting password protection entirely. Misconfigured or buggy NIS servers will happily distribute such files; consequently, the protocol is very dangerous.

74.5 The World Wide Web

The World Wide Web (WWW) is the fastest-growing protocol on the Internet. Indeed, in the popular press it *is* the Internet. There is no denying the utility of the Web. At the same time, it is a source of great danger. Indeed, the Web is almost unique in that the danger is nearly as great to clients as to servers.

74.5.1 Client Issues

The danger to clients comes from the nature of the information received. In essence, the server tells the client “here is a file, and here is how to display it.” The problem is that the instructions may not be benign. For example, some sites supply troff input files; the user is expected to make the appropriate control entries to link that file type to the processor. But troff has shell escapes; formatting an arbitrary file is about as safe as letting unknown persons execute any commands they wish.

The problem of buggy client software should not be ignored either. Several major browsers have had well-publicized bugs, ranging from improper use of cryptography to string buffer overflows. Any of these could result in security violations.

A third major area for concern is **active agents**: pieces of code that are explicitly downloaded to a user’s machine and executed. Java [Arnold and Gosling 1996] is the best known, but there are others.

Active agents, by design, are supposed to execute in a restricted environment. Still, they need access to certain resources to do anything useful. It is this conflict, between the restrictions and the resources, that leads to the problems; sometimes the restrictions are not tight enough. And even if they are in terms of the architecture, implementation bugs, inevitable in such complex code, can lead to security holes [Dean and Wallach 1996].

74.5.2 Server Issues

Naturally, servers are vulnerable to security problems as well. Apart from bugs, which are always present, Web servers have a challenging job. Serving up files is the easy part, though this, too, can be tricky; not all files should be given to outsiders.

A bigger problem is the so-called **common gateway interface (CGI) scripts**. CGI scripts are, in essence, programs that process the user’s request. Like all programs, CGI scripts can be buggy. In the context of the Web, this can lead to security holes.

A common example is a script to send mail to some destination. The user is given a form to fill out, with boxes for the recipient name and the body of the letter. When the user clicks on a button, the script goes to work, parsing the input and, eventually, executing the system’s mailer. But what happens if the user — someone on another site — specifies an odd-ball string for the recipient name? Specifically, what if the recipient string contains assorted special characters, and the shell is used to invoke the mailer?

Administering a WWW site can be a challenge. Modern servers contain all sorts of security-related configuration files. Certain pages are restricted to certain users or users from certain IP addresses. Others must be accessed using particular user ids. Some are even protected by their own password files.

Not surprisingly, getting all of that right is tricky. But mistakes here do not always lead to the sort of problem that generates user complaints; hackers rarely object when you let them into your machine.

A final problem concerns the uniform resource locators (URLs) themselves. Web servers are stateless; accordingly, many encode transient state information in URLs that are passed back to the user. But parsing this state can be hard, especially if the user is creating malicious counterfeits.

74.6 Using Cryptography

Cryptography, though not a panacea, is a potent solution to many network security issues. The most obvious use of cryptography is to protect network traffic from eavesdroppers. If two parties share the same secret key, no outsiders can intercept any messages. This can be used to protect passwords, sensitive files being transferred over a network, etc.

Often, though, secrecy is less important than authenticity. Cryptography can help here, too, in two different ways. First, there are cryptographic primitives designed to authenticate messages. Message authentication codes (MACs) are commonly used in electronic funds transfer applications to validate their point of origin.

More subtly, decryption with an invalid key will generally yield garbage. If the message is intended to have any sort of semantic or syntactic content, ordinary input processing will likely reject such messages. Still, care must be taken; noncryptographic **checksums** can easily be confused with a reasonable probability. For example, TCP's checksum is only 16 bits; if that is the sole guarantor of packet sanity, it will fail about once in 2^{16} packets.

74.6.1 Key Distribution Centers

The requirement that every pair of parties share a secret key is in general impractical for all but the smallest network. Instead, most practical systems rely on trusted third parties known as **key distribution centers (KDC)**. Each party shares a long-term secret key with the KDC; to make a secure call, the KDC is asked to (in effect) introduce the two parties, using its knowledge of the shared keys to vouch for the authenticity of the call.

The Kerberos authentication system [Bryant 1988, Kohl and Neuman 1993, Miller et al. 1987, Steiner et al. 1988], designed at Massachusetts Institute of Technology (MIT) as part of Project Athena, is a good example. Although Kerberos is intended for user-to-host authentication, most of the techniques apply to other situations as well.

Each party, known as a *principal*, shares a secret key with the KDC. User keys are derived from a pass phrase; service keys are randomly generated. Before contacting any service, the user requests a **Kerberos ticket-granting ticket (TGT)** from the KDC,

$$K_c [K_{c,tgs} K_{tgs} [T_{c,tgs}]]$$

where $K[X]$ denotes the encryption of X by key K . K_c is the client's key; it is used to encrypt the body of the message. In turn, the body is a ticket-granting ticket, encrypted by a key known only to the server, and an associated session key $K_{c,tgs}$ to be used along with the TGT. TGTs and their associated session keys normally expire after about 8 hours, and are cached by the client during this time; this avoids the need for constant retyping of the user's password.

The TGT is used to request credentials — tickets — for a service s ,

$$s, K_{tgs} [T_{c,tgs}], K_{c,tgs} [A_c]$$

That is, the TGT is sent to the KDC along with an encrypted *authenticator* A_c . The authenticator contains the time of day and the client's IP address; this is used to prevent an enemy from replaying the message.

The KDC replies with

$$K_{c,tgs} [K_s [T_{c,s}], K_{c,s}]$$

The session key $K_{c,s}$ is a newly chosen random key; $K_s [T_{c,s}]$ is the ticket for user c to access service s . It is encrypted in the key shared by the KDC and s ; this ensures s of its validity. It contains a lifetime, a session key $K_{c,s}$ that is shared with c , and c 's name. A separate copy of $K_{c,s}$ is included in the reply for use by the client. When transmitted by c to s , an authenticator is sent with it, encrypted by $K_{c,s}$; again, this ensures freshness.

Finally, c can ask s to send it a message encrypted in the same session key; this protects the client against someone impersonating the server.

There are several important points to note about the design. First, cryptography is used to create *sealed* packages. Tickets and the like are encrypted along with a checksum; this protects them from tampering. Second, care is taken to avoid repetitive password entry requests; human factors are quite important, as users tend to bypass security measures they find unpleasant. Third, messages must be protected against replay; an attacker who can send the proper message may not need to know what it says. Cut-and-paste attacks are a danger as well, though they are beyond the scope of this chapter.

It is worth noting that the design of cryptographic protocols is a subtle business. The literature is full of attacks that were not discovered until several years after publication of the initial protocol. See, for

example, Bellovin and Merritt [1991] and Stubblebine and Gligor [1992] for examples of problems with Kerberos itself.

74.7 Firewalls

Firewalls [Cheswick and Bellovin 1994] are an increasingly popular defense mechanism. Briefly, a firewall is an electronic analog of the security guard at the entrance to a large office or factory. Credentials are checked, outsiders are turned away, and incoming packages — electronic mail — is handed over for delivery by internal mechanisms.

The purpose of a firewall is to protect more vulnerable machines. Just as most people have stronger locks on their front doors than on their bedrooms, there are numerous advantages to putting stronger security on the perimeter. If nothing else, a firewall can be run by personnel whose job it is to ensure security.

For many sites, though, the real issue is that internal networks *cannot* be run securely. Too many systems rely on insecure network protocols for their normal operation. This is bad, and everyone understands this; too often, though, the choice is between accepting some insecurity or not being able to use the network productively. A firewall is often a useful compromise; it blocks attacks from a high-threat environment, while letting people use today's technology.

Seen that way, a firewall works because of what it is not. It is not a general purpose host; consequently, it does not need to run a lot of risky software. Ordinary machines rely on networked file systems, remote log-in commands that rely on address-based authentication, users who surf the Web, etc. A firewall does none of these things; accordingly, it is not affected by potential security problems with them.

74.7.1 Types of Firewalls

There are four primary types of firewalls: packet filters, dynamic packet filters, **application gateways**, and **circuit relays**. Each has its advantages and disadvantages.

74.7.1.1 Packet Filters

The cheapest and fastest type of firewall is the packet filter. Packet filters work by looking at each individual packet, and, based on source address and destination addresses and port numbers, making a pass/drop decision. They are cheap because virtually all modern routers already have the necessary functionality; in effect, you have already paid the price, so you may as well use it. Additionally, given the comparatively slow lines most sites use for external access, packet filtering is fast; a router can filter at speeds higher than, say, a DSL line (1,500,000 bits/second).

The problem is that decisions made by packet filters are completely context free. Each packet is examined, and its fate decided, without looking at the previous input history. This makes it difficult or impossible to handle certain protocols. For example, file transfer protocol (FTP) [Mills 1985] uses a secondary TCP connection to transfer files; by default, this is an incoming call through the firewall [Bellovin 1994]. In this situation, the call should be permitted; the client has even sent a message specifying which port to call. But ordinary packet filters cannot cope.

Packet filters must permit not only outgoing packets but also the replies. For TCP, this is not a big problem; the presence of one header bit [the acknowledgment (ACK) bit] denotes a reply packet. In general, packets with this bit set can safely be allowed in, as they represent part of an ongoing conversation. Datagram protocols such as UDP do not have the concept of conversation and hence do not have such a bit, which causes difficulties: when should a UDP packet be allowed in? It is easy to permit incoming queries to known safe servers; it is much harder to identify replies to queries sent from the inside. Ordinary packet filters are not capable of making this distinction. At best, sites can assume that higher numbered ports are used by clients and hence are safe; in general, this is a bad assumption.

Services built on top of Sun's remote procedure call [Sun 1988, 1990] pose a different problem: the port numbers they use are not predictable. Rather, they pick more or less random port numbers and

register with a directory server known as the portmapper. Would-be clients first ask portmapper which port number is in use at the moment, and then do the actual call. But since the port numbers are not fixed, it is not possible to configure a packet filter to let in calls to the proper services only.

74.7.1.2 Dynamic Packet Filters

Dynamic packet filters are designed to answer the shortcomings of ordinary packet filters. They are inherently stateful and retain the context necessary to make intelligent decisions. Most also contain application-specific modules; these do things like parse the FTP command stream so that the data channel can be opened, look inside portmapper messages to decide if a permitted service is being requested, etc. UDP queries are handled by looking for the outbound call and watching for the responses to that port number. Since there is no end-of-conversation flag in UDP, a timeout is needed. This heuristic does not always work well, but, without a lot of application-specific knowledge, it is the only possibility.

Dynamic packet filters promise everything: safety and full transparency. The risk is their complexity; one never knows exactly which packets will be allowed in at a given time.

74.7.1.3 Application Gateways

Application gateways live at the opposite end of the protocol stack. Each application being relayed requires a specialized program at the firewall. This program understands the peculiarities of the application, such as data channels for FTP, and does the proper translations as needed.

It is generally acknowledged that application gateways are the safest form of firewall. Unlike packet filters, they do not pass raw data; rather, individual applications, invoked from the inside, make the necessary calls. The risk of passing an inappropriate packet is thus eliminated.

This safety comes at a price, though. Apart from the need to build new gateway programs, for many protocols a change in user behavior is needed. For example, a user wishing to telnet to the outside generally needs to contact the firewall explicitly and then redial to the actual destination. For some protocols, though, there is no user visible change; these protocols have their own built-in redirection or proxy mechanisms. Mail and the World Wide Web are two good examples.

74.7.1.4 Circuit Relays

Circuit relays represent a middle ground between packet filters and application gateways. Because no data are passed directly, they are safer than packet filters. But because they use generic circuit-passing programs, operating at the level of the individual TCP connection, specialized gateway programs are not needed for each new protocol supported.

The best-known circuit relay system is socks [Koblas and Koblas 1992]. In general, applications need minor changes or even just a simple relinking to use the socks package. Unfortunately, that often means it is impossible to deploy it unless a suitable source or object code is available. On some systems, though, dynamically linked run-time libraries can be used to deploy socks.

Circuit relays are also weak if the aim is to regulate outgoing traffic. Since more or less any calls are permissible, users can set up connections to unsafe services. It is even possible to tunnel IP over such circuits, bypassing the firewall entirely. If these sorts of activities are in the threat model, an application gateway is probably preferable.

74.7.2 Limitations of Firewalls

As important as they are, firewalls are not a panacea to network security problems. There are some threats that firewalls cannot defend against.

The most obvious of these, of course, is attacks that do not come through the firewall. There are always other entry points for threats. There might be an unprotected modem pool; there are always insiders, and a substantial portion of computer crime is due to insider activity. At best, internal firewalls can reduce this latter threat.

On a purely technical level, no firewall can cope with an attack at a higher level of the protocol stack than it operates. Circuit gateways, for example, cannot cope with problems at the simple mail transfer protocol (SMTP) layer [Postel 1982]. Similarly, even an application-level gateway is unlikely to be able to deal with the myriad security threats posed by multimedia mail [Borenstein and Freed 1993]. At best, once such problems are identified a firewall may provide a place to deploy a fix.

A common question is whether or not firewalls can prevent virus infestations. Although, in principle, a mail or FTP gateway could scan incoming files, in practice it does not work well. There are too many ways to encode files, and too many ways to spread viruses, such as self-extracting executables.

Finally, firewalls cannot protect applications that must be exposed to the outside. Web servers are a canonical example; as previously described, they are inherently insecure, so many people try to protect them with firewalls. That does not work; the biggest security risk is in the service that of necessity must be exposed to the outside world. At best, a firewall can protect other services on the Web server machine. Often, though, that is like locking up only the bobcats in a zoo full of wild tigers.

74.8 Denial of Service Attacks

Denial of service attacks are generally the moral equivalent of vandalism. Rather than benefitting the perpetrator, the goal is generally to cause pain to the target, often for no better reason than to cause pain.

The simplest form is to flood the target with packets. If the attacker has a faster link, the attacker wins. If this attack is combined with source address spoofing, it is virtually untraceable as well.

Sometimes, denial of service attacks are aimed more specifically. A modest number of TCP open request packets, from a forged IP address, will effectively shut down the port to which they are sent. This technique can be used to close down mail servers, Web servers, etc.

The ability to interrupt communications can also be used for direct security breaches. Some authentication systems rely on primary and backup servers; the two communicate to guard against replay attacks. An enemy who can disrupt this path may be able to replay stolen credentials.

Philosophically, denial of service attacks are possible any time the cost to the enemy to mount the attack is less, relatively speaking, than the cost to the victim to process the input. In general, prevention consists of lowering your costs for processing unauthenticated inputs.

74.9 Conclusions

We have discussed a number of serious threats to networked computers. However, except in unusual circumstances — and they do exist — we do not advocate disconnection. Whereas disconnecting buys you some extra security, it also denies you the advantages of a network connection.

It is also worth noting that complete disconnection is much harder than it would appear. Dial-up access to the Internet is both easy and cheap; a managed connection can be more secure than a total ban that might incite people to evade it. Moreover, from a technical perspective an external network connection is just one threat among many. As with any technology, the challenge is to control the risks while still reaping the benefits.

Defining Terms

Active agents: Programs sent to another computer for execution on behalf of the sending computer.

Address spoofing: Any enemy computer's impersonation of a trusted host's network address.

Application gateway: A relay and filtering program that operates at layer seven of the network stack.

Back door: An unofficial (and generally unwanted) entry point to a service or system.

Checksums: A short function of an input message, designed to detect transmission errors.

Choke point: A single point through which all traffic must pass.

Circuit relay: A relay and filtering program that operates at the transport layer (level four) of the network protocol stack.

Common gateway interface (CGI) scripts: The interface to permit programs to generate output in response to World Wide Web requests.

Connection hijacking: The injection of packets into a legitimate connection that has already been set up and authenticated.

Cryptography: The art and science of secret writing.

Denial of service: An attack whose primary purpose is to prevent legitimate use of the computer or network.

Firewall: An electronic barrier restricting communications between two parts of a network.

Kerberos ticket-granting ticket (TGT): The cryptographic credential used to obtain credentials for other services.

Key distribution center (KDC): A trusted third party in cryptographic protocols that has knowledge of the keys of other parties.

Magic cookie: An opaque quantity, transmitted in the clear and used to authenticate access.

Network file system (NFS) protocol: Originally developed by Sun Microsystems.

Packet filter: A network security device that permits or drops packets based on the network layer addresses and (often) on the port numbers used by the transport layer.

r-Commands: A set of commands (**sh**, **rlogin**, **rcp**, **rdist**, etc.) that rely on address-based authentication.

Remote procedure call (RPC) protocol: Originally developed by Sun Microsystems.

Routing protocols: The mechanisms by which network switches discover the current topology of the network.

Sequence number attacks: An attack based on predicting and acknowledging the byte sequence numbers used by the target computer without ever having seen them.

Topological defense: A defense based on the physical interconnections of two networks. Security policies can be based on the notions of inside and outside.

Transmission control protocol (TCP): The basic transport-level protocol of the Internet. It provides for reliable, flow-controlled, error-corrected virtual circuits.

Trust: The willingness to believe messages, especially access control messages, without further authentication.

User datagram protocol (UDP): A datagram-level transport protocol for the Internet. There are no guarantees concerning order of delivery, dropped or duplicated packets, etc.

75.5 Conclusion and Further Resources

75.1 Introduction

With both commercial and scientific data sets growing at an extremely rapid rate, methods for retrieving knowledge from this data in an efficient and reliable manner are constantly needed. To do this, many knowledge discovery techniques are employed to analyze these large data sets. Generally, knowledge discovery is the process by which data is cleaned and organized, then transformed for use for pattern detection and evaluation tools and then visualized in the most meaningful manner for the user [13].

Two areas of research — information retrieval (IR) and data mining (DM) — are used to try to manage these data sets as well as gain knowledge from them. Data mining concentrates on finding and exploiting patterns found within a given data set to gain knowledge about that data set. As databases developed and became larger and more complex, the need to extract knowledge from these databases became a pressing concern. Data mining uses various algorithms that extract patterns from the data to gain knowledge about the data set. It borrows techniques from statistics, pattern recognition, machine learning, data management, and visualization to accomplish the pattern discovery task. Information retrieval is the study of techniques for organizing and retrieving information from databases [30]. Modern information retrieval concerns itself with many different types of databases. It studies returning information matching a user's query that is relevant in a reasonable amount of time. It also focuses on other complex problems associated with a static query that will be needed time and time again. In this chapter we explore both the topics of data mining and information retrieval. We discuss how these two approaches of obtaining knowledge from data can work in a complementary manner to create more effective knowledge discovery tools. We look at a common application of knowledge discovery tools where these approaches work together, namely search engines. Finally, we address future work in data mining and information retrieval.

75.2 Information Retrieval

As mentioned above, information retrieval investigates problems that are concerned with organizing and accessing information effectively. This is a broad area of research that currently encompasses many disciplines. Here, we primarily focus on text information retrieval, and then briefly mention emerging areas such as web and multimedia information retrieval.

75.2.1 Text Retrieval Issues

Text retrieval systems usually need to perform efficient and effective searches on large text databases, often with data that is not well organized. Text retrieval is generally divided into two categories: problems that concentrate on returning relevant and reliable information to the user and problems that concentrate on organizing data for long-term retrieval needs. Concerning the first problem, methods here usually investigate techniques for searching databases based on a user query. The user can enter a query and the text retrieval system searches the database, returning results based on the user's query. These results can be ranked or ordered according to how close the text retrieval system feels the results satisfy the query. Another type of text retrieval system is one that is used for long-term information needs. These employ text categorization, text routing, and text filtering techniques to enhance the user's ability to query the database effectively. These techniques essentially preprocess a portion of the querying process, whether it is classifying the text or creating a user profile to better semantically query the database or use filters on the database before beginning the search [30].

Text retrieval systems have many issues that they must address in order to effectively perform searches on a database, specifically text databases. Many of these issues result from the vernacular usage of words and phrases within a given language as well as the nature of the language. Two prominent issues that must be addressed by text retrieval systems related to this problem are synonymy and polysemy.

- *Synonymy* refers to the problem of when words or phrases mean similar things. This problem sometimes is solved and usually results in a text retrieval system needing to expand upon a query, incorporating a thesaurus to know which words or terms are similar to the words or terms in the user's query. This allows the system to return results that might be of interest to the user but would normally be returned for another word that has a similar meaning to the word or phrase used within the query.
- *Polysemy* refers to when one word or phrase has multiple meanings [30]. Work to address this problem has included creating user profiles so that the text retrieval system can learn what type of information the user is generally interested in as well as semantic analysis of phrases within queries [17].

Other common problems that text retrieval systems must be concerned with are phrases, object recognition, and semantics. Phrases within languages tend to have a separate meaning from what each individual word in the phrase means. Many text retrieval systems use phrase-based indexing techniques to manage phrases properly [10]. Object recognition usually concerns itself with a word or phrase. These word phrases usually have a specific meaning separate to itself from the meaning of the individual words. For example, the word "labor" means to work and the word "day" refers to a period of time. However, when these two words are placed next to each other to form "Labor Day," this refers to a holiday in September in the United States. Common parts of sentences that are considered objects are proper nouns, especially proper names, noun phrases, and dates.

A text retrieval system that can manage objects sometimes uses pattern recognition tools to identify objects [30]. All these problems can generally be thought of by considering how the word or phrase is used semantically by the user.

FIGURE 75.1 A general diagram for an inverted file.

75.2.2 Text Retrieval Methods

To address these problems, there are some common practices for processing and filtering data that help text retrieval tools be more effective. One very common practice is to use inverted files as an indexing structure for the database the tools search upon. An inverted file is a data structure that can index keywords within a text. These keywords are organized so that quick search techniques can be used. Once a keyword is found within the indexing structure, information is retained about the documents that contain this keyword and those documents are returned to fulfill the query.

Figure 75.1 illustrates the general concept behind inverted files. In this figure, there is an organized structuring of the keywords. This structuring can be formed through using various data structures, such as the B-tree or a hash table. These keywords have references or pointers to the documents where they occur frequently enough to be considered a content-bearing word for that document. Deciding whether or not a word is content bearing is a design issue for the information retrieval system. Usually, a word is considered to be content bearing if it occurs frequently within the document. Algorithms such as Zipf's law [39] or taking the term frequency with respect to the inverse document frequency (tf.idf) [31] can be used to determine whether or not a word is a content-bearing word for a document.

Other effective methods include stopwords lists, stemming, and phrase indexing. Stopword lists, commonly seen when searching the World Wide Web using Google, exploit the idea that there are great occurrences of common words, such as "the," "a," and "with," within documents in a given text database. Because these words rarely add to the meaning of the query, they are disregarded and filtered out of the query so that the text retrieval tool can concentrate on the more important words within the query. Stemming utilizes the concept that many words within a query can be a variation on tense or case of another word. For example, the word "jumping" has the root word "jump" in it. The concepts related to "jumping" and "jump" are very similar. Therefore, if a query requests information about "jumping," it is highly likely that any information indexed for "jump" would also interest the user. Stemming takes advantage of this idea to make searching more efficient. Stemming can help improve space efficiency as well as help generalize queries. Generalized queries help to ensure documents that the user may want but might not have been included within the search results because of the wording of the query will be included. However, this can also lead to false positives if the stemming algorithm does not process a word properly [12,29].

(a)

(b)

FIGURE 75.2 The effect of stemming on the inverted file: (a) represents an inverted file that does not use stemming; (b) represents an inverted file that uses stemming.

For example, Figure 75.2 demonstrates some of the issues stemming faces. Figure 75.2a represents how an index containing the words “cent,” “center,” “central,” “century,” “incent,” and “percent” might be organized. Figure 75.2b demonstrates how each of these words can be reduced to the root “cent.” Notice in Figure 75.2a that each word indexes different documents. However, in Figure 75.2b, all the documents that were reduced to the root “cent” are now indexed by cent. Stemming, while it might return related documents to the query, can also return many unrelated documents to the user. Also, while all of the terms in this figure can be reduced to the root “cent,” it is not appropriate in some cases to do so. In the case of “percentage” and “incent,” the issue of whether or not a prefix should be stripped arises. In this example, the prefixes are stripped off to demonstrate the problems of stemming. However, in general, prefixes are not stripped to reduce a word to its root because many prefixes change the meaning of the root.

75.2.3 Text Retrieval Systems and Models

Applying the above concepts to help filter and retrieve meaningful data, there are many methods for creating text retrieval systems. The most popular one is the Boolean keyword text retrieval system. In this system, the user enters a series of keywords joined by Boolean operators such as “and” or “or.” These systems can be extended to employ ranking of search results as well as the ability to handle wildcard or “don’t care” characters [33,40,41].

One popular model for text retrieval systems is the vector-space model [31,32]. In vector-space models, documents are viewed as vectors in N-dimensional space, where N is the number of keywords within the database. The values within the vector represent whether a particular keyword is present in the given document. These values can be as simple as 0 if the keyword is not present within the document or 1 if it is present. Also, the text retrieval system can use functions where the resulting value represents the importance of that keyword within the document. When querying the system, the user's query is transformed into a vector and then that vector is compared with the vectors within the database. Documents with similar vectors are returned to the user, usually ranked with respect to how similar the document's vector is to the original query. While this technique does allow for effective similarity searches, the dimensionality of the vectors can increase greatly, depending on the number of keywords.

Other popular text systems include probabilistic models as well as the employment of machine learning and artificial intelligence techniques. Probabilistic models test how well a document satisfies a user query. These techniques can employ Bayesian networks to represent both the document and the query. Machine learning and artificial intelligence techniques use natural language processing, rule-based systems, and case-based reasoning for information retrieval in text-based documents.

75.2.4 Web and Multimedia Information Retrieval

While there is great interest in the text-based methods previously mentioned, there is also currently a lot of research within the areas of Web-based information retrieval and multimedia information retrieval. Web-based information retrieval can best be seen in the techniques used to index Web sites for search engines as well as the techniques used to track usage [8,17]. Issues concerning this type of information retrieval will be reviewed later in this chapter. Multimedia information retrieval addresses issues involved with multimedia documents such as images, music, and motion pictures. Unlike text, multimedia documents use various formats to display information. Because this information is in different formats, before any retrieval algorithms are used on it, the documents must be mapped to a common format. Otherwise, there will be no standard representation of the document, making retrieval harder. Moreover, because most information retrieval algorithms apply to text documents, these algorithms either need to be modified or new algorithms must be developed to perform retrieval. Also, most tools can only process information about the format of the document, not its content [23].

In addition to issues concerning the data that is comprised in a multimedia database, other issues concerning the query also cause great difficulties. Because the query would be for multimedia information, naturally the user might want to use a multimedia format to author the query. This creates problems with user authoring tools. For example, if someone is searching for a particular piece of music and only knows a couple of notes from the song (and knows nothing about the title or artist), he or she must enter those notes. This creates issues concerning how the user enters these notes as well as how are these notes matched against a database of songs. Most multimedia databases allow only keyword search, thereby eliminating the authoring problem. Databases that allow only keyword search usually use whatever metadata about the images within the database (such as captions and file names) to index the data. The query is then matched against this data. A good example of this type of search tool is Google's Image Search (<http://www.google.com>). However, there are many research projects underway to allow users to author multimedia documents (such as images or segments of music) as queries for databases [20].

Currently there are many efforts for developing techniques to both process and retrieve multimedia data. These efforts combine numerous fields outside of information retrieval, including image processing and pattern recognition. Current popular techniques use relevance feedback as well as similarity measures such as Euclidean distance for multimedia information retrieval. Relevance feedback is a technique where the user continually interacts with the retrieval system, refining the query until he or she is satisfied with the results of the search. Similarity measures are used to match queries against database documents. However, current similarity measures, such as Euclidean distance and cosine distance for vector models, are based

on the properties of text retrieval. Therefore, relevance feedback practices have performed better than the similarity measures [20]. One project by the Motion Picture Expert Group (MPEG) is called MPEG-7. MPEG-7 tries to create models for various types of multimedia documents so that all the information contained within the documents can be specified through metadata. This data can then be searched through the usual text retrieval methods [26,27].

75.2.5 Evaluating IR Systems

Information retrieval systems are evaluated based on many different metrics. The two most common metrics are recall and precision:

1. *Recall* measures the percentage of relevant documents retrieved by the system with respect to all relevant documents within the database. If the recall percentage is low, then the system is retrieving very few relevant documents.
2. *Precision* describes how many false hits the system generates. Precision equals the number of relevant documents retrieved divided by the total number of documents retrieved. If the precision percentage is low, then most of the documents retrieved were false hits.

Most IR systems experience a dilemma concerning precision and recall. To improve a system's precision, the system needs strong measures for deciding whether a document is relevant to a query. This will help minimize the false hits, but it will also affect the number of relevant documents that are retrieved. These strong measures can prevent some important relevant documents from being included within the set of documents that satisfy the query, thereby lowering the recall.

In addition to precision and recall, there are other measures that can be used to evaluate the effectiveness of an information retrieval system. One very important evaluation measure is ranking. *Ranking* refers to the evaluation techniques by which the search results are ordered and then returned to the user, presented in that order. In ranking, a rating is given to the documents that the information retrieval system considers a match for the query. This rating reflects how similar the matched document is to the user's query. One of the most popular algorithms for ranking documents on the World Wide Web is PageRank [5,28]. PageRank, developed by Page et al., is for understanding the importance for documents retrieved from the Web. It is similar to the citation method of determining the importance of a document. Basically, in this algorithm, the relevance of a Web site to a particular topic is determined by how many well-recognized Web pages (Web pages that are known to be a reliable reference to other pages) link to that page. In addition to precision, recall, and ranking, which are based on system performance, there are also many measures such as coverage ratio and novelty ratio that indicate the effectiveness of the information retrieval system with respect to the user's expectations [18]. Table 75.1 summarizes some of the measures that can be used to determine the effectiveness of an information retrieval system.

TABLE 75.1 Measures for Evaluating Information Retrieval Systems

Measure	Purpose
Precision	Describes the number of false hits.
Recall	Measures percentage of relevant documents retrieved with respect to all relevant documents within the database.
Citation	Measures importance of a document through the number of other documents referencing it.
Coverage	Measures the number of relevant documents retrieved the user was previously aware of.
Novelty	Measures the number of relevant documents retrieved the user was not previously aware of.
PageRank	This is similar to the citation measure, except for Web documents.

75.3 Data Mining

Data mining refers to the extraction or discovery of knowledge from large amounts of data [13,37]. Other terms with similar meaning include knowledge mining, knowledge extraction, data analysis, and pattern analysis. The main difference between information retrieval and data mining is their goals. Information retrieval helps users search for documents or data that satisfy their information needs [6]. Data mining goes beyond searching; it discovers useful knowledge by analyzing data correlations using sophisticated data mining techniques. Knowledge may refer to some particular patterns shared by a subset of the data set, some specific relationship among a group of data items, or other interesting information that is implicit or not directly inferable.

Data mining is an interdisciplinary field contributed to by a set of disciplines including database systems, statistics, machine learning, pattern recognition, visualization, and information theory. As a result, taxonomies of data mining techniques are not unique. This is due to the various criteria and viewpoints of each discipline involved with the development of the techniques. One generally accepted taxonomy is based on the data mining functionalities such as association rule mining [1], classification [7], clustering [4], and concept description. To be a comprehensive and effective data mining system, the above functionalities must be implemented within the system. These functionalities also give a portal to the understanding of general data mining system construction.

75.3.1 Concept Description

The explosive increase of data volume, especially large amounts of data stored in great detail, requires a succinct representation for the data. Most users prefer an overall picture of a class of data so as to distinguish it from other comparative classes. On the other hand, the huge volume of data makes it impossible for a person to give, intuitively, such a concise while accurate summarization for a given class of data. However, there exist some computerized techniques to summarize a given class of data in concise, descriptive terms, called concept description [8,9]. These techniques are essential and form an important component of data mining.

Concept description is not simply enumeration of information extracted from the database. Instead, some derivative techniques are used to generate descriptions for characterization and discrimination of the data. According to the techniques used to derive the summary, concept description can be divided into characterization analysis and discrimination analysis. *Characterization analysis* derives the summary information from a set of data. To do characterization, the data generalization and summarization-based method aims to summarize a large set of data and represent it at a higher, conceptual level. Usually, attribute-oriented induction is adopted to guide the summarization process from a lower conceptual level to a higher one by checking the number of distinct values of each attribute in the relevant set of data. For example, Table 75.2 shows the original data tuples in a transactional database for a chain company. If some generalization operation regarding the geographical locations of stores has already been established, then the store ID in the location field can be replaced by a higher-level description, namely geographical areas. In addition, generalization can be done on the time field by replacing it with a higher-level concept, say month. Table 75.3 shows generalized sales for the database in Table 75.2, where the generalizations are performed with respect to the attributes “time” and “location.”

TABLE 75.2 Original Data in a Transactional Database

Item	Unit Price	Time	Payment	Location	Quantity
Printer	\$45.00	14:02 7/5/2002	Visa	0089	1
Scanner	\$34.56	11:09 8/1/2002	Cash	0084	1
Camcorder	\$489.95	13:00 7/14/2002	Master	0100	1
⋮	⋮	⋮	⋮	⋮	⋮

TABLE 75.3 Generalized Sales for the Same Transactional Database in Table 75.2

Item	Unit Price	Time	Payment	Location	Quantity
Printer	\$45.00	July, 2002	Visa	Essex County, NJ	1
Scanner	\$34.56	August, 2002	Cash	Hudson County, NJ	1
Camcorder	\$489.95	July, 2002	Master	Essex County, NJ	1
⋮	⋮	⋮	⋮	⋮	⋮

Discrimination analysis puts emphasis on the distinguishing features among sets of data. Discrimination analysis can be accomplished by extending the techniques proposed for characterization analysis. For example, by performing the generalization process among all data classes simultaneously and synchronously, the same level of generalization for all of the classes can be reached, thus making the comparison feasible. In previous examples, we assume the attributes selected for characterization or discrimination are always relevant. However, in many cases, not all the attributes are relevant for data characterization or comparison. Analytical characterization techniques are one kind of attribute relevance analysis. They are incorporated into data description or comparison to identify and exclude those irrelevant or weakly relevant attributes.

Concept description tries to capture the overall picture of a class of data by inducing the important features of it through conceptual generalization or comparison with a class of comparative data. By grasping the common features presented by the data class as a whole, it looks at the class of data as an entirety while ignoring the relationship among its component items. However, in many cases, exploring the relationship within component items is valuable. This forms another important data mining process: association rule mining.

75.3.2 Association Rule Mining

Association rule mining [2,3,22] is the process of finding interesting correlations among a large set of data items. For example, the discovery of interesting association relationships in large volumes of business transactions can facilitate decision making in marketing strategies. The general way of interpreting an association rule is that the appearance of the item(s) on the left-hand side of the rule implies the appearance of those item(s) on the right-hand side of the rule.

There are two parameters to measure the interestingness for a given association rule: support and confidence. For example, consider the following association rule discovered from a transaction database:

$$B \rightarrow C[\text{support} = 30\%, \text{confidence} = 66\%]$$

The usefulness of an association rule is measured by its support value. Given the above rule, it means that within the whole transactions of the database, 30% transactions contain both items B and C. The confidence value measures the certainty of the rule. Again, for the above rule, it means for all those transactions containing B, 66% of them also contain C. Figure 75.3 shows an example of finding association rules from a set of transactions. For rule $A \rightarrow C$, the number of transactions containing both A and C is 2, so the support for this rule is 2 divided by the total number of transactions (5), which is equivalent to 40%. To calculate confidence, we find the number of transactions containing A is 3, so we get the confidence as 66.7%.

An acceptable or interesting rule will have its two parameter values greater than a user-specified threshold. These two parameters are intuitively reasonable for measuring the interestingness of an association rule. The support parameter guarantees that there are statistically enough transactions containing the items appearing in the rule. The confidence parameter implies the validness of the right-hand side given the left-hand side of the rule, with certainty.

Given the two parameters, support and confidence, finding association rules requires two steps. First, find all frequent itemsets that contain all the itemsets so that, for each of them, its number of appearances

Transaction list:	Association Rules:
1. (A, B, C)	A --> C [support=40%, confidence=66.7%]
2. (A, C)	A --> B [support=40%, confidence=66.7%]
3. (D, E)	
4. (B, C)	B --> C [support=40%, confidence=66.7%]
5. (A, B)	

FIGURE 75.3 A simple example of finding association rules.

as a whole in the transactions must be greater than the support value. Next, generate association rules that satisfy the minimum support and minimum confidence, from the above frequent itemsets.

The well-known *a priori* [2,3,22] data-mining algorithm can demonstrate the principles underlying association rule mining. *A priori* is a classic algorithm to generate all frequent itemsets for discovering association rules given a set of transactions. It iteratively scans the transaction set to find frequent itemsets at one particular size a time. During each iteration process, new frequent candidate itemsets with size one larger than the itemsets produced at the previous iteration are generated; and the acceptable itemsets are produced and stored through scanning the set and calculating the support value for each of the candidate itemsets. If no new frequent itemsets can be produced, *a priori* stops by returning all itemsets produced from every iteration stage.

Given the frequent itemsets, finding association rules is straightforward. For each itemset, divide the items in it into two subsets with one acting as the left-hand side of the association rule and the other as the right-hand side. Different divisions will produce different rules. In this way, we can find all of the candidate association rules. It is obvious that each association rule satisfies the requirement of minimum support. By further verifying their confidence values, we can generate all the association rules.

Concept description and association rule discovery provide powerful underlying characteristics and correlation relationships from known data. They put emphasis on the analysis and representation of the data at hand while paying little attention in regard to constructing some kind of model for those data coming but still not available. This kind of model pays more attention to “future” data cases. In the data mining domain, classification and prediction accomplish the establishment of this kind of model. Many applications, such as decision making, marketing prediction, and investment assessment all benefit from these two techniques.

75.3.3 Classification and Prediction

In many cases, making a decision is related to constructing a model, such as a decision tree [25], against which unknown or unlabeled data could be categorized or classified into some known data class. For example, through the analysis of customer purchase behavior associated with age, income level, living area, and other factors, a model can be established to categorize customers into several classes. With this model, new customers can be classified properly so that an appropriate advertising strategy and effective promotion method could be set up for maximizing profit.

Classification is usually associated with finding a known data class for the given unknown data, which is analogous to labeling the unlabeled data. Therefore, the data values under consideration are always discrete and nominal. On the other hand, prediction aims to manage continuous data values by constructing a statistical regression model. Intuitively, a regression model tries to find a polynomial equation in the multidimensional space based on the given data. The trends presented by the equation give some possible predictions. Typical applications include investment risk analysis and economic growth prediction.

In the past, several classification approaches have been developed. The major models include decision tree induction, Bayesian classification, Bayesian belief networks, and neural network classification [35]. Although each model has its particular trait, all of them share a common two-step processing feature: a training stage and a classification stage. During the training stage, a model describing a predetermined set of data classes is established by analyzing database tuples comprised of attribute values. These tuples constitute the training data set. The acceptability of the model is measured in the classification stage where another data set, called the testing data set, is used to estimate the accuracy of the classification. If the model passes the classification stage, it means that its classification accuracy is acceptable and is ready to be used for classifying future data tuples or objects whose class labels are unknown.

In regard to prediction, the available regression techniques include linear regression, nonlinear regression, logistic regression, and Poisson regression [14]. Linear regression attempts to find a linear equation to represent the trend shown in the given database. Nonlinear regression uses a polynomial equation to represent the trend, instead of a linear equation, showing higher accuracy in those cases of complex trend prediction. Logistic regression and Poisson regression, also called generalized regression models, can be used to model both contiguous and discrete data.

As described above, classification starts with a set of known labeled data and its training stage is guided by the labeled data. We call this kind of training or learning “supervised learning,” where both the label of each training datum and the number of data classes to be learned are known. On the other hand, there exist many cases in which the knowledge about the given set of data is very limited. Neither is the label for each datum known nor has the number of data classes been given. Clustering, known as “unsupervised learning,” is aimed at handling those cases.

75.3.4 Clustering

Clustering is the process of grouping data objects into clusters without prior knowledge of the data objects [16,17,36]. It divides a given set of data into groups so that objects residing in the same group are “close” to each other while being far away from objects in other groups. Figure 75.4 illustrates the general concept underlying clustering. It has shown that object-dense regions, represented as point sets, are found and objects are clustered into groups according to the regions.

The objective of clustering is to enable one to discover distribution patterns and correlations among data objects by identifying dense vs. sparse regions in the data distribution. Unlike classification, which requires a training stage to feed predetermined knowledge into the system, clustering tries to deduce knowledge based on knowledge from which the clustering can proceed. Clustering analysis has a wide range of applications, including image processing, business transaction analysis, and pattern recognition.

FIGURE 75.4 (a) A set of spatial points, and (b) a possible clustering for the spatial points.

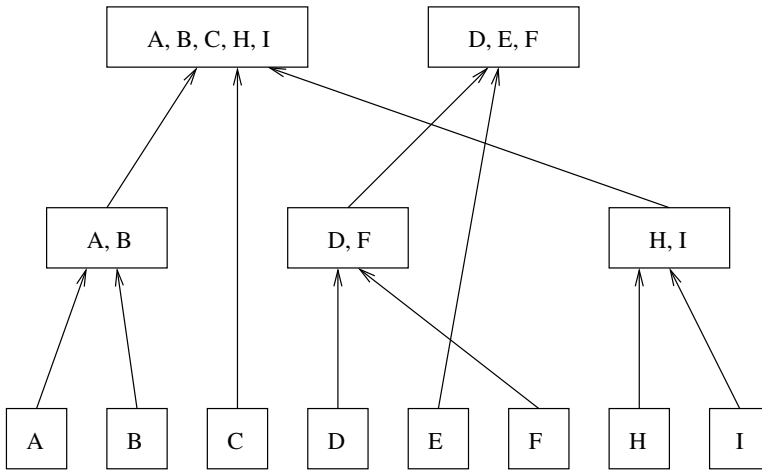

FIGURE 75.5 Agglomerative clustering.

The “learning from nothing” feature poses a set of typical requirements for an effective and efficient clustering analysis. These requirements, as discussed in [13], include scalability, the capability of dealing with different types of data, the ability to cope with noisy and high-dimensional data, the ability to be guided by clustering constraints, and the capability to cluster arbitrary shapes. To meet these requirements, researchers have proposed many clustering algorithms by taking advantage of the data under analysis and the characteristics of the application. The major categorization of clustering methods could be partition methods [21], hierarchical methods [16], and grid-based methods [38].

The well-known k-means algorithm [21] and its variation k-medoid [16] are two partition methods that accept n data objects and an integer k , and then divide the n objects into k groups satisfying the following two conditions. First, each group must contain at least one object. Second, each object must belong to exactly one group. During clustering, partition methods adopt iterative relocation techniques to try to find a different, more “reasonable” group for each data object and move data objects between groups until no group change occurs.

Hierarchical methods, such as agglomerative clustering, adopt a bottom-up strategy for tree construction. As shown in Figure 75.5, the leaf nodes are original objects. The clustering process goes from the bottom up along the tree, with each internal node representing one cluster. On the other hand, divisive clustering [16] uses top-down tactics to accomplish the same goal.

Both density-based methods and grid-based methods can handle arbitrary shape clustering. Density-based methods [11] accomplish this by distinguishing object-dense from object-sparse regions. On the other hand, grid-based methods use a multidimensional grid data structure to accommodate data objects. Through manipulation on the quantized grid cells, data objects are clustered. Model-based methods assume that the data is generated by a mixture of underlying probability distributions; thus, the goal of clustering becomes finding some mathematical model to fit the given data.

75.4 Integrating IR and DM Techniques into Modern Search Engines

With the development of the World Wide Web as well as developments in information retrieval and data mining, there are many applications in which one can exploit IR and DM techniques to help people discover knowledge they need. The most common instances of these applications tend to be in search tools. In this section we review some popular uses of information retrieval and data mining concerning the World Wide

Web. We provide examples to illustrate how data mining is being used to make Web-based search engines more effective.

75.4.1 Web Mining and Retrieval

One popular approach for trying to improve the recall of Web-based search engines is to employ data mining techniques to learn more about both the data retrieved as well as user preferences. Data mining techniques not only help in ensuring that the results of the query are precise but also to help the user sort through the search results that match a query. By using both data mining and information retrieval techniques to analyze the data, two extremely effective methods of analysis can work together to provide users with the most relevant information for which they are searching.

Currently, there are a lot of applications being developed where data mining is applied to Web information retrieval problems. These problems can be classified into certain groups: Web content mining, Web structure mining, and Web usage mining. Web content mining discovers useful knowledge within data on the World Wide Web. This analysis studies the content of Web sites as well as procedures for extracting and analyzing that content. Web structure mining looks at how various Web sites are related to one another. This analysis usually tries to discover the underlying connections of Web sites on the Internet (usually through the analysis of hyperlinks) so as to discover relationships and information about the Web sites. Finally, Web usage mining studies the behavior of a group of users with respect to the Web sites they view. From these studies, it can be observed what Web sites various groups of people with similar interests consider important. In this section, we concentrate solely on Web content mining because this type of mining is what most users have direct experience with [24].

One of the most popular applications of Web content data mining is clustering. Clustering algorithms are ideal for analyzing data on the Web. The premise behind clustering is that given a data set, find all groupings of data based on some data dimension. As discussed, clustering, unlike some other popular data mining techniques such as classification, does not require any mechanism for the tool to learn about the data.

Below we survey a couple of search engines that employ clustering to help users have meaningful and effective search experiences.

75.4.2 Vivisimo

Vivisimo (<http://www.vivisimo.com>) [34] is a meta-search engine that uses clustering and data mining techniques to help users have a more effective search experience. The search engine developed by the Vivisimo company offers users both on the Web and through enterprise solutions the ability to cluster information extracted by a search tool immediately or “on-the-fly” [34]. Concentrating on Vivisimo’s Web-based search engine, this tool creates an extremely useful searching environment. In this Web search tool, the user can enter a query similarly to any popular search engine. When this query is entered, the Vivisimo search tool sends the query to its partner Web search tools. Some of Vivisimo’s partners include Yahoo! (<http://www.yahoo.com>), GigaBlast (<http://www.gigablast.com>), DogPile (<http://www.dogpile.com>), MSN (<http://www.msn.com>), and Netscape (<http://www.netscape.com>). Once the results of the searches for the query on these search tools are complete, the results are returned to the Vivisimo search tool. Vivisimo then employs proprietary clustering techniques to the resulting data set to cluster the results of the search. The user can then search through the results either by browsing the entire list, as with most popular search tools, or by browsing the clusters created.

In addition to the traditional Web-based meta-search, Vivisimo allows users to search by specifying certain Web sites, especially news Web sites. For those users who want to search for very current information, this tool can search a specific Web site for that information. It also organizes the information categorically for the user. For example, a user can use the Vivisimo cluster tool to search a news Web site for current information in which he or she is interested. However, the user can only specify Web sites for this type of search from a list Vivisimo provides for the user.

75.4.3 KartOO

Another search tool that searches the Web using clustering techniques is KartOO (<http://www.kartoo.com>) [15]. KartOO is also a meta-search engine, similar to Vivisimo's search tool. However, KartOO's visualization methods add a new dimension for users to a data set. Similar to Vivisimo, KartOO uses a number of popular search engines for the initial search. The tool allows the user to select which search engines are included within the search. Once the results are returned, KartOO evaluates the result, organizing them according to relevance to the query. The links most relevant to the query are then returned as results. When the results are presented, the results are represented in an interactive graph for the user. Each node, or "ball" of the graph, represents a Web site that was returned to KartOO as fulfilling the query. Each node is connected to other nodes through edges that represent semantic links between the Web sites modeled within the node. The user can then browse the graph looking for the information in which he or she is interested. While browsing, if the user rolls the mouse over a node, information about the link it connects is displayed. When the user rolls the mouse over one of the semantic links, he or she can elect to refine the search to purposely include that semantic information within the query by clicking on the plus "+" sign or purposely exclude that semantic information within the query by clicking on the minus "-" sign. If the user does not want to include or exclude that information, he or she can take no action. Through this interaction with the semantic links, the user can refine his or her query in a very intuitive way. Moreover, with the graphical representation of the results, a user can see how various results are related to one another, thus identifying different clusters of results.

75.4.4 SYSTERS Protein Family Database

Looking at more domain-specific search tools, many research Web sites are also employing data mining techniques to make searching on their Web sites more effect. SYSTERS Protein Family Database (<http://systers.molgen.mpg.de/>) [19] is another interesting search tool that uses both clustering and classification to improve upon searching a data set. The SYSTERS Protein Family Database looks at clustering information about biological taxonomies based on genetic information and then classifies these clusters of proteins into a hierarchical structure. This database can then be searched using a variety of methods [19].

At the core of this tool are the clustering and classification algorithms. To place a protein sequence into the database, the database first uses a gapped BLAST search, which is a sequence alignment tool, to find what sequences the protein is similar to. However, because the alignment is asymmetric, this step is only used to narrow down the possible sequences the original might be similar to. Next, a pairwise local alignment is performed, upon which the clustering of the protein sequences will be based. Because these are biological sequences, all the sequences will have some measure of similarity. Sequences that are extremely similar are clustered together, creating superfamilies. These superfamilies are then organized hierarchically to classify their relationships. Users can then search this database on a number of key terms, including taxon (organism) names and cluster identification terms such as cluster number and cluster size. From this search, information about the specific query term is returned, as well as links to related information in the cluster. The user can then browse this information by traversing the links.

75.4.5 E-Commerce Systems

In addition to search tools, Web content data mining techniques can be used for a host of applications on the World Wide Web. Many E-commerce sites use association rule mining to recommend to users other items they might possibly like based on their previous selections. Association rule mining allows sites to also track the various types of usage on their site. For example, on an E-commerce site, information about the user's interactions with the site can help the E-commerce site customize the experience for the user, improve customer service for the user, and discover customer shopping trends [13]. Also, concerning

financial issues, classification and clustering can be used to target new customers for products based on previous purchases. Data mining can also give companies insight into how well a marketing strategy is enticing customers into buying certain products [13].

75.5 Conclusion and Further Resources

Information retrieval and data mining are two very rich fields of computer science. Both have many practical applications while also having a rich problem set that allows researchers to continually improve upon current theories and techniques. In this chapter, we have looked at some of these theories and applications. Information retrieval has evolved from a field that was initially created by the need to index and access documents into a robust research area that studies techniques for not only retrieving data but also discovering knowledge in that data. Data mining, while a much younger field, has evolved to explore intriguing relationships in very complex data. The future promises to be very exciting with the developments in multimedia information retrieval and data mining as well as the movement toward trying to understand semantic meanings with the data.

While this chapter introduces these topics, there are many other resources available to readers who wish to study specific problems in-depth. In the field of information retrieval, there are a number of introductory texts that discuss information retrieval very comprehensively. Some excellent introductory texts include Salton's *Automatic Text Processing: The Transformation, Analysis, and Retrieval of Information by Computer* [31], Korfhage's *Information Storage and Retrieval* [18], and Baeza-Yates' and Ribeiro-Neto's *Modern Information Retrieval* [6]. Also, there are several conferences in which state-of-the-art research results are published. These include the Text Retrieval Conference (TREC, <http://trec.nist.gov/>) and ACM's Special Interest Group on Information Retrieval (SIGIR) Conference. Concerning data mining, there are also a number of introductory texts to this subject; see, for example, Han's and Kamber's *Data Mining: Concepts and Techniques* [13]. In addition, there are numerous data mining resources available as well as technical committees and conferences. A major conference is ACM's Special Interest Group on Knowledge Discovery in Data (SIGKDD) Conference, among others.

76.1 Introduction

Over the past few years, data compression has become intimately integrated with information available in digital form; text, documents, images, sound, and music are all compressed before storage on a digital medium. However, depending on whether one is storing text, a document, or an image, there are different requirements on the type of compression algorithm that can be used. This is directly related to issues about the amount of compression that can be achieved and the quality with which the compressed data can be uncompressed. In this chapter we introduce the techniques behind data compression, especially those that apply to text and image compression.

Definition 76.1 Data compression is the method of representing a data object that takes B bits of storage, by a data object that takes B' bits of storage, where $B' < B$, often significantly.

Although there is no definitive taxonomy of data compression methods, they can be divided into two disjoint categories: informationally *lossless* methods and informationally *lossy* methods. Informationally lossless methods *exactly* reproduce the input data stream on decompression; that is, there is no loss of information between the application of the compression and decompression operations. Lossy methods produce a parameter-dependent approximation to the original data; that is, the compression and decompression operations cause information loss. For this reason, lossless compression is almost always used to compress text because text needs to be reproduced exactly, and lossy compression is useful in applications such as facsimile transmission (fax) where an approximation to the original data is acceptable. Under lossless compression are two major subcategories: *entropy coding* (Section 76.2.3) and *dictionary-based coding* (Section 76.2.4). There are other methods such as *run-length coding* (Section 76.2.5.2) that fall into neither of these sub-categories, and still others, such as *prediction with partial matching* (Section 76.2.5.1) that are a hybrid of these subcategories. The lossy compression category can also be subdivided into two major subcategories: *data domain* techniques (Section 76.3.1) and *transform domain* methods (Section 76.3.2). Because text compression algorithms invariably belong to the lossless compression category, and most image, document, audio, and video compression algorithms belong to the lossy compression subcategory, another way to categorize algorithms can be based on their use rather than on their structure.

76.2 Lossless Compression

One of the issues key in a discussion of lossless image compression methods is the evaluation of their performance. Some *metrics* need to be defined that can be used to judge the performance of the different algorithms. We use two metrics to judge the performance of the algorithms described in this chapter:

1. Compression ratio (CR)
2. Information content

In the next sections, we discuss these metrics in some detail.

76.2.1 Metric: Compression Ratio

Definition 76.2 Compression ratio \mathcal{C} is defined as the ratio of the total number of bits used to represent the data before encoding to the total number of bits used to represent the data after encoding:

$$\mathcal{C} = \frac{B'}{B}$$

where B is the size of the original data, and B' is the size of the compressed representation of the data.

The total number of bits $B' = B'_d + B'_o$, where B'_d is the number of bits used to represent the actual data and B'_o is the number of bits used to represent any additional information that is needed to decode* the data. B'_o is known as the *overhead*, and can be significant in computing the performance of compression algorithms. For example, if two compression schemes produce the same size compressed data representation, B'_d , then the one with larger overhead B'_o will produce the poorer compression ratio. Also, if B'_o is constant (i.e., all data regardless of its characteristics has the same associated overhead), then larger data sets will tend to have better data-to-overhead ratios, resulting in more efficient representation of encoded data.

This metric is universally applicable to both lossless and lossy compression techniques. However, one needs to be careful when applying this metric to lossy compression. Just because a compression method achieves better data compression does *not* automatically make it better overall because the quality of the decompressed data is significant. This observation is not relevant to lossless compression schemes because the decompressed data and the original data are identical.

76.2.2 Metric: Information

Central to the idea of compression is the concept of *information*. “Information” is a word that is part of most everybody’s everyday lexicon. However, when one speaks of information in the context of data compression, one assigns it a very particular meaning. Consider a random experiment, and let \mathcal{B} be a possible event in this random experiment. Let $p = \Pr\{\mathcal{B}\}$ be the probability that event \mathcal{B} occurs. In this experiment, information depends only on the *probability* of occurrence of \mathcal{B} , and not on the *content* of \mathcal{B} . In other words, because we already know *what* \mathcal{B} is, this does not provide any information. However, because we do not know *when* \mathcal{B} occurs, the frequency with which \mathcal{B} occurs (i.e., the probability with which it occurs) does give us insight, or information, about \mathcal{B} . So, we want to define a quantity that will measure the amount of this “information” associated with the probability of occurrence of \mathcal{B} .

Let $I(p)$ denote the information associated with $p(\mathcal{B})$, the probability that “ \mathcal{B} has occurred.” We want to determine the functional form of $I(\cdot)$ by first listing a set of requirements that $I(\cdot)$ should satisfy.**

*We use *decode* and *decompress* interchangeably throughout this chapter.

**The material in this section is based, in part, on Chapter 9.3 in *A First Course in Probability*, third edition, by Sheldon Ross. Interested readers should consult this source for the proof of Theorem 76.1.

Definition 76.3 $I(p)$ is a non-negative real-valued function defined for all $0 < p \leq 1$, that satisfies the following requirements:

1. $I(1) = 0$ (i.e., if \mathcal{B} is *certain* to occur), then “ \mathcal{B} has occurred” conveys no information.
2. $I(p)$ is a strictly monotonically *decreasing* function of p (i.e., the *more* likely \mathcal{B} is to occur), the *less* is the information conveyed by “ \mathcal{B} has occurred.” Formally, if $0 < p_1 < p_2 \leq 1$ then $I(p_1) > I(p_2)$.
3. $I(p)$ is a *continuous* function of p (i.e., small changes in p will not produce a large change in $I(p)$).
4. If $p = p_1 p_2$ with $0 < p_1 \leq 1$ and $0 < p_2 \leq 1$ then $I(p) = I(p_1 p_2) = I(p_1) + I(p_2)$.

The last requirement can be justified using the following argument. Suppose event \mathcal{B} is the result of the *joint* occurrence of two independent, elementary events \mathcal{B}_1 and \mathcal{B}_2 with respective probabilities p_1 and p_2 . Then, $\mathcal{B} = \mathcal{B}_1 \cap \mathcal{B}_2$, and

$$p = \Pr\{\mathcal{B}\} = \Pr\{\mathcal{B}_1 \cap \mathcal{B}_2\} = \Pr\{\mathcal{B}_1\} \Pr\{\mathcal{B}_2\} = p_1 p_2.$$

It is intuitive that the independence of events \mathcal{B}_1 and \mathcal{B}_2 should cause their associated information to *add* when they occur jointly.

Theorem 76.1 *The only function that satisfies the four requirements in Definition 76.3 is*

$$I(p) = -c \log_a(p)$$

where the constant c is positive but otherwise arbitrary, and $a > 1$.

The convention is to let the $c = 1$. The units of $I(p)$ are called *bits* when $a = 2$, *Hartleys* when $a = 10$, and *nats* when $a = e$.

Definition 76.4 Let X be a discrete random variable and let \mathcal{X} be the associated set of possible values of X . For each $x \in \mathcal{X}$, the associated probability is $p(x) = \Pr\{X = x\}$ and the corresponding information is $I(p(x)) = -\log_2(p(x))$. The *expected* (average) information associated with X is then

$$\mathcal{H}(X) = - \sum_{x \in \mathcal{X}} p(x) \log_2(p(x)).$$

This expected value is known as the *entropy* of the random variable X .

To paraphrase Definition 76.4, if values of the random variable X are generated repeatedly and, for each observation x , the associated information $-\log_2(p(x))$ is computed, then the average over (infinitely) many observations would be $\mathcal{H}(X)$. If $|\mathcal{X}| = n$ then it can be shown that the largest possible value of $\mathcal{H}(X)$ is $\log_2(n)$ and this value is attained if, and only if, all n possible values are equally likely. In this case,

$$p(x) = \frac{1}{n} \quad \text{for all } x \in \mathcal{X}$$

and each possible value of X conveys exactly the same amount of information, namely:

$$\mathcal{H}(X) = - \sum_x p(x) \log_2(p(x)) = - \sum_x (1/n) \log_2(1/n) = \log_2(n).$$

The converse that all n values are equally likely when the entropy is maximum is also true. We will use this measure to define the efficiency of lossless compression algorithms in the next section.

76.2.3 Methods

Before delving into a description of what it means to losslessly compress a data stream, and the techniques used to achieve this goal, we need to define what we mean by a *data stream* and how it is represented.

Definition 76.5 A data stream, $d = s_1s_2s_3 \cdots s_ns_{n+1} \cdots$, is a sequence of symbols s_i drawn from an alphabet \mathcal{A} .

The index i does not represent the order in which the symbols occur in the alphabet; rather, it represents the order in which the symbols occur in the data stream. Input and output data streams draw symbols from different alphabets. For instance, when compressing English text, the input data stream comprises of all the letters of the English alphabet, the numbers, and punctuation marks. The output data stream can be a set of symbols derived from recurring patterns in the input data stream, or from the frequency of occurrence of symbols in the data stream. In either case, it depends on the characteristics of the input data rather than the raw data itself.

Definition 76.6 A symbol s can represent a single character, c , or a sequence of characters $c_1c_2 \cdots c_n$ concatenated together.

Again, the differentiation is more in terms of symbols drawn from the alphabet for the input data stream vs. symbols drawn from the alphabet for the output data stream. Typically, the input alphabet \mathcal{A}_i has symbols that represent a single character, whereas the output alphabet \mathcal{A}_o can have symbols that represent concatenated strings of recurring characters. (See Section 76.2.4 for details).

Definition 76.7 An alphabet $\mathcal{A} = \{s_1, s_2, \dots, s_S\}$ is the set of S possible symbols that can be present in a data stream.

Typically, alphabets for the input data stream are known *a priori*; that is, they are derived from a known source such as the English alphabet. The alphabet for the output data stream is generally generated on-the-fly from the patterns in the input data stream (LZW compression,¹ Section 76.2.4.1), or from the frequency of occurrence of symbols (Huffman coding² Section 76.2.3.2). However, output alphabets that have been determined previously are also used when *canonical* Huffman codes are used for entropy coding (see Section 76.2.3 and Section 76.3.2).

With these concepts in mind, lossless compression can be categorized into two major groups:

1. **Entropy coding.** In entropy-coding schemes, the number of bits used to represent a symbol (i.e., the length of the symbol) is proportional to its probability of its occurrence in the data stream. However, each symbol is considered independent of all previously occurring symbols.
2. **Dictionary-based coding.** In dictionary-based coding schemes, recurring patterns are assigned fewer bits.

76.2.3.1 Entropy Coding

Suppose we are attempting to compress an electronic version of this chapter. The symbol alphabet in this case comprises of the lower and upper case English characters, numbers, punctuation marks, and spaces. If we assume that every symbol has equal significance — it occurs with equal frequency in the text — then an equal number of bits, B , should be assigned to represent every symbol. This is known as uniform, fixed length coding.

Definition 76.8 If $b_{s_i}, i = 0, \dots, S-1$ represents the number of bits that are used to represent (encode) the symbol s_i , and S is the total number of symbols in the alphabet, then for uniform, fixed-length coding, $b_{s_i} = B, i = 0, \dots, S-1$.

We can rewrite Definition 76.4 in terms of the above definitions:

$$\mathcal{H}(d_i) = - \sum_{s \in \mathcal{A}} p[s] \log_2(p[s]).$$

where, because of the (removable) singularity associated with $p[s] = 0$, the summation is only over those symbols s_i for which $p[s] > 0$. The entropy is, in a sense, a measure of how well data can be

compressed. Shannon* showed that the best compression ratio that a lossless compression scheme can achieve is bounded above by the entropy of the original signal.³ In other words, the best compression ratio is achieved when the average bits per symbol is equal to the entropy of the signal:

$$\bar{b} = \frac{1}{S} \sum_{i=0}^{S-1} b_{s_i} = \sum_{i=0}^{S-1} w[s_i] p[s_i] = \mathcal{H}(s_i),$$

where $w[s_i]$ is the length of the codeword representing symbol s_i .

Intuitively, then, to achieve the best possible lossless compression, the symbol distribution of the data needs to be examined and the number of bits assigned to represent each symbol set as a function of the probability of occurrence of that particular symbol; that is:

$$b_{s_i} = f(p_{s_i}) \quad i = 0, \dots, S - 1,$$

where $p_{s_i} = p[s_i], i = 0, \dots, S - 1$. The codes generated using this type of compression are called variable-length codes.

The above method outlines the basic idea of how to achieve maximum lossless compression but, aside from the vague *number of bits assigned should be inversely proportional to the frequency of occurrence*, it does not specify how such an assignment should be made. There are several ways in which this can be done:

1. The probability distribution of the data stream can be generated and then used to *manually* assign a unique code for each symbol. This technique would be efficient only for data streams with very small input alphabets.
2. A model-based approach can be used where the input data is assumed to have some standard probability distribution. The same set of encoded representations can then be used for all data. While this technique is automatic *once the initial encoding has been assigned*, it is inefficient because, in general, the symbols are encoded suboptimally.
3. An automatic technique that assigns minimum redundancy unique codes based upon the probability distribution of the input data stream, such as *Huffman coding*,² can be used.

76.2.3.2 Huffman Coding

Huffman codes belong to the class of *optimum* prefix codes.

Definition 76.9 An optimum code is a code whose average length, \bar{b} , does not exceed the average length of any other code, \bar{b}_k :

$$\bar{b} \leq \bar{b}_k \quad \forall k$$

and which has the following properties:

1. Symbols that occur more frequently have shorter associated codes.
2. The two symbols that occur least frequently have the same length code.
3. The two least frequently occurring symbols have a Hamming distance of 1; that is, they differ only in one bit location.

Huffman codes can be generated using the following algorithm:

Algorithm 76.1

1. Sort the S -element probability distribution array p in descending order; that is,

$$p'[0] = \max(p[l]) \quad \text{and} \quad p'[S - 1] = \min(p[l]), \quad l = 0, \dots, S - 1.$$

*Claude E. Shannon: father of modern communication theory.

- Combine the last two elements of p' into a new element, and store it in the second to last location in p' :

$$p'[S - 2] = p'[S - 1] + p'[S - 2]$$

reduce the number of elements in the array by one: $S = S - 1$. This operation of combining the last two elements into a new element and reducing the size of the array is called *Huffman contraction*.⁴

- Assign the code $x[l]$ to each combined symbol by prefixing a 0 to the symbol(s) in the $p'[S - 1]$ location and a 1 to the symbol(s) in the $p'[S - 2]$ location.
- Go to Step 1 and repeat until all the original symbols have been combined into a single symbol.

Example 76.1

Suppose we are given the probability distribution array:

l	0	1	2	3	4	5	6	7	8
$p[l]$	0.22	0.19	0.15	0.12	0.08	0.07	0.07	0.06	0.04

The entropy of this sequence is: $\mathcal{H} = -\sum_{p[l]>0} p[l] \log_2(p[l]) = 2.703$. Let l_S represent the set of indices for the Huffman contracted arrays. Table 76.1 shows the process as the Huffman codes are generated one

TABLE 76.1 Huffman Coding

l_9	0	1	2	3	4	5	6	7	8
$p[l]$	0.22	0.19	0.15	0.12	0.08	0.07	0.07	0.06	0.04
l_8	0	1	2	3	(7 8)		4	5	6
$x[l]$					(0 1)				
$p'[l]$	0.22	0.19	0.15	0.12	0.10		0.08	0.07	0.07
l_7	0	1	2	(5 6)	3		(7 8)		4
$x[l]$				(0 1)			(0 1)		
$p'[l]$	0.22	0.19	0.15	0.14	0.12		0.10		0.08
l_6	0	1	(7 8 4)		2		(5 6)		3
$x[l]$			(00 01 1)				(0 1)		
$p'[l]$	0.22	0.19	0.18		0.15		0.14		0.12
l_5	(5 6 3)			0	1		(7 8 4)		2
$x[l]$	(00 01 1)						(00 01 1)		
$p'[l]$	0.26			0.22	0.19		0.18		0.15
l_4	(7 8 4 2)				(5 6 3)			0	1
$x[l]$	(000 001 01 1)				(00 01 1)				
$p'[l]$	0.33				0.26			0.22	0.19
l_3	(0 1)		(7 8 4 2)				(5 6 3)		
$x[l]$	(0 1)		(000 001 01 1)				(00 01 1)		
$p'[l]$	0.41		0.33				0.26		
l_2	(7 8 4 2 5 6 3)							(0 1)	
$x[l]$	(0000 0001 001 01 100 101 11)							(0 1)	
$p'[l]$	0.59							0.41	
l_1	7	8	4	2	5	6	3	0	1
$x[l]$	00000	00001	0001	001	0100	0101	011	10	11
l_1	7	8	4	2	5	6	3	0	1
l_0	0	1	2	3	4	5	6	7	8
$x[l]$	10	11	001	011	0001	0100	0101	00000	00001
$w[l]$	2	2	3	3	4	4	4	5	5

At each iteration the two symbols with the smallest probabilities are combined into a new symbol and the list resorted. Text in teletype font shows the symbols that have been combined so far, their combined probabilities, and the codeword assigned thus far.

symbol at a time. The average codeword length with this encoding is:

$$\begin{aligned}\bar{b} &= \sum_{l=0}^8 p[l]w[l] = 2(0.22 + 0.19) + 3(0.15 + 0.12) + 4(0.08 + 0.07 + 0.07) + 5(0.06 + 0.04) = 3.01 \\ &= 0.86\mathcal{H}\end{aligned}$$

The compression ratio that the Huffman code achieves is $C_a = 4/3.01 = 1.33$, whereas the predicted compression ratio is $C_p = 4/2.70 = 1.48$. So, $C_a = 0.86C_p$, which says that Huffman coding is about 90% effective in compressing the input data stream. Because there are $S = 9$ symbols, the input alphabet is uniformly encoded at 4 bits per symbol, where the codewords are simply the binary representation symbols. The output (encoding) alphabet and associated codeword lengths are given in the last block of [Table 76.1](#).

The code generated in [Example 76.1](#) satisfies the criteria for an optimum code:

- The symbols with the largest frequency have the fewest bits assigned to them.
- The two lowest frequency symbols are represented with the same number of bits.
- The two longest codewords have a Hamming distance of 1.
- None of the codewords is a prefix of any other codeword, so the generated code is uniquely decodeable.

An alternative way of generating the Huffman code is to use a binary tree representation. This can be done because the Huffman code is a prefix code, so the insertion of a 0 or 1 at the beginning of the code is equivalent to going down another level in the tree. To generate the Huffman codes from the binary tree representation, use the following algorithm:

Algorithm 76.2

1. Traverse from the symbol to be encoded to the end (root) of the binary tree.
2. The codeword is formed by prefixing 0 or 1 to the codeword generated so far along the path, depending upon whether the left (0) or right (1) branch is taken.

Example 76.2

$$\begin{array}{l} l : 0 \quad 1 \quad 2 \quad 3 \quad 4 \\ p[l] : 0.4 \quad 0.2 \quad 0.2 \quad 0.1 \quad 0.1 \end{array}$$

To compute the code for $p[3]$ in [Figure 76.1](#), traverse from $p'_3(0.1)$ to (1.0) , passing through points a, b, c, d . Reading backward from d to a , $x[3] = 0010$. The rest of the codewords can be similarly found:

$$\begin{array}{l} l : 0 \quad 1 \quad 2 \quad 3 \quad 4 \\ p[l] : 0.4 \quad 0.2 \quad 0.2 \quad 0.1 \quad 0.1 \\ x[l] : 1 \quad 01 \quad 000 \quad 0010 \quad 0011 \\ w[l] : 1 \quad 2 \quad 3 \quad 4 \quad 4 \end{array}$$

This Huffman code is optimal based upon the criteria given in [Definition 76.9](#). The entropy for this code is $\mathcal{H} = 2.12$ and the average code length is $\bar{b} = 2.20$. If fixed-length representation is used, $\bar{b} = 3.0$.

Definition 76.10 The difference between the entropy and the average code length is called the redundancy: $\mathcal{R} = \mathcal{H} - \bar{b}$.

Clearly, Huffman codes reduce the overall redundancy in the data when compared with a fixed-length encoding; see [Examples 76.1](#) and [76.2](#). However, the redundancy is completely eliminated (i.e., $\mathcal{R} = 0$)

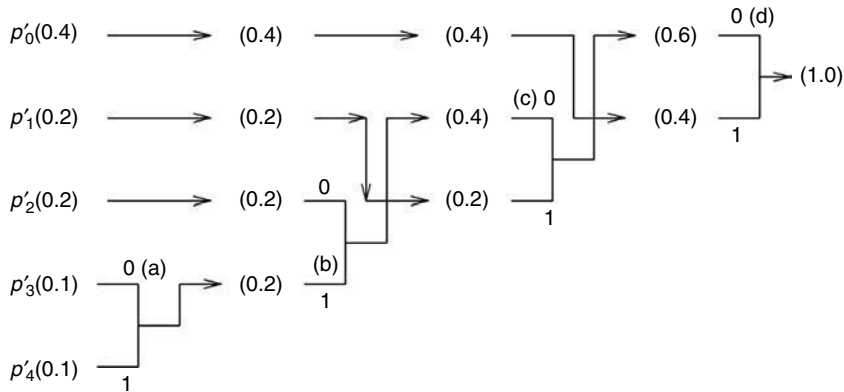

FIGURE 76.1 Generating Huffman codes using a binary tree representation.

if, and only if, the probabilities with which symbols are distributed are given by $p[l] = 2^{-k}$, $k \geq 0$, $l = 0, \dots, L - 1$. In this case, $\mathcal{H} = \bar{b}$.

Once the Huffman code has been generated, encoding the data stream is simply the task of replacing each input symbol by its Huffman coded representation. In practice, because the codewords are of variable length and do not necessarily end on *word* boundaries, the encoded data needs to be buffered before transmission or storage, so that data-word boundaries are preserved.

Huffman decoding is very straightforward. It is best understood using the binary tree representation of the encoding process. This is described in the following algorithm.

Algorithm 76.3

1. Generate the binary tree representation of the Huffman code from the encoding dictionary.
2. Upon receipt of each bit, d_n , take the left or the right branch of the tree, depending on whether d_n was 0 or 1, respectively.
3. If the node is a terminal node (i.e., it has no children), then the value it contains is the decoded value.
4. If there is more data, go back to Step 1.
5. Terminate decoding.

Implicit in this algorithm is the assumption that the dictionary used to generate the Huffman code is available to the decoder.

Example 76.3

Following Example 76.2, if the sequence 0010 was received, then the path taken from the root node to $p[3]$ would pass through d, c, b, a , (Figure 76.1) which is the decoded sequence.

A major drawback of Huffman codes is that in order to be optimal, they must be data dependent. Because the generation of the codewords depends on the probability distribution of the data, a dictionary, or look-up table, must be built for each data stream that is being encoded. Since this dictionary is required for decoding, this means that the dictionary must be transmitted along with the data. This overhead significantly affects the overall compression ratio. An adaptive version of Huffman coding that builds the Huffman tree as data is received eliminates the need for transmitting the dictionary. However, its performance is always suboptimal compared to that of non-adaptive Huffman coding for a known probability distribution, and it is significantly slower in encoding and decoding the data.

Because of the substantial overhead that can occur with Huffman coding, it is typically not used for image compression directly. However, it is an integral part of image coding schemes such as JPEG compression,⁵ where a fixed dictionary is used for all cases. This type of Huffman coding is called *canonical* Huffman coding. The idea is that given enough exposure to typical data streams, a model can be developed that is near-optimal for most data streams. The Huffman code for this model can then be used to encode all the data streams without incurring the overhead.

Because Huffman codes are built one symbol at a time, the smallest codeword length is 1 bit. So Huffman codes have a (loose) lower bound of 1 bit. In other words, for most cases, the average length of Huffman encoded data is bounded by $\bar{b} = \mathcal{H} + 1$. It can be shown that a tighter bound is $\bar{b} = \mathcal{H} + p_{max} + 0.086$, where p_{max} is the largest probability in the probability distribution.⁶ For most general cases, the input alphabet \mathcal{A}_i is large and, thus, p_{max} is fairly small. This implies that the difference between \bar{b} and \mathcal{H} is usually not very significant. This can be of significance, however, when encoding data with a *skewed* probability density distribution in the sense that one symbol occurs much more frequently than others. Because p_{max} is larger in such a case, Huffman codes would tend to be relatively inefficient. Better redundancy reduction can be achieved by encoding “blocks” of symbols: instead of using one symbol from the input data stream at a time, we use a pair of symbols, or three, or more. Encoding this requires the probability distribution of all possible combinations of the symbols in the original alphabet taken two at a time, or more, depending on the block size. For example, if the original input alphabet is $\mathcal{A}_i = \{a_1, a_2, a_3\}$, then the modified input alphabet would be $\mathcal{A}'_i = \{a_1a_1, a_1a_2, a_1a_3, a_2a_1, a_2a_2, a_2a_3, a_3a_1, a_3a_2, a_3a_3\}$. Clearly, although the average word length of a Huffman code is much closer to the entropy, the size of the alphabet, and thus the overhead, increase exponentially.

76.2.3.3 Arithmetic Coding

Because of the exponentially increasing dictionary size, block Huffman coding is not used for large alphabets. What is needed is a method that can be used to encode blocks of symbols without incurring the exponential overhead of block Huffman. Arithmetic coding⁶⁻⁹ is the name given to a set of algorithms that generate unique output “tags” — codewords — for blocks of symbols from the input data stream. The key idea to comprehend in arithmetic coding is tag generation. In practice, the tag is a *binary* fraction representation of the input data sequence.

Suppose we have an input data sequence composed of symbols from an alphabet $\mathcal{A}_i = \{a_1, a_2, \dots, a_S\}$. A typical input data stream can be $d_i = \dots s_n s_{n+1} s_{n+2} s_{n+3} \dots$, where $s_n \in \mathcal{A}_i$. The idea, then, is to generate a tag that uniquely identifies this, and only this, data stream. Because there is an infinite number of possible data streams, an infinite number of unique tags is needed. Any interval $\mathcal{I} = (\mathcal{I}_l, \mathcal{I}_h]$, where \mathcal{I}_l is the lower limit of the interval and \mathcal{I}_h is the upper limit of the interval, on the real number line provides a domain that can support this requirement. Without loss of generality, $(\mathcal{I}_l, \mathcal{I}_h] = (0, 1]$. Let $p[a_i], i = 1, \dots, S$ be the probabilities associated with the symbols $a_i, i = 1, \dots, S$, and $\mathcal{P}_i, i = 0, \dots, S$ be the cumulative probability density (CPD) defined as:

$$\begin{aligned} \mathcal{P}_0 &= 0 \\ \mathcal{P}_l &= \mathcal{P}_{l-1} + p[a_l], \quad l = 1, \dots, S - 1 \\ \mathcal{P}_S &= 1 \end{aligned}$$

where S is the total number of symbols in the alphabet. The CPD naturally partitions the unit interval $\mathcal{I} = (0, 1]$. The tag \mathcal{T} that encodes the input data stream is generated using Algorithm 76.4.

Algorithm 76.4

1. Compute the CPD for the alphabet \mathcal{A}_i and partition the $(0, 1]$ interval.
2. Read the next symbol $s_i = a_k, k \in \{1, \dots, S\}$ from the data stream and move to the interval $(\mathcal{P}_{k-1}, \mathcal{P}_k]$.

3. Partition the $(\mathcal{P}_{k-1}, \mathcal{P}_k]$ interval into S partitions using:

$$\mathcal{P}_0 = \mathcal{P}_{k-1}$$

$$\mathcal{P}_l = \mathcal{P}_{l-1} + p[a_l]/(\mathcal{P}_k - \mathcal{P}_{k-1}), \quad l = 1, \dots, S - 1$$

$$\mathcal{P}_S = \mathcal{P}_k$$

4. Go back to Step 2 and repeat until the data stream is exhausted.

5. The tag \mathcal{T} for the sequence read thus far is any point in the interval $(\mathcal{P}_{k-1}, \mathcal{P}_k]$. Typically, \mathcal{T} is the binary representation of $\mathcal{T}_v = (\mathcal{P}_k + \mathcal{P}_{k-1})/2$, where \mathcal{T}_v is the midpoint of the interval \mathcal{I} .

Example 76.4

Suppose we are encoding a sequence that contains symbols from the alphabet $\mathcal{A}_i = \{a_1, a_2, a_3\}$. Let $p_1 = 0.1$, $p_2 = 0.7$, and $p_3 = 0.2$, and $p_i = p[i]$. Then, $\mathcal{P}_0 = 0$, $\mathcal{P}_1 = 0.1$, $\mathcal{P}_2 = 0.8$, and $\mathcal{P}_3 = 1$. The data stream to be encoded is $a_2 a_3 a_2 a_1 a_1$. The progression of the encoding algorithm is shown in Table 76.2, which shows the current interval, the limits of the partitions contained in the interval, the \mathcal{T}_v associated with each partition, and the selected partition (i.e., the one associated with the received symbol). The tag \mathcal{T} is just the binary representation of the midpoint with the leading “0.” dropped.

As the length of the sequence gets longer, one needs greater precision to generate the tag. When the last symbol of the sequence a_1 was received, the upper and lower limits of the interval started to differ only in the fourth decimal place. This suggests that the next symbol to be read would cause the interval to shrink even further. This, of course, is of considerable significance for a computer implementation of the arithmetic coding algorithm. There are several modifications of the above algorithm needed for an efficient and finite precision implementation of the algorithm outlined above. The interested reader is referred to Sayood⁶ and Bell⁸ for a detailed discussion of such implementations.

If we look at Example 76.4 in terms of compression that has been achieved, then we see that a five-symbol sequence is now being represented by 11 bits. The choice of using 11 bits to represent the tag is dictated

TABLE 76.2 Arithmetic Coding

Symbol	\mathcal{I}		k	Partition \mathcal{P}			Selected Partition
	\mathcal{I}_l	\mathcal{I}_h		\mathcal{P}_{k-1}	\mathcal{P}_k	\mathcal{T}_v	
a_2	0.000000	1.000000	1	0.000000	0.100000	0.050000	
			2	0.100000	0.800000	0.450000	←

$$\mathcal{T}_v = 0.67449; \mathcal{T} = 10101100101$$

Each interval \mathcal{I} is divided into $S = 3$ partitions, $(\mathcal{P}_{k-1}, \mathcal{P}_k]$, $k = 1, 2, 3$. The midpoint of each partition provides the tag value \mathcal{T}_v at that point in the encoding process. The partition in which the CDF associated with the input symbol falls is marked with the ← symbol. This partition becomes the interval for the next iteration.

by the probability distribution of the symbols. Because the tag value had to fall *within* the final interval, a precision of (at least) 11 bits was required to represent the tag (i.e., at least 11 bit precision was needed to represent \mathcal{T}_v). The entropy of the original data is $\mathcal{H} = 1.157$ bits per symbol. For the five symbols encoded thus far, the average length is $11/5 = 2.2$. This is considerably different from the entropy, but the discrepancy can be easily explained. Of the five symbols that were encoded, three (a_3, a_1, a_1) belonged to the group that had a combined probability of occurrence of 0.3; so they occurred twice as frequently as expected. However, the redundancy would decrease as the length of the sequence increases. For a sequence of infinite length, redundancy would be arbitrarily close to 0.

Decoding arithmetic encoded data is considerably more complicated than decoding Huffman encoded data. The following algorithm describes the decoding operation:

Algorithm 76.5

1. Initialize the current interval to the unit interval (0, 1].
2. Obtain the decimal fraction representation \mathcal{T}_v of the transmitted tag \mathcal{T} .
3. Determine in which partition of the current interval \mathcal{T}_v falls by picking that partition, $(P_{i-1}, P_i]$ which contains \mathcal{T}_v .
4. Partition the current interval using the procedure outlined in the Step 4 of the encoding algorithm.
5. Using the value \mathcal{T}_v from Step 2, go to Step 3 and repeat until the sequence has been decoded.

Example 76.5

We will decode the encoded sequence 10101100101 generated in Example 76.4, using the input alphabet and associated probabilities given in the example. The decoding sequence is shown in Table 76.3. The decoded sequence is, of course, identical to the sequence that was encoded in Example 76.4.

As is evident from Examples 76.1 and 76.2 for Huffman coding and decoding, and Examples 76.4 and 76.5 for arithmetic coding and decoding, the latter requires arithmetic computations at each step, whereas the former primarily requires comparisons only. For this reason, Huffman coding tends to be

The associated symbol is decoded. The new limits of the interval \mathcal{I} are the limits of the relevant partition $(P_{i-1}, P_i]$. The decoded sequence $d_o = a_2 a_3 a_2 a_1 a_1 = d_i$.

faster than arithmetic coding, both in the encoding and the decoding process. However, the superiority of the arithmetic code in terms of the overall redundancy reduction and the compression ratio make it a better encoder. The eventual choice of which entropy coder to use is, of course, application dependent. Applications where speed is more important than the compression ratio may rely on Huffman coding in preference to arithmetic coding, and vice versa. Both methods perform adequately when used for text and image compression. In most cases, images have fairly large alphabets and unskewed probability density distributions — univariate histograms — so both methods provide similar compression ratios.

76.2.4 Dictionary-Based Techniques

Entropy coding techniques exploit the frequency of distribution of symbols in a data stream but do not make use of structures or repeating patterns that the same data stream contains. There are other coding techniques that utilize the occurrence of recurring patterns in the data to achieve better compression. If we can build a dictionary that allows us to map a block, or sequence, of symbols into a single codeword, then we can achieve considerable compression. This is the basic idea behind what is generally called *dictionary methods*. The following sections describe the *Lempel-Ziv-Welch* (LZW) compression¹ method, which is based on the seminal papers by Ziv and Lempel.^{10,11} The methods described by Ziv and Lempel are popularly known as LZ77 and LZ78, where the digits refer to the year of publication. They also form the cornerstone of several other lossless image compression methods. LZW is part of CompuServe's Graphic Interchange Format (GIF), and is supported under the Tagged Image File Format (TIFF). LZ77, LZ78, LZW, and several variants are used for the UNIX COMPRESS, GNU's GZIP, BZIP, and the PKZIP and other lossless compression utilities commonly used for data archiving.

The idea for dictionary based techniques is quite straightforward and is best explained with an illustration for text compression.

Example 76.6

Suppose we are encoding a page of text from your favorite book. The alphabet, which is the set of all the symbols that can occur in the text, has a certain probability distribution that can be exploited by a coding technique such as Huffman coding to generate efficient codewords for the symbols. However, it is also obvious that there are a number of symbol pairs, digrams, that occur together with a high probability; for example, "th," "qu," and "in." If we could encode these digrams efficiently by representing them with a single codeword, then the encoding can become more efficient than those techniques such as Huffman coding that encode the data one symbol at a time. The same procedure could be performed for trigrams — combination of three letters from the alphabet at a time (e.g., "ing" and "the") — and for larger and larger sequences of symbols from the alphabet.

So, how can we construct such a dictionary? Suppose we consider the text that we are compressing to be comprised of symbols that are independent and identically distributed (*iid*).^{*} Of course, this is not a realistic model of text, but it serves to make the point. Consider an alphabet^{**} \mathcal{A}_i that consists of just the lower-case English letters and the characters $\{\square, \dots\}$. Because there is a total of 30 symbols, a binary representation would require 5 bits per symbol, and the fact that the source is *iid* means that an entropy coding algorithms would generate equal-length codewords that are 5 bits long. Hence, \mathcal{A}_i would contain 2^5 such symbols if we assume that the size of \mathcal{A}_i is a power-of-two. Now also suppose that before encoding, we form a new alphabet \mathcal{A}'_i where the symbols in \mathcal{A}'_i are formed by by grouping symbols in \mathcal{A}_i in blocks of four. Thus, each symbol in \mathcal{A}'_i is 20 bits long. Again, with the *iid* assumption in mind, there are a

^{*}This simply means that they have an equally likely probability of occurrence and the occurrence of one does not affect the probability of occurrence of another symbol.

^{**}This material is derived substantially from Reference 6.

FIGURE 76.2 The average codeword length \bar{b} as a function of the probability of the symbol being encoded in the dictionary p .

total of 2^{20} such symbols. If we build a dictionary of all these entries, then the dictionary would require $2^{20} = 1024^2 \approx 1,000,000$ entries! Suppose we perform the following exercise:

1. Put the N most frequently occurring patterns in a look-up table (i.e., a dictionary). The in-table entries can each be represented by $\log_2 N$ bits.
2. When the pattern to be encoded is found in the dictionary, transmit a 0 followed by the look-up table index.
3. When it is not in the dictionary, send a 1 followed by the 20-bit representation.

If the probability of finding a symbol in the dictionary is p , then the average number of bits needed to encode a sequence of symbols drawn from this alphabet is:

$$\begin{aligned} \bar{b} &= p(\log_2 N + 1) + (1 - p)(20 + 1) \\ &= 21 - (20 - \log_2 N)p \end{aligned}$$

The average codeword length \bar{b} as a function of p is shown in Figure 76.2. \bar{b} is a linear, monotonically decreasing function of p . Setting $\bar{b} = 20$ and solving for p ,

$$p_1 = p = \frac{1}{(20 - \log_2 N)}$$

As can be seen from Figure 76.2, for this experiment to be successful, $\bar{b} < 20$ and $p_1 > 0.062$. In addition, for *iid* symbols, the probability of finding a sequence in the look-up table is given by

$$p_2 = p = N/2^{20} = 2^{(\log_2 N - 20)} = \frac{1}{2^{(20 - \log_2 N)}}$$

This means that $p_2 \leq 0.00195$. So, whereas the first requirement dictates that $p \geq 0.062$, the reality is that $p \leq 0.00195$, about 32 times smaller! This situation is quite unlikely to occur because of the unrealistic *iid* assumption. In most practical applications, better context-dependent dictionaries can be (manually) constructed to exploit the structure of the text being encoded — novel, C program, etc. However, the problem of poor compression performance remains to some extent because of the static nature of the dictionary. Code words are defined that may never be used in the actual encoding of the symbol sequence.

When static techniques do not work well, then adaptive (or dynamic) techniques may do better. The problem, then, is to define a method, which allows adaptive encoding of a sequence of symbols drawn from an alphabet so that it makes use of recurring patterns in the sequence. The technique that allows one to perform this operation is Lempel-Ziv-Welch (LZW) encoding.

76.2.4.1 LZW Compression

The idea for LZW encoding is conceptually quite simple. The data stream is passed through the LZW encoder one symbol at a time. The encoder maintains a dictionary of symbols, or sequence of symbols, that it has already encountered. In LZW, the dictionary is primed, or preloaded, with N entries, where $N = 128$ for text (7-bit printable ASCII characters) and $N = 256$ for images. This priming means that the first symbol read from the data stream is *always* in the dictionary.

Algorithm 76.6

1. Initialize the process by reading the first symbol α from the data stream.
2. Read the next symbol β from the data stream.
3. Set $\alpha' = \alpha$, and concatenate α and β to form $\alpha = \alpha\beta$.
4. Check if α is in the dictionary.
5. If YES, go to Step 2.
6. If NO, then add α to the dictionary, output the code for α' , set $\alpha = \beta$, and go to Step 2.
7. Repeat until the data stream is exhausted.

Thus, the dictionary for the LZW encoding is built *on-the-fly*, and exploits all the recurring patterns in the input data stream. The longer the recurring patterns, the more compact the final representation of the data stream. Example 76.7 illustrates the encoding process.

Example 76.7

Suppose we are encoding a text sequence that contains symbols derived from an alphabet $\mathcal{A}_i = \{c, e, i, h, m, n, o, r, y, ', \sqcup, ', '-\}$. The initial dictionary would then be primed with all the symbols in \mathcal{A}_i . Then the initial dictionary looks like this:

Index	1	2	3	4	5	6	7	8	9	10	11	12	13
Symbol	<i>c</i>	<i>e</i>	<i>h</i>	<i>i</i>	<i>m</i>	<i>n</i>	<i>o</i>	<i>r</i>	<i>y</i>	,	\sqcup	.	-

Suppose that the sequence we are encoding is:

chim-chimney, chim-chimney, chim-chim, cheroo

Stepping through the sequence then, when the first symbol, '*c*' is received, the encoder checks to see if it is in the dictionary; because it is, the encoder reads in the next symbol forming the sequence '*ch*'. '*ch*' is not in the dictionary so it is added to the dictionary and assigned the index value 14. The code (index) for '*c*', 1, is sent to the output. The next symbol '*i*' is read and concatenated with '*h*' to form '*hi*'. Since '*hi*' is not in the dictionary, it is added in and assigned the next index which is 15. The code for '*h*' is then sent. This process is repeated until the sequence is completely encoded. The dictionary at that point looks like this:

1.	<i>c</i>	11.	\sqcup	21.	<i>ne</i>	31.	\sqcup <i>ch</i>
2.	<i>e</i>	12.	.	22.	<i>ey</i>	32.	<i>him</i>
3.	<i>h</i>	13.	-	23.	<i>y</i> ,	33.	<i>m-ch</i>
4.	<i>i</i>	14.	<i>ch</i>	24.	, \sqcup	34.	<i>him</i> ,
5.	<i>m</i>	15.	<i>hi</i>	25.	\sqcup <i>c</i>	35.	, \sqcup <i>c</i>
6.	<i>n</i>	16.	<i>im</i>	26.	<i>chim</i>	36.	<i>che</i>
7.	<i>o</i>	17.	<i>m-</i>	27.	<i>m-c</i>	37.	<i>er</i>
8.	<i>r</i>	18.	- <i>c</i>	28.	<i>chimm</i>	38.	<i>ro</i>
9.	<i>y</i>	19.	<i>chi</i>	29.	<i>ney</i>	39.	<i>oo</i>
10.	,	20.	<i>imn</i>	30.	<i>y</i> , \sqcup		

The sequence that is transmitted is:

1 3 4 5 13 14 16 6 2 9 10 11 19 17 26 21 23 25 15 27 32 24 14 2 8 7 7

The size of the dictionary, and hence the length of the codewords, are a function of the particular implementation. Typically, fixed-length codes are used to represent the symbols: LZW gets its compression from encoding *groups of symbols* (i.e., recurring patterns) efficiently and not from representing each symbol efficiently. The size of the dictionary is usually adaptive, and adjustments are made depending upon the number of symbols that are added to the dictionary as the encoding process continues. For example, the initial length of the codewords used for GIF and TIFF versions of LZW is 9 bits; that is, the dictionary has space for 512 entries. The first 128 elements in the dictionary are set to the ASCII code values. When the number of entries in the dictionary reaches 512, its size is doubled; that is, the codewords are represented as 10-bit numbers. This happens until the codewords are 16 bits wide. Beyond that, no new entries are added to the dictionary and it becomes static. Other implementations use different adaptation schemes for dictionary size.

The LZW decoder mimics the operations of the encoder. Because the encoder adds a symbol to the directory before it uses it for encoding, the decoder only sees symbols that already have an entry in the dictionary that it is building. The decoder dictionary is primed the same way as the encoder dictionary. Thus, the index of the first symbol to be decoded is always in the dictionary when the decoding process starts. Let the first symbol to be decoded be α . Then to decode the rest of the coded data stream, use Algorithm 76.7.

Algorithm 76.7

1. Read in the next codeword from the data stream, and decode the symbol β .
2. Concatenate β to α and add to the dictionary.
3. Set $\alpha = \beta$.
4. Go to Step 1 until the encoded data stream is exhausted.

Because the dictionaries at the encoder and decoder are built identically, they are in lock-step with each other during the encoding and decoding processes. Thus, any change on the encoder side is reflected immediately on the decoder side. This makes this method valid for any alphabet, including images.

Example 76.8 demonstrates the decoding operation.

Example 76.8

For the initial dictionary given in Example 76.7, and the transmitted sequence, we need to build the dictionary at the decoder so we can decode the transmitted sequence. We will ignore, without loss of generality, the buffering required to preserve the word boundaries in an actual software implementation. The first codeword received by the encoder is 1. The first codeword is always in the dictionary, so it is decoded as 'c'. When the second codeword 3 is received, it is decoded as 'h', which is then concatenated with 'c' to form 'ch' which is then added to the dictionary, and assigned index 14. In a similar manner, the arrival of codewords 4, 5, and 13 cause the sequences *hi*, *im*, and *m-* to be added to the dictionary with indices 15, 16, and 17, respectively. At this point, the cache consists of the symbol -. When symbol 14 is received, it is decoded as 'ch'. The first character of the decoded sequence, 'c', is concatenated with the '-' forming '-c'. The dictionary is searched to see if it already contains '-c'. Since it does not, '-c' is added to the dictionary and assigned the index 18, and the symbol string *ch* is cached. The next received index is 6 which is decoded as *i*. This is concatenated with the *ch*, forming *chi*, which is then added to the dictionary. When the final encoded symbol has been received, the dictionaries at the encoder and decoder are perfectly in sync with each other, so the sequence can be encoded at one end and decoded at the other completely losslessly.

It is difficult to predict the amount of compression an LZW encoder can achieve. LZW encodes increasingly longer sequences with a single codeword if the pattern being represented by the sequence occurs

frequently in the data stream. So it can achieve “better”-than-entropy performance. Conversely, if the sequence does not contain many recurring patterns, then the performance of the LZW encoding is much poorer than entropy coding schemes. In fact, for data streams that contain few recurring patterns, the fixed-length dictionary indices can cause the data size of the compressed data stream to be larger than the original data stream! Compression ratios of between 2:1 and 4:1 are not uncommon with LZW for text; images, however, can be more difficult to compress because of the significantly larger alphabet — 8 bits per symbol as compared to 7 bits per symbol for text.

Although conceptually simple, LZW presents a number of programming challenges. The chief challenge is the search procedure used for checking if a symbol (or a sequence of symbols) already has an entry in the dictionary. Suppose after several presentations of symbols that the dictionary has grown to 8192 entries. At this point, for any incoming symbol, the entire dictionary must be searched to see if the symbol was previously encountered and thus already has an entry in the code book or dictionary. On average, this search will take ~ 4096 comparisons before finding whether there is an entry for the symbol. This represents a considerable overhead for processing. Hash tables and other search space reduction techniques are often used to speed up the process.

76.2.5 Other Methods

76.2.5.1 Prediction with Partial Matching (PPM)

A technique that has been gaining popularity recently, and which has several variations, is *prediction with partial matching* (PPM). Conceptually, PPM is relatively straightforward and provides better compression than LZW. LZW achieves its compression by representing strings of symbols by fixed-length codewords. As the length of the string increases, so does the compression efficiency. Suppose we are encoding a data stream that consists of just two alternating symbols, $d_i = \alpha\beta\alpha\beta \dots \alpha\beta \dots$. While the compression efficiency increases as each new symbol is encoded, it turns out that for this particular d_i , each dictionary entry is used only once in the output data stream. The size of each entry also increases rapidly, and, of course, each entry is represented using (semi-)fixed encoding. PPM is a symbol-wise coding scheme and gets away from these problems inherent to the LZW encoding process.

The basic idea behind PPM is this: instead of allowing the strings of symbols to grow without a limit as in LZW, there is a maximum predefined length to which the strings can grow. Several tables are kept in which *contexts* for different symbols are stored for a given context length. For instance, a table for context-2 would have all the pairs of symbols that have occurred thus far that provide a context to the current symbol. For example, a context-2 table might contain an entry ‘th’ that provides a context to symbols ‘e’, ‘i’, ‘o’, and so on. For each of these symbols, a frequency count is maintained; and based upon the number of symbols and the frequency count for each context, an arithmetic code is generated. So, to encode a symbol, use Algorithm 76.8.

Algorithm 76.8

1. Let \mathcal{N} be the maximum context length. The context tables store contexts and symbols encountered thus far that have occurred in those contexts.
2. Search in the context- \mathcal{N} table for the occurrence of the string made up of contexts in that table and the current symbol.
3. If a match is found, then that context is used to arithmetic encode the symbol.
4. Otherwise, reduce context size by 1, $\mathcal{N} = \mathcal{N} - 1$, and go to Step 2.
5. If the symbol is not found in any previously encountered context, then a predetermined default representation is used.

The maximum size of the context is algorithm definable but typically does not exceed 5.

76.2.5.2 Run-Length Coding

LZW and other dictionary-based techniques achieve compression by exploiting the structure of recurring patterns in the input sequence. However, they do not exploit the spatial structure of symbol distribution to

achieve redundancy reduction. Many images, for instance, contain regions where the intensity values are either unchanging or slowly changing. The structure of these slowly changing values is exploited by several schemes for redundancy reduction. One of the simplest of these schemes is run-length coding (RLC).

Definition 76.11 An image can be thought of as a two-dimensional matrix I where the elements of the matrix $I[i_1, i_2], i_1 = 0, \dots, N_1 - 1; i_2 = 0, \dots, N_2 - 1$ are the intensity values at each pixel location, and N_1, N_2 are the number of rows and the number of columns, respectively.

For simplicity we will assume that the images under consideration are grayscale, and $I[i_1, i_2] \in \{0, \dots, 2^\kappa - 1\}$, where κ is the number of bits per pixel. For typical images, $\kappa = 8$.

Many images have large areas of constant intensity representing an area in a scene where there are few details. An example would be the part of the image that depicts the sky in an outdoor scene. RLC exploits this spatial structure by representing *runs* of a constant value by a pair of numbers (γ_k, λ_k) , where $\gamma_k = I[i_1, i_2]$ at some $i_1 < N_1, i_2 < N_2$, and λ_k is the number of consecutive pixels that have the value γ_k .

Example 76.9

Suppose we have the following sequence that we need to encode:

3 3 3 3 4 5 5 5 6 6 7 7 7 7 7 2 2 2.

Then the RLC representation would look like:

(3, 4) (4, 1) (5, 4) (6, 2) (7, 6) (2, 3).

The initial sequence is 20 symbols long, and each symbol is represented by 3 bits, for a total of 60 bits. Suppose we let the γ_k be represented by 3 bits, and the λ_k by 5 bits, allowing for a maximum run length of 32. With this representation, each (γ_k, λ_k) pair is represented by 8 bits. Because there are a total of six pairs needed to represent the original sequence, the total number of bits required to represent the RLC'd sequence is 48 bits long. So we have succeeded in compressing the data to 80% of its original size by this simple technique.

It is difficult to predict the compression ratio that can be achieved by RLC because it is highly image dependent. Images that are amenable to RLC generally have low mean spatial detail; such images have large areas of constant, or slowly changing, intensity values. Images with high mean spatial detail can actually cause the size of the encoded image to grow larger than the size of the unencoded image. This will happen when there are very short runs of gray level values; RLC doubles the amount of data if $\lambda_k = 1, \forall k$.

RLC is an integral part of a number of different encoding techniques, although it is seldom used as a stand-alone compression engine. It is used in JPEG before the data is entropy coded. It is also used in JBIG⁶ (Joint Bi-level Imaging Group), which, among other things, provides the standard for facsimile (fax) transmission. We will not discuss the JBIG standard; however, RLC as it applies to binary ($b = 1$) images, does deserve a comment.

When the image being encoded is binary (i.e., the pixels can only take the values 0 and 1), the RLC scheme can be further simplified. In such a situation, the representation (γ_k, λ_k) can be reduced to simply λ_k if we make the assumption that the first value in the image is a 0. The RLC'd image is then an alternating sequence of runs of 0 and runs of 1.

Example 76.10

Suppose we are encoding the following segment of a binary image:

1 0 0 0 0 0 1 1 1 0 0 0 1 0 0 1 1 1.

The encoded sequence would then be:

0 1 6 3 3 1 2 3.

Note that the first element of the encoded sequence is a 0. This is because of our assumption that the first element of the image is a 0. Because the first element of the sequence we are encoding is a 1, this means there are 0 zeroes. For Example 76.10, the encoded sequence uses more bits than the original sequence. However, the RLC'd sequence can be entropy encoded, as is done in JPEG (Section 76.3.2) to gain further compression. Additionally, in actual situations where the binary version of RLC is used, the runs of numbers are substantially longer, thereby reducing the amount of data considerably. This is especially true for fax transmissions.

76.3 Lossy Compression

Thus far we have discussed lossless compression methods as they apply to text and image compression. We now move solely to the domain of image compression. Images are much more forgiving than text when it comes to compression. The human visual system (HVS) is capable of tolerating considerable loss in information before noticing a deterioration in image quality. Compression methods based on this observation adhere to the principle of *perceptual losslessness*.

Definition 76.12 An image is said to be encoded in a perceptually lossless manner if an observer does not *notice* any difference between the original image and the image decompressed from the encoded data.

There is, however, a loss in the total amount of information that is conveyed by the image. Most of this loss occurs in areas of high spatial details.

76.3.1 Data Domain Compression

As mentioned in the beginning of this chapter, lossy compression techniques can be partitioned into two distinct categories: data domain and transform domain. In this section we describe several data domain techniques.

Definition 76.13 Data domain techniques are those techniques that only operate on the unmodified input data stream, d_i .

In other words, the data is not preprocessed to make it more amenable to compression in any way.

76.3.1.1 Quantization: Pulse Code Modulation (PCM)

Pulse code modulation (PCM) is not an image compression technique *per se*; it is a way of representing the continuous, infinite precision domain of *visual scenes* by the discrete, finite precision domain of *digital images*. This process is also known as *scalar quantization* and *analog-to-digital (A/D) conversion*. The reason PCM is worth mentioning in the context of image compression is because it lies at the heart of image creation. The number of quantization levels \mathcal{L} determine the quality of the formed image: the greater the number of levels, the finer the quantization and the fewer the errors — artifacts — that are introduced into the digital image. Images with fewer artifacts are typically more amenable to compression. However, images that have been formed with coarser quantization have less need to be compressed. So the number of quantization levels used in image formation is application dependent: applications where a high degree of fidelity between the scene and image is needed dictate higher quantization levels; applications where the emphasis is on having as little data as possible without a real regard to image fidelity dictate coarser quantization.

The quantization operation is defined using the following pair of equations:

$$I'[i_1, i_2] = \mathcal{Q}_\kappa(I[i_1, i_2])$$
$$\mathcal{Q}_\kappa(x) = \left\lfloor \frac{\mathcal{L}x}{x_R} \right\rfloor$$

where $\kappa = \log_2(\mathcal{L})$ is the number of bits per pixel, x_R is the range of the variable x over which quantization is performed and is the floor function that returns the largest integer less than or equal to its argument.

FIGURE 76.3 The original image is shown on the left, the quantized version with $\kappa = 3$ bits per pixel in the middle, and the difference image on the right. One can just begin to see artifacts in the lower left corner and in the details on the leaves.

This kind of quantization is called Uniform Quantization \mathcal{U} because all the quantization intervals are of equal length. There are several other methods available for quantization, such as nonlinear quantization based on Gaussian, Laplacian, or Gamma distributions, and the Lloyd-Max optimal quantizer. However, the result of using these other techniques affects the type and amount of quantization error rather than the compression operation, which remains the same.

Definition 76.14 Quantization error \mathcal{Q}_e is defined as the difference between the original image I and its quantized representation $\mathcal{Q}_\kappa(I)$:

$$\mathcal{Q}_e[i_1, i_2] = I[i_1, i_2] - \mathcal{Q}_\kappa(I[i_1, i_2])$$

Typically, the quantization error can be modeled as having a Gaussian distribution with mean $\mu_{\mathcal{Q}_e} = 0$ and a standard deviation $\sigma_{\mathcal{Q}_e}$ that is dependent on the quantization method.

The quantization operation itself, then, is the compression operation. For instance, if we start with an image at $\kappa = 8$ bits per pixel and quantize it to $\kappa = 6$ bits per pixel, then a compression ratio of $\mathcal{C} = 1.3$ has been achieved. The modified image may also be more amenable to entropy coding techniques.

Example 76.11

Figure 76.3 shows an original image at $\kappa = 8$ bits per pixel, a quantized version at $\kappa = 3$ bits per pixel, and the difference between by the two obtained by subtracting the quantized version from the original. The entropy is $\mathcal{H} = 7.435$ for the original image, and $\mathcal{H} = 2.476$ for the quantized version, giving a compression ratio $\mathcal{C} = 3$.

The difference between the original (left) and the quantized version (middle) is difficult to see with the naked eye. However, looking at the difference image (right), it is easy to see that the quantized version is actually substantially different from the original. The differences are primarily in areas of high spatial detail.

76.3.1.2 Differential Pulse Code Modulation (DPCM)

As a compression technique, PCM exploits neither the spatial structure in an image nor the frequency distribution of its symbols. If, however, one examines the spatial structure of the image (i.e., the regional distribution of intensity values), then one can exploit this structure to achieve better compression. For instance, in regions of slowly changing, or unchanging, intensity values, redundancy can be reduced if the gray levels are represented *relative* to a constant gray scale rather than absolutely. An example elucidates this concept.

Example 76.12

Suppose we have an initial data sequence $d_i = 5\ 5\ 4\ 4\ 6\ 6\ 4\ 3$. We would need 3 bits per symbol to represent these (absolute) values for fixed-length encoding. However, suppose we subtract 5 from each element,

giving a new sequence $d'_i = 0\ 0\ -1\ -1\ 1\ 1\ -1\ 2$. The range of this new sequence is 3; thus, this new sequence can be represented by 2 bits per symbol. Given the subtrahend, 5 in this case, we can completely recover the original sequence by adding the subtrahend back into the new sequence.

Coding schemes that make use of this type of strategy are called differential pulse code modulation (DPCM) schemes. In general, however, instead of using a constant subtrahend for the entire sequence, differences between neighboring elements are generated. Using this method on the sequence shown in Example 76.12 results in $d'_i = 5\ 0\ 1\ 0\ -2\ 0\ 2\ 1$, where the new values $x_d[i], i = 1, \dots, N$, N is the length of the sequence, are obtained from the elements $x[i]$ of the original sequence by:

$$x_d[i] = x[i] - x[i + 1]; \quad i \geq 0; \quad x[0] = 0.$$

It might seem that this has not resulted in a gain in redundancy reduction because the dynamic range has increased to 7. However, if the first symbol is sent at the fixed-length representation of the original sequence, then the range of the remaining sequence is 4, which can be represented by 2 bits per symbol. For the sequence in Example 76.12, the second method does not seem to provide much of an improvement over the first method. In general, however, the second method is more effective, especially near edges in an image, where the intensity values change rapidly.

76.3.1.3 Predictive Differential Pulse Code Modulation (DPCM)

The method outlined in the previous section can also be described as a *predictive* DPCM (PDPCM) method. When we transmit the differences between neighboring samples, we are implicitly predicting the value of the current sample in terms of its predecessor. This is *nearest neighbor* prediction. If the original value of the current symbol is $x[i]$ and the predicted value is p , then the value being encoded (x_d) is the difference between the actual value of the symbol and the predicted value, which in this case is simply equal to the previous symbol $x[i - 1]$. Thus,

$$\begin{aligned} x[0] &= x[0] \\ x_d[i] &= x[i - 1] - x[i]; \quad 0 < i < N \end{aligned}$$

which is essentially the same expression shown above for DPCM. PDPCM makes use of the spatial structure of the gray-scale distribution because it is most effective when neighboring pixel values are either close to each other or are the same.

There are several different ways in which the value of the current sample can be predicted, based upon previous samples. We have listed the simplest method above, where the predicted value of the current sample is equal to the previous sample value. More accurate estimates of the current sample value can be obtained using:

$$p = \rho_x x[i - 1]$$

where ρ is the correlation coefficient of the image and measures the similarity between neighboring samples. The higher the correlation, the more similar the neighboring samples. Other prediction schemes use more than just the previous sample for predicting the current sample value to form even finer estimates of the current sample. In imaging applications, the current sample value is typically predicted based upon its three nearest past neighbors:

$$\begin{aligned} I_d[i_1, i_2] &= I[i_1, i_2] - p[i_1, i_2] \\ p[i_1, i_2] &= \rho_{xx} I[i_1, i_2 - 1] + \rho_{yy} I[i_1 - 1, i_2] + \rho_{xy} I[i_1 - 1, i_2 - 1] \end{aligned}$$

where ρ_{xx} , ρ_{yy} , and ρ_{xy} are the horizontal, vertical, and diagonal correlation coefficients, respectively. Instead of computing these coefficients, several implementations assume $\rho_{xx} = \rho_{yy} = 1$ and $\rho_{xy} = -1$. The lossless compression mode in JPEG uses PDPCM for encoding. Algorithm 76.9 outlines the procedure for PDPCM encoding an $N_1 \times N_2$ image I .

Algorithm 76.9

1. Compute the prediction image, p using

$$\begin{aligned} p[0, i_2] &= p[i_1, 0] = 0 \\ p[i_1, i_2] &= I[i_1, i_2] - (I[i_1 - 1, i_2] + I[i_1, i_2 - 1] - I[i_1 - 1, i_2 - 1]) \\ &\text{where } i_1 = 1, \dots, N_1 - 1 \quad \text{and} \quad i_2 = 1, \dots, N_2 - 1 \end{aligned}$$

The first equation ensures that first row and first column of I_d is the same as the first row and column of I . These need to be transmitted with their original values to initialize the decoding process.

2. Form the difference image I_d :

$$I_d[i_1, i_2] = I[i_1, i_2] - p[i_1, i_2] \quad i_1 = 0, \dots, N_1 - 1, i_2 = 0, \dots, N_2 - 1$$

The choice of unit magnitude weighting factors ensures that I_d has integer values provided that I has integer values.

3. Quantize I_d and transmit the result, $\mathcal{Q}_\kappa[I_d]$, where $\mathcal{Q}_\kappa[\cdot]$ is the quantization process described previously.

Algorithm 76.10 outlines the procedure for decoding a PDPCM encoded image.

Algorithm 76.10

1. The first row and column of the decoded image I' are the first row and column of the received image $\mathcal{Q}_\kappa[I_d]$. Dequantize the rest of the received image to form the difference image I'_d .
2. Predict $I'[i_1, i_2]$ based upon

$$\begin{aligned} I'[i_1, i_2] &= I_d[i_1, i_2] + (I_d[i_1 - 1, i_2] + I_d[i_1, i_2 - 1] - I_d[i_1 - 1, i_2 - 1]) \\ &\quad i_1 = 1, \dots, N_1 - 1, i_2 = 1, \dots, N_2 - 1, \end{aligned}$$

where the expression in parentheses is the predicted value of $I'[i_1, i_2]$.

We have glossed over two significant issues in the above algorithm description for PDPCM encoding and decoding: how localized is the error propagation, and how is the quantization performed? We address these issues in the next two comments.

Error propagation in PDPCM is cumulative. Only the first row and the first column of a (P)DPCM encoded image are transmitted without processing. Recall that the difference image is quantized before transmission. Depending on the severity of the quantization (i.e., the number of levels used to represent the differenced image), there will be an error when the difference image is dequantized. In other words:

$$Q[I_d[i_1, i_2]] - I_d[i_1, i_2] = e_Q$$

where e_Q is the quantization error. As can be seen from Algorithm 76.10, each predicted value after $p[1, 1]$ depends on values that have been reconstructed from previously reconstructed values. If there is a significant error in any of these reconstructed values, then this error will propagate to all the reconstruction values henceforth. This error accumulates with each step and the $p[i_1, i_2]$ are going to be poorer and poorer predictions of the original data. Certainly, we can perform (near)-perfect reconstruction if we have sufficient quantization resolution. However, the reason for performing DPCM and PDPCM is to make further gains in redundancy reduction. Thus, the number of quantization levels used to represent the encoded image *must* be less than the number of quantization levels used to represent the original image. If the probability density function of the error space is examined, then it is seen to closely follow the

Laplacian distribution $e^{-\alpha|x|}$. This means that the errors are clustered fairly tightly around a zero mean, and there are only a few outliers. This, of course, is exactly the behavior we hope to exploit. If the error function indeed clusters around the center, then the dynamic range within a few standard deviations from the mean can be well represented by a few quantization levels.

The magnitude of the outliers is really the major issue that needs to be resolved. For an \mathcal{L} -level quantization, the range of the error image is $2\mathcal{L}$. Thus, by using the differencing technique, we can potentially double the range we need to represent, at the same time that we need to reduce the number of quantization levels used to represent the data. The outliers in the error image typically occur near the edge locations in an image: the more *strong* edges there are in an image, the greater the number of these outliers. So how does one deal with these outliers? There is no simple answer! Several approaches could be adopted, each with its associated trade-offs:

1. Use \mathcal{Q}_k with $x_R = 2(\mathcal{L}/8)$. This would provide good results for all the values that fall within the specified range. However, this approach would work only if there were *very* few outliers, and hence only very few points where the residual error can increase.
2. Use the method outlined in Step 1, except use the following method to deal with the outliers. Instead of using a single codeword to represent the magnitude of the outliers, use a sequence of codewords. For example, if $\mathcal{L} = 256$ for the original image and the difference image is being encoded with $\mathcal{L}' = 64$ gray levels, then quantize all values of the difference image between ± 31 at 6 bits per symbol. If, however, $d[i_1, i_2] > 31$, say 120, then send 111111 as an escape and follow it by the 9-bit representation of the difference. The values between $\pm \mathcal{L}/8$ are mapped to $[0, \mathcal{L}/4]$, and conversely. A similar operation is performed for the 9-bit representation. This will result in (nearly) lossless reconstruction. However, the redundancy reduction is going to be reduced if there are a number of outliers.

76.3.1.4 Vector Quantization

The final technique that we will describe, very briefly, is vector quantization (VQ). In PCM, or scalar quantization, the data stream is quantized one symbol at a time, hence the name scalar quantization. The VQ process is conceptually very similar to PCM except that in VQ each data element is made of several elements from the input data stream. The idea, then, is to construct a dictionary of *prototype vectors* and encode the data using this dictionary. The encoding process is in Algorithm 76.11.

Algorithm 76.11

1. Construct a dictionary \mathcal{D} of size N , where each entry \mathcal{D}_i is a prototype vector of length L symbols.
2. Partition the input data stream into input vectors $v_k, k \geq 1$.
3. For the k th input vector v_k , find the \mathcal{D}_i such that some metric between v_k and \mathcal{D}_i is minimized. A typical metric is the normalized distance d between the vectors:

$$d = \frac{\|v_k - \mathcal{D}_i\|^2}{\|\mathcal{D}_i\|^2}$$

where $\|v\|^2 = \sum_{j=0}^{L-1} v_j^2$, for some vector v of length L .

4. Encode v_k by the index i of \mathcal{D}_i that minimizes d .

Hence, each vector of length L symbol is represented by a single index i . The compression ratio is $\mathcal{C} = Ll_i/l$, where l_i is the representation length of each symbol in \mathcal{D}_i and $l = \log_2 N$. So, the smaller the size of the dictionary, the larger the compression ratio \mathcal{C} . However, the smaller the size of the dictionary, the larger the distortion error between the original and the decompressed data. Thus, there are two competing requirements — high compression ratio and low distortion error — both of which cannot be satisfied simultaneously.

Decoding VQ is very straightforward. The transmitted index i is used to retrieve the entry \mathcal{D}_i from the dictionary \mathcal{D} . The decompressed vector is $v'_k = \mathcal{D}_i$. Thus, the larger the d , the less similar is the decompressed vector v'_k to v_k . This, of course, implies that the dictionary used to encode the data needs to be available to the decoder as well. One can transmit this dictionary as overhead, agree upon a predefined dictionary, or come up with adaptive methods to generate the dictionary on-the-fly. Different implementations use different methods to make the dictionary available to the encoder and the decoder.

Whereas it is easy to see that fewer dictionary entries lead to a better compression ratio, it may be not as obvious why smaller dictionary sizes lead to more distortion. The reason is, however, quite straightforward: With fewer dictionary entries, the distance d between the input vector v_k and the dictionary entry \mathcal{D}_i is, on average, larger. Because \mathcal{D}_i is the same as v'_k , the reconstructed data vector, the distortion error between v_k and v'_k is the same as d . Hence, smaller d leads to less distortion and better image quality.

We have completely skipped describing one of the aspects of VQ that is essential to the process: the construction of the dictionary. The basic idea is to derive N representative features from the data space. This can be done by taking all length L vectors v_k in the data space and then computing the mean vector μ_k . The vector μ_k can then be perturbed in a variety of ways to form two other vectors $\mu'_k = \mu_k + e$ and $\mu''_k = \mu_k - e$, where e is a perturbation vector. These two vectors can be similarly perturbed to form additional vectors, until the desired number of representative vectors has been generated. These representative vectors are then the entries of the dictionary \mathcal{D} . There are several other techniques used to generate the dictionary entries but we do not discuss them here. The interested reader is referred to References 6 and 12 for additional information.

VQ is a nonsymmetrical process in that whereas it takes computation of metrics and comparisons to find the encoding index, the decoding only requires an entry to be retrieved from the dictionary \mathcal{D} . Hence, VQ is slow on encoding and fast on decoding, a fact that is useful in practical implementations where more processor power is typically available for preparing the data for transmission than is available for decoding the compressed data. An example could be transmission of television signals where the transmitters (e.g., studios) can use high-powered computers to encode the data fast, but the receivers (e.g., televisions) do not have similar processor capacity and thus need to have relatively simple decoding techniques in order to process the data in real-time. There are several flavors of VQ that are now being used in practical systems. The interested reader is referred to Gersho and Gray¹² for a complete treatment of VQ.

76.3.2 Transform Domain Compression

In many cases, the original data d_i can be modified by the application of a transform \mathcal{T} resulting in a new data stream $d_{\mathcal{T}} = \mathcal{T}[d_i]$ that is more amenable to compression. The transform \mathcal{T} is usually reversible, that is, there exists an inverse transform \mathcal{T}^{-1} such that $\mathcal{T}^{-1}[\mathcal{T}[d_i]] = d_i$. The transformed data contains all the information that was in the original data, although it is a completely different representation. One can exploit this representation to produce compressed data that, when uncompressed, is perceptually lossless. The degree of difference between the original and decompressed data depends on the degree of compression. Typically, the higher the compression, the higher the difference between the original and the decompressed image (Figure 76.4). In fact, the assumption about the compression being perceptually lossless quickly loses its validity as the compression ratios increase.

Example 76.13: JPEG

JPEG — Joint Photographic Experts Group — is the *de facto* image compression standard for still images.⁵ It is based on the discrete cosine transform (described later) and attempts to incorporate the contrast sensitivity of the human visual response into the quantization maps used to quantize the luminance and the chrominance channels. It uses the $Y C_b C_r$ color space and quantizes the chrominance channels (C_b and C_r) at twice as coarse a resolution as it does the luminance component Y .

Figure 76.5 shows the contrast sensitivity of the HVS to different wavelengths as a function of the spatial frequency. Luminance sensitivity peaks between 2 and 5 cycles/degree. Sensitivity is greatly diminished for frequencies greater than 100 cycles/degree. Thus, intensity changes in objects of the size of about 0.2 cm,

FIGURE 76.4 The figure shows an original image (left image) that has been compressed in a perceptually lossless manner using JPEG (center image $C \approx 4$) and a compressed image also compressed using JPEG that exhibits obvious artifacts (right image $C \approx 20$).

FIGURE 76.5 The contrast sensitivity (CS) of the human visual system as a function of the spatial frequency. The HVS is less sensitive to changes in color than in changes in luminance.

viewed from a distance of 1 m, can just be resolved; intensity changes in smaller objects cannot be resolved. Similarly, details finer than 0.01 cm cannot be resolved.

Chrominance (red-green; blue-yellow) response is coarser and peaks at about 1 cycle/degree. It becomes negligible at about 12 cycles/degree, which translates into an object of 0.07 cm viewed from a distance of 1 m. Hence, chrominance information can be more coarsely quantized than luminance information because the HVS is less sensitive to it. This is the justification for coarsely quantizing the chrominance maps in the JPEG compression algorithm.

At the heart of JPEG is the Discrete Cosine Transform (DCT).^{13–15} DCT is one of many transforms used to convert the data domain representation into a form that is more amenable to compression. The best of such transforms is the Principal Component Transform (PCT),^{15–17} which is also known as the Karhunen-Loeve Transform (KLT) or Hotelling Transform. The PCT is an optimal transform in the sense that it completely decorrelates the input data. In other words, all the information in the data domain representation gets transformed to a diagonal matrix representation in the transform domain, where the diagonal elements represent the standard deviation for the coefficient in that location. However, although the PCT is the optimal decorrelator, it is computationally intensive and image dependent. That is, the PCT must be computed afresh for each new data stream; it does not have a canonical, closed form that allows pre-computation and thus efficient implementation. The DCT decorrelates data almost as efficiently as

the PCT for those data sets that have a high inter-coefficient correlation. And because the DCT has a fast implementation and the actual transform is not data dependent, it is preferred over the PCT for practical implementations.

The fast implementation of the DCT typically relies on the Fast Fourier Transform (FFT)¹⁸⁻²¹ implementation of the Discrete Fourier Transform (DFT).²²⁻²⁴ The DFT is a way of representing discrete data in terms of its spectral components.

Definition 76.15 The Discrete Fourier Transform (DFT) $\hat{X}[v]$ of the discrete data sequence $x[n]$ is given by:

$$\hat{X}[v] = \frac{1}{N} \sum_{n=0}^{N-1} x[n] \exp[-i2\pi vn/N], \quad v = 0, \dots, N-1$$

$$x[n] = \sum_{v=0}^{N-1} \hat{X}[v] \exp[i2\pi vn/N], \quad n = 0, \dots, N-1.$$

where the second equation gives the Inverse DFT (IDFT).

The DFT transforms the data stream into its frequency domain representation given in terms of sums of sinusoids. High-frequency terms correspond with fine detail in the scene and the low-frequency terms with smoothness. The $\hat{X}[0]$ terms gives the mean value μ of the data stream. The DFT is an inherently complex transform, which means that each coefficient comprises a real and imaginary part. This is primarily the reason why the DFT itself is not used for compression; the conversion from data to transform domain doubles the size of the data. The DFT is also very sensitive to small changes in phase: small phase changes translate into large quality changes.

The two-dimensional (2-D) DFT is given by:

$$\hat{X}[v_1, v_2] = \frac{1}{N_1 N_2} \sum_{n_1=0}^{N_1-1} \sum_{n_2=0}^{N_2-1} x[n_1, n_2] \exp[-i2\pi(v_1 n_1/N_1 + v_2 n_2/N_2)],$$

$$v_1 = 0, \dots, N_1 - 1, v_2 = 0, \dots, N_2 - 1.$$

2-D DFT is a separable transform, which means that it can be implemented by first applying the 1-D DFT to the columns of the 2-D matrix x and then applying the 1-D transform to the rows of the result.^{25,26}

Definition 76.16 The 2-D forward and reverse DCT is defined as:

$$\hat{C}[v_1, v_2] = \alpha[v_1, v_2] \sum_{i_1=0}^{N_1-1} \sum_{i_2=0}^{N_2-1} I[i_1, i_2] \cos\left[\frac{(2i_1+1)v_1\pi}{2N_1}\right] \cos\left[\frac{(2i_2+1)v_2\pi}{2N_2}\right]$$

$$I[i_1, i_2] = \sum_{v_1=0}^{N_1-1} \sum_{v_2=0}^{N_2-1} \alpha(v_1, v_2) C[v_1, v_2] \cos\left[\frac{(2i_1+1)v_1\pi}{2N_1}\right] \cos\left[\frac{(2i_2+1)v_2\pi}{2N_2}\right]$$

where

$$\alpha[v_1, v_2] = \begin{cases} \sqrt{\frac{1}{N_1 N_2}} & \text{for } v_1 = v_2 = 0 \\ \frac{2}{\sqrt{N_1 N_2}} & \text{for } v_1 \neq 0, v_2 = 0 \text{ or } v_2 \neq 0, v_1 = 0 \\ \sqrt{\frac{2}{N_1 N_2}} & \text{else} \end{cases}$$

\hat{C} is the $N_1 \times N_2$ DCT of the $N_1 \times N_2$ image I , and $[v_1, v_2]$ are the (discrete) spatial frequency variables.

FIGURE 76.6 Generating the length- $2N$ sequence from the length- N sequence.

It is a common misconception that the DCT is the real part of the DFT. It is not! However, there is a very nice (mathematical) relationship between the two transforms. Consider a 1-D sequence $f[n]$, $n = 0 \dots, N - 1$, where f can be real or integer valued. Construct a new sequence f' such that

$$f'[n] = \begin{cases} f[n] & n = 0, \dots, N - 1 \\ f[2N - n - 1] & n = N, \dots, 2N - 1 \end{cases}$$

So, f' is formed by reflecting f about the imaginary line halfway between $k = N - 1$ and $k = N$. Figure 76.6 shows an instance of this process, with $N = 21$. Taking the Fourier transform of f'

$$\hat{F}[v] = \frac{1}{2N} \sum_{n=0}^{2N-1} f'[n] \exp[-(i2\pi v n)/2N]$$

Using the definition of f' from above and substituting,

$$\begin{aligned} \hat{F}[v] &= \frac{1}{2N} \left[\sum_{n=0}^{N-1} f'[n] \exp[-(i2\pi v n)/2N] + \sum_{n=N}^{2N-1} f'[n] \exp[-(i2\pi v n)/2N] \right] \\ &= \frac{1}{2N} \left[\sum_{n=0}^{N-1} f[n] \exp[-(i2\pi v n)/2N] + \sum_{n'=0}^{N-1} f[n'] \exp[-(i2\pi v (2N - n' - 1))/2N] \right] \\ &= \frac{1}{2N} \left[\sum_{n=0}^{N-1} f[n] \exp[-(i2\pi v n)/2N] + \sum_{n'=0}^{N-1} f[n'] \exp[(i2\pi v (n' + 1))/2N] \right] \\ &= \frac{1}{2N} \sum_{n=0}^{N-1} f[n] (\exp[-(i2\pi v n)/2N] + \exp[(i2\pi v (n + 1))/2N]) \end{aligned}$$

Multiplying both sides of the equation by $\exp[-(i2\pi v)/2N]$,

$$\begin{aligned} \hat{F}[v] \exp[-(i2\pi v)/2N] &= \frac{1}{2N} \sum_{n=0}^{N-1} f[n] \left(\exp \left[-\frac{i\pi v(2n+1)}{2N} \right] + \exp \left[\frac{i\pi v(2n+1)}{2N} \right] \right) \\ &= \frac{2}{2N} \sum_{n=0}^{N-1} f[n] \cos \left[\frac{(2n+1)v\pi}{2N} \right]. \end{aligned}$$

The expression on the right-hand side of the above equation should be recognizable as 1-D DCT, without the normalization factor α . The inverse kernel for the DCT is the same as the forward kernel. In other words, a DCT'd sequence passed back through the DCT returns the original sequence.

DCT is typically not applied to the image as a whole. Instead, the image is first broken up into non-overlapping square blocks*, and the DCT is performed on each block. At this point, the image has not been compressed; it has just been transformed to the DCT space. To achieve perceptually lossless compression, JPEG performs a series of operations on each block of the image.

Algorithm 76.12

1. Level shift the image by subtracting 2^{b-1} from each of its pixels, where $b = \log_2 L$ and L is the number of gray levels that a pixel in the image can take. This minimizes the variation in the DC component from block to block. The only impact this has on the DCT coefficients is to change the value of $C[0, 0]$.
2. Partition the image into $\lambda = N_1 N_2 / B^2$ non-overlapping $B \times B$ blocks p_l . Then, $I = \bigcup p_l, l = 0, \dots, \lambda - 1$.
3. Perform the 2-D DCT given in Definition 76.16 on each block, $p_l, l = 0, \dots, \lambda - 1$.
4. Quantize the DCT coefficients $\hat{C}[v_1, v_2]$ using threshold coding:

$$Q[v_1, v_2] = \left\lfloor \frac{\hat{C}[v_1, v_2]}{Z[v_1, v_2]} + 0.5 \right\rfloor$$

where $Q[v_1, v_2]$ are the quantized DCT coefficients and the $Z[v_1, v_2]$ values are obtained from a quantization map.** The quantization maps are a function of the quality factor, and are derived from a pre-defined base representation. A typical quantization map is shown below.

$$Z[v_1, v_2] = \begin{bmatrix} 16 & 11 & 10 & 16 & 24 & 40 & 51 & 61 \\ 12 & 12 & 14 & 19 & 26 & 58 & 60 & 55 \\ 14 & 13 & 16 & 24 & 40 & 57 & 69 & 56 \\ 14 & 17 & 22 & 29 & 51 & 87 & 80 & 62 \\ 18 & 22 & 37 & 56 & 68 & 109 & 113 & 92 \\ 24 & 35 & 55 & 64 & 81 & 104 & 113 & 92 \\ 49 & 64 & 78 & 87 & 103 & 121 & 120 & 101 \\ 72 & 92 & 95 & 98 & 112 & 100 & 103 & 99 \end{bmatrix}$$

5. Zigzag scan each block as shown in Figure 76.7. Because the zigzag scan starts at the $Q[0, 1]$ coefficient, it includes just the AC coefficients of the transformed block. The higher threshold values in the quantization map, Z , coincide with higher frequencies. This gives rise to regions of zero values. Raster scanning these regions from right-to-left results in sequence that contain runs of zeros interspersed with other values. Zigzag scanning the same block tends to clump the zeroes together without the interspersed values. These long(er) runs of zeroes can be run-length encoded more efficiently. Other scanning schemes such as Peano scanning^{27,28} also provide regional clustering but have not been adopted by the JPEG standard.
6. The $\hat{C}[0, 0]$ coefficient is the scaled DC component (mean) of each block and typically has the largest magnitude in the block. JPEG encodes the AC and DC coefficients differently.

The DCT'd image has λ non-overlapping blocks, so there are a total of λ DC coefficients that need to be encoded. If a sequence $d[k], k = 0, \dots, \lambda - 1$ of these DC components is formed, then

*A variation of this scheme for overlapping blocks is called the Lapped Orthogonal Transform.

**Mathematically, $\lfloor -|x| \rfloor = -(\lfloor |x| \rfloor + 1)$ and not $\lceil -|x| \rceil$. For example, $\lfloor -2.3 \rfloor = -3$ and not -2 .

TABLE 76.4 Difference Categories for Canonical Huffman Encoding

Range	DC Difference Category	AC Category

FIGURE 76.7 Zigzag scan for JPEG coefficient quantization.

we can use nearest neighbor DPCM to form a sequence with reduced redundancy, that encodes the difference between adjacent DC coefficients. The difference value Δ is encoded based upon the category in which it falls, and its position within that category. The categories are disjoint (i.e., each category represents differences that are not contained in any other category). The union of the categories, however, completely covers the dynamic range between $\mp 2^{15} - 1$. The categories and the corresponding difference values are tabulated in Table 76.4. For a difference value Δ , the category c is given by $c = \lfloor \log_2 |\Delta| \rfloor + 1$ in hexadecimal notation. The location within c is encoded as b_Δ , the binary representation of $|\Delta|$, if Δ is positive, or by $\overline{b_\Delta}$,* if Δ is negative. The canonical Huffman codes for encoding the categories are specified in Table 76.5. As an example, for a difference of 5, $c = \lfloor 2.32 \rfloor + 1 = 3$, which is encoded as **00** from Table 76.5. The location within c is given by $d = 5$ is given by **101**, the binary representation of 5. Hence, the codeword representing $d = 5$ is **00 101**. For a difference of -5 , the codeword would be **00 010**.

7. The AC coefficients are encoded using Table 76.6. The value of the coefficient is used to obtain the category C to which the coefficient belongs, and the number Z of zero-valued coefficients

* \overline{b} is the binary complement of b . For example, if $b = 0101$, then $\overline{b} = 1010$.

TABLE 76.5 Canonical Huffman Codes for Difference Categories

Category	Base Code	Length of Codeword	Category	Base Code	Length of Codeword
0	010	3	6	1110	10
1	011	4	7	11110	12
2	100	5	8	111110	14
3	00	5	9	1111110	16

preceding the non-zero coefficient to be coded form a pointer *Z/C* to a specific Huffman code as shown (partially) in Table 76.6.* This is done because threshold coding followed by zigzag scanning usually produces few non-zero values separated by runs of zeros. If we encode *only* these non-zero values and indicate how many zeros there were between the current and the previous non-zero value, we can code the scan very efficiently.

The symbols **EOB** and **ZRL** have special meaning: EOB (end-of-block) indicates that the rest of the coefficients in the block are 0, and ZRL indicates that a run of 15 zeros was encountered.

- Once all the coefficients have been encoded, they can be transmitted or archived.

Example 76.14

As an example of the JPEG encoding process, consider the fragment of an image,

$$I[i_1, i_2] = \begin{bmatrix} 36 & 54 & 41 & 64 & 59 & 47 & 44 & 48 \\ 48 & 41 & 66 & 33 & 44 & 56 & 65 & 89 \\ 50 & 70 & 45 & 52 & 78 & 84 & 108 & 120 \\ 46 & 41 & 56 & 59 & 53 & 105 & 91 & 85 \\ 44 & 59 & 49 & 47 & 48 & 53 & 78 & 44 \\ 52 & 44 & 47 & 64 & 28 & 49 & 54 & 48 \\ 51 & 51 & 61 & 84 & 73 & 77 & 62 & 37 \\ 40 & 37 & 46 & 69 & 115 & 93 & 55 & 67 \end{bmatrix}.$$

According to step 0 of the algorithm, we need to subtract 2^{b-1} from each pixel. Because $b = 8$, this means subtracting 128 from each pixel. The only impact this operation has is to change the value of $\hat{C}[0, 0]$ from

*For a complete table of these coefficients see, for instance, *Digital Image Processing*, R.C. Gonzalez and R.E. Woods, Addison-Wesley Publishers, 1996, pp. 398–399.

$\bar{\mu}_l \sqrt{B^2}$ to $(\bar{\mu}_l - 128) \sqrt{B^2}$, where $\bar{\mu}_l$ is the mean of the square block of side B . The output of this operation is not shown. The DCT of the mean adjusted fragment is:

$$\hat{C}[v_1, v_2] = \begin{bmatrix} -548.50 & -69.09 & -12.04 & 9.46 & -6.75 & 1.85 & -0.97 & -8.16 \\ -4.67 & -16.13 & 46.03 & -24.11 & -8.22 & -8.56 & -1.77 & 3.88 \\ -10.74 & 16.01 & -39.52 & 3.26 & 29.80 & -21.94 & 3.91 & 6.35 \\ -66.61 & 61.05 & -5.74 & -15.56 & -5.18 & 24.97 & -11.88 & -10.70 \\ -7.25 & -3.90 & -26.13 & 16.74 & 0.50 & -8.36 & -2.98 & -0.77 \\ 21.07 & -1.28 & -19.94 & 8.90 & -1.73 & 9.62 & -2.52 & -19.38 \\ 6.07 & -11.38 & 7.41 & 1.05 & 14.45 & -11.10 & -15.48 & -8.00 \\ 13.57 & 5.81 & -4.26 & 4.49 & -2.33 & -10.64 & -30.98 & 8.07 \end{bmatrix}$$

Performing the threshold coding results in the quantized matrix:

$$Q[v_1, v_2] = \begin{bmatrix} -34 & -6 & -1 & 1 & 0 & 0 & 0 & 0 \\ 0 & -1 & 3 & -1 & 0 & 0 & 0 & 0 \\ -1 & 1 & -2 & 0 & 1 & 0 & 0 & 0 \\ -5 & 4 & 0 & -1 & 0 & 0 & 0 & 0 \\ 0 & 0 & -1 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}$$

Because we are dealing with a single block here, the DC coefficient vector consists of a single element, -34 , which belongs to category 6. So it is represented by (see Step 5 of algorithm 76.1) **1110 011101** (category-code position-in-category).

Zigzag scanning the AC coefficients produces:

$$[-6 \ 0 \ -1 \ -1 \ -1 \ 1 \ 3 \ 1 \ -5 \ 0 \ 4 \ -2 \ -1 \ 0 \ 0 \ 0 \ 0 \ 0 \ 1 \ 0 \ 0 \ -1 \ -1 \ 1 \ 0 \ \dots \ 0]$$

The first element of the scan is -6 , which belongs to category 3. The run of zeros preceding it is of length 0. So the code we use to represent -6 is the base code for $Z/C = 0/3$ to which is appended the code representing the position of -6 in category 3. This results in -6 being represented by **100 001**. The second non-zero coefficient in the scan is -1 , which is preceded by 1 zero. Hence, it is encoded as **1100 0**— $Z/C = 1/1$. Encoding the rest of the non-zero elements in the sequence produces:

$$\begin{array}{cccccccc} -1 & -1 & 1 & 3 & 1 & -5 & 4 & -2 & -1 \\ 00\ 0 & 00\ 0 & 00\ 1 & 01\ 11 & 00\ 1 & 100\ 010 & 1111001\ 100 & 01\ 01 & 00\ 0 \\ 1 & -1 & -1 & 1 & \mathbf{EOB} & & & & \\ 1111011\ 1 & 11011\ 0 & 00\ 0 & 00\ 1 & 1010 & & & & \end{array}$$

So, the total number of bits used to represent the 64 coefficients is:

$$6 + 5 + 3 + 3 + 3 + 4 + 3 + 6 + 10 + 4 + 3 + 8 + 6 + 3 + 3 + 4 = 74$$

which gives a compression ratio of $\mathcal{C} = (8)(64)/(74) = 7.92$ or 1.16 bits per pixel as opposed to 8 bits per pixel.

JPEG decompression is relatively straightforward when compared with JPEG compression. In this sense, the JPEG compression algorithm is asymmetric because it takes longer to compress the data than to decompress it.

Algorithm 76.13 To decompress JPEG compressed data we essentially reverse Algorithm 76.12.

1. The first step in the decompression process is to recreate the thresholded coefficients $Q[v_1, v_2]$. This is easily done via a lookup table because the JPEG compressed input sequence is Huffman coded.
2. The thresholded coefficients then need to be turned into the DCT coefficients $\hat{C}'[v_1, v_2]$ by applying

$$\hat{C}'[v_1, v_2] = Q[v_1, v_2]Z[v_1, v_2].$$

3. Performing the inverse DCT on \hat{C}' gives I' , which is the reconstructed representation of I after lossy JPEG compression.

Example 76.15

Continuing from Example 76.14, we first use the lookup table to generate the threshold coded image Q , which is exactly the same Q shown in Example 76.14. It is reproduced here for convenience:

$$Q[v_1, v_2] = \begin{bmatrix} -34 & -6 & -1 & 1 & 0 & 0 & 0 & 0 \\ 0 & -1 & 3 & -1 & 0 & 0 & 0 & 0 \\ -1 & 1 & -2 & 0 & 1 & 0 & 0 & 0 \\ -5 & 4 & 0 & -1 & 0 & 0 & 0 & 0 \\ 0 & 0 & -1 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}$$

The coefficients are denormalized by the process described in Step 2 of Algorithm 76.12. For example, the DC coefficient is denormalized as

$$\hat{C}'[0, 0] = Q[0, 0]Z[0, 0] = (-34)(16) = -544$$

Recall that $C[0, 0] = -548.5$, so this is a relatively close approximation of the DC coefficient. Building the rest of the image,

$$\hat{C}'[v_1, v_2] = \begin{bmatrix} -544 & -66 & -10 & 16 & 0 & 0 & 0 & 0 \\ 0 & -12 & 42 & -19 & 0 & 0 & 0 & 0 \\ -14 & 13 & -32 & 0 & 40 & 0 & 0 & 0 \\ -70 & 68 & 0 & -29 & 0 & 0 & 0 & 0 \\ 0 & 0 & -37 & 0 & 0 & 0 & 0 & 0 \\ 24 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}$$

Performing the inverse DCT on this data and adding 128 back to each pixel results in:

$$I'[i_1, i_2] = \begin{bmatrix} 50 & 46 & 53 & 66 & 58 & 39 & 40 & 57 \\ 54 & 45 & 41 & 48 & 54 & 60 & 71 & 83 \\ 58 & 54 & 47 & 48 & 67 & 92 & 105 & 104 \\ 49 & 58 & 59 & 55 & 69 & 94 & 98 & 84 \\ 39 & 54 & 56 & 45 & 47 & 61 & 60 & 47 \\ 51 & 56 & 54 & 45 & 42 & 47 & 47 & 43 \\ 56 & 50 & 53 & 66 & 74 & 69 & 61 & 59 \\ 39 & 30 & 45 & 84 & 105 & 91 & 69 & 60 \end{bmatrix}.$$

Subtracting I' from I shows the location and magnitude of reconstruction errors due to the lossy compression:

$$I[i_1, i_2] - I'[i_1, i_2] = \begin{bmatrix} -14 & 8 & -12 & -2 & 1 & 8 & 4 & -9 \\ -6 & -4 & 25 & -15 & -10 & -4 & -6 & 6 \\ -8 & 16 & -2 & 4 & 11 & -8 & 3 & 16 \\ -3 & -17 & -3 & 4 & -16 & 11 & -7 & 1 \\ 5 & 5 & -7 & 2 & 1 & -8 & 18 & -3 \\ 1 & -12 & -7 & 19 & -14 & 2 & 7 & 5 \\ -5 & 1 & 8 & 18 & -1 & 8 & 1 & -22 \\ 1 & 7 & 1 & -15 & 10 & 2 & -14 & 7 \end{bmatrix}.$$

One measure of the *quality* of reconstruction is the mean square error (MSE) between the original image I and the reconstructed image I' . The smaller the MSE, the *closer* the images are to each other. However, even large MSEs may be tolerable to the viewer, depending on the content of the image.

Example 76.16

The mean square error between the original image I in Example 76.14 and the reconstructed image I' in Example 76.15 is 95.6. The fidelity, which is a measure of how closely I and I' resemble each other, is 0.76.

The JPEG algorithm described here is the *sequential baseline system*. Other JPEG compression modes such as *progressive* compression also exist but will not be discussed in this introduction to JPEG. JPEG is a relatively simple compression scheme that results in significant compression, albeit lossy, of the original data stream. It is the *de facto* image compression standard. However, everything about JPEG is not sunshine and light, especially at high compression ratios. Because JPEG makes use of block DCT, at high compression ratios, the edges of these blocks become evident. This phenomenon is often referred to as *block artifacts* or, more affectionately(!), as *jpeggies*. The only way to eliminate these artifacts is to reduce the compression ratios (i.e., use more data).

JPEG is an evolving standard. In its (proposed) next version, the JPEG committee has recommended moving away from block DCT because of the jpeggies, and use wavelet compression. Wavelet encoding provides compression ratios equivalent to the block DCT based approach outlined in Algorithm 76.12, but does not produce the very annoying jpeggies at the higher compression ratios. However, it has its attendant problems, chief among which is the speed of compression. We introduce the basic ideas of wavelet compression in the remainder of this chapter.

76.3.2.1 Wavelets and Subband Coding

Wavelet analysis^{29–36} is a general mathematical formulation that allows a signal to be analyzed at increasingly finer (or coarser) resolutions using basis functions generated by translating and scaling a *mother* wavelet. In most image compression applications, wavelet compression refers to a particular method known as subband coding.^{37,38}

Definition 76.17 Subband coding, very simplistically, decomposes a signal into (approximately) disjoint frequency components that can be represented by fewer samples than the original, and which contain all the information required to reconstruct the original signal.

Suppose we have a discrete sequence $f[k], k = 0, \dots, N - 1$. This sequence can be divided into two N -element sequences y and z generated in the following manner:

$$y[k] = \frac{f[k] + f[k + 1]}{2}; \quad z[k] = \frac{f[k] - f[k + 1]}{2}, \quad k = 0, \dots, N - 1$$

In some sense, y is a smoothed version of f , and z is a sharpened version of f . In other words, y and z approximate the low and high passed components of f . Low passed versions are amenable to better

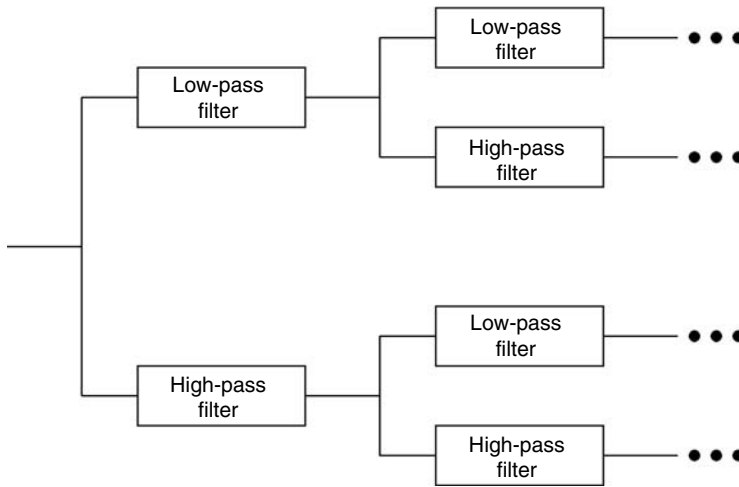

FIGURE 76.8 Subband decomposition of a signal.

entropy coding, and high passed version are similar to the DPCM scheme discussed in [Section 76.3.1](#). The original sequence can be completely recovered by adding y and z ; however, we have doubled the amount of data because both y and z are the same size as f . Suppose, now, that we send every other element in y and z , so that

$$y[2k] = \frac{f[2k] + f[2k + 1]}{2}; \quad z[2k] = \frac{f[2k] - f[2k + 1]}{2}, \quad k = 0, \dots, N - 1$$

Certainly, the total amount of data in y and z now is equal to the amount of data in f . But can f be recovered from this version of y and z ? The answer is obviously “Yes!” Otherwise, we would not be talking about this compression method! To recover the original sequence, we first add the new y and z and then subtract them:

$$y[2k] + z[2k] = x[2k]; \quad y[2k] - z[2k] = x[2k + 1], \quad k = 0, \dots, N - 1$$

So what this method allows us to do is to represent the original sequence by two sequences, each of which has characteristics that make it more amenable to compression than the original sequence, while keeping the total number of samples the same. In subband coding, each signal is decomposed into its low-frequency and high-frequency components. Each of these components can be further decomposed into low- and high-frequency components, leading to a cascade of stages where the spatial resolution is getting coarser and coarser. The scheme is shown in Figure 76.8.

The most popular pair of filters is known as the *quadrature mirror filter* (QMF) or the *conjugate mirror filter*.^{37,39,40} These filters have a very nice property that relates the impulse response $h[n]$ of the low-pass filter l to the impulse response of the high-pass filter z ; namely:

$$\begin{aligned} l[n] &= h[n] & n &= 0, \dots, N - 1 \\ z[n] &= (-1)^n h[N - n - 1] \end{aligned}$$

QMFs can be symmetric, in which case

$$h[N - n - 1] = h[n] \quad n = 0, \dots, N/2 - 1$$

and only half the coefficients need to be defined; or they can be asymmetric, in which case all the coefficients need to be defined.

Subband coding for images is typically implemented in a separable way using one-dimensional filters, first transforming the columns of the image and then the rows of the resulting transformed image. However, there is a slight twist to two-dimensional subband coding. Unlike two-dimensional DFT, and DCT where there is a single analysis and a single synthesis filter, two-dimensional subband coding uses scaled and translated versions of the “base” filter to generate four analysis filters and four synthesis filters. These filters are described below.

1. *Low-low*. These filters are obtained by taking the *outer* product of the low-pass, one-dimensional filters: $LL = ll^T$

$$\begin{bmatrix} LL_{0,0} & LL_{0,1} & \dots & LL_{0,N-1} \\ LL_{1,0} & LL_{1,1} & \dots & LL_{1,N-1} \\ \vdots & \vdots & \ddots & \vdots \\ LL_{N-1,0} & LL_{N-1,1} & \dots & LL_{N-1,N-1} \end{bmatrix} = \begin{bmatrix} l_0 \\ l_1 \\ \vdots \\ l_{N-1} \end{bmatrix} [l_0 \quad l_1 \quad \dots \quad l_{N-1}]$$

where l is the column vector representation of the filter l . They are equivalent to the low-pass, one-dimensional filter.

2. *High-low*. These filters are obtained by taking the outer product of the one-dimensional, high-pass filter h and low-pass filter l : $HL = hl^T$. These are *directional* filters and pick out the horizontal edges in an image.
3. *Low-high*. These filters are obtained by taking the outer product of the one-dimensional, low-pass filter l and high-pass filter h : $LH = lh^T$, where h is the column vector representation of the filter h . These are *directional* filters and pick out the vertical edges in an image.
4. *High-high*. These filters are obtained by taking the outer product of the one-dimensional, high-pass filter h : $HH = hh^T$. These are *directional* filters and pick out the diagonal edges in an image.

The subband coding algorithm can be described using the steps in Algorithm 76.14.

Algorithm 76.14

1. *Analysis*. Convolve the $N_1 \times N_2$ input image with the four filters described above. At this juncture, there are four $N_1 \times N_2$ filtered representations of the original image, which implies that there is a lot of redundancy that can be exploited for data compression.
2. *Subsampling or decimation*. To reduce the amount of total data generated by the convolution operations, subsample the filtered representations of the image by the factor $[S_1, S_2]$, where S_1 is the sampling rate in the N_1 dimension and S_2 is the sampling rate in the N_2 dimension. Typically, if there are K analysis filters, then $S_1 = S_2 = K^{1/d}$, where d is the number of dimensions of the signal. For example, for an image $d = 2$, and $S_1 = S_2 = \sqrt{K}$.
3. *Encoding or quantization*. The subband coding process is completely reversible if no encoding of the subsampled signals occurs. Several different encoding schemes can be employed at this point, with different bands being amenable to different types of encoding.
4. The encoded data can then be transmitted.

To reconstruct the data, the procedure outlined in Algorithm 76.14 is essentially applied in the reverse order.

Algorithm 76.15

1. *Decoding or dequantization*. The encoded data stream is decoded to form the $S_1 \times S_2$ subbands at each decomposition level (see Figure 76.9).
2. *Interpolation*. The subbands are interpolated (see Definition 76.19) to form signals that are the correct size for the level (i.e., the size they were before they were subsampled).
3. *Synthesis*. The synthesis filters are applied to combine the $S_1 \times S_2$ subbands into the single image I' .

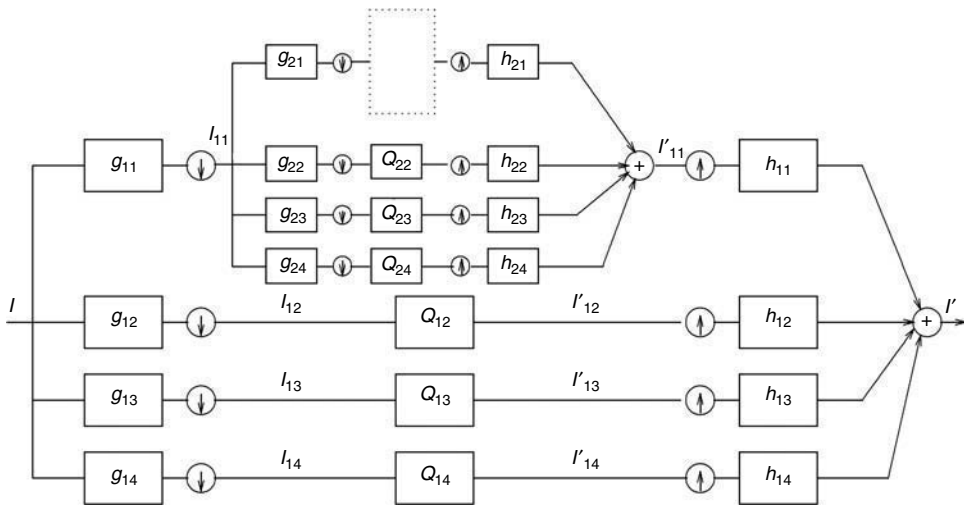

FIGURE 76.9 I is operated on by analysis filters g and down-sampled to produce critically sampled representations $I_{i_1 i_2}$: I_{11} is the LL version of I . The analysis filters are repeatedly applied to I_{kk} until the coarsest resolution has been achieved. The synthesis filters $h_{i_1 i_2}$ combined with the up-samplers generate the reconstructed image components $I'_{i_1 i_2}$, which are then combined to form the final image I' . The Q are the quantizers/encoders at different resolutions.

The general subband encoding and decoding processes are shown in Figure 76.9.

The $g_{i_1 i_2}$ are the analysis filters, where the index i_1 corresponds to the *level* of decomposition, and the index i_2 represents which of the analysis filters is being used: $i_2 = 1, 2, 3, 4$ implies LL, LH, HL, HH filters, respectively. The $Q_{i_1 i_2}$ are the quantization maps designed to maximize data compression and quality of transmission for each subband coded band, and the $h_{i_1 i_2}$ are the synthesis filters. I is the input image and I' is the image reconstructed from the lossy compressed data. The down-arrows in a circle represent subsampling and the up-arrows in a circle represent interpolation.

Definition 76.18 Subsampling by (S_1, S_2) means that sampled image I_s consists of the samples of I located at $(0, 0), (0, S_2), (0, 2S_2), \dots, (0, \lfloor N_2/S_2 \rfloor S_2), \dots, (\lfloor N_1/S_1 \rfloor S_1, \lfloor N_2/S_2 \rfloor S_2)$.

If an $N_1 \times N_2$ image is reconstructed from the subsampled data, it will contain *aliasing* artifacts. Aliasing is the phenomenon that results from not sampling the data at a high enough temporal or spatial resolution, that is, at a rate less than the Nyquist rate. The Nyquist rate is the minimum rate at which data can be sampled for artifact-free reconstruction and is given as twice the maximum frequency of the signal being sampled.

Definition 76.19 Interpolation is the phenomenon of providing sample values at locations where sample values are undefined by using the values at known locations. It is achieved by inserting in an image Q zeros between each sample in a row image, and P rows of zeros between each row, and then convolving by an interpolation kernel. Typical kernels are Gaussian, bilinear, and bi-cubic.

The combination of the application of analysis filters, down-sampling, up-sampling, and then the application of synthesis filters defines the subband coding operation. For this process to result in perfect reconstruction, certain constraints must be placed on the analysis and synthesis filters. As shown in comment 17, the impulse response of the high- and low-pass analysis filters have a certain relationship. Similarly, the synthesis filters and the analysis filters are related to each other: the impulse responses of the analysis filters are the time-reversed version of the impulse response of the synthesis filters:

$$\begin{aligned}
 g_1[n] &= l[-n] = h[-n] & &= h[N-1-n] = (-1)^n z[n] \\
 g_2[n] &= z[-n] = h[n+1-N] = h[n] & &= l[n]
 \end{aligned}$$

where g_i are the synthesis filters used to obtain the two-dimensional synthesis filter s . So, the low-pass analysis filter is used to reconstruct the high-pass subband signal, and the high-pass analysis filter is used to reconstruct the signal.

The strength of the subband coding algorithm lies in the design of different quantizers for different subbands. Several schemes have been proposed, some of which make use of the minimization of the MSE as the design parameter. However, the one that has been accepted most widely, and put in commercial applications, is the embedded zero-tree wavelet (EZW) coefficient coding scheme designed by Jerome Shapiro.⁴¹

EZW was the *de facto* standard for wavelet compression for a considerable time and much effort was expended by many a researcher to beat Shapiro's original design. The actual process is composed of four parts:

1. Discrete wavelet transform as described above for subband coding
2. Zero-tree encoding, which is based on the prediction of *insignificance* across the scales (more on this later)
3. Application of successive approximation quantization (SAQ)
4. Application of universal lossless data compression to the quantized data stream

We discuss parts 2 and 3 in more detail below.

Definition 76.20 Given an amplitude threshold T , a wavelet coefficient is said to be insignificant with respect to T if $|x| < T$. The SAQ sequentially applies a sequence of thresholds T_0, \dots, T_{N-1} to determine significance, where $T_i = T_{i-1}/2$. The initial threshold T_0 is chosen so that $|x_j| < 2T_0$ for all transform coefficients x_j .

Two lists are maintained during the encoding and decoding process:

1. The *dominant list* contains the coordinates of those coefficients that have not yet been found to be significant. The order of the list follows the order of the scan, which is carried out in raster order on each subband at a particular level. The scan moves from *LL* to *HL* to *LH* to *HH*.
2. The subordinate list contains the magnitudes of coefficients found to be significant.

Each list is scanned once for each threshold.

Carrying the idea of insignificance a little further, it is reasonable to hypothesize that if a coefficient at a coarser scale is insignificant with respect to a threshold T_i , then *all* the coefficients of similar orientation at the same spatial location at finer scales will also be insignificant with respect to T_i . Even more generally, the magnitude of a coefficient tends to be larger than that of its children. Each coefficient at a given scale can thus be related to a set of coefficients at the next finer scale (see Figure 76.10). The exception is, of course, the highest frequency subbands. This defines a parent-child relationship between the coefficients: the coefficient at the coarser resolution is called the parent, and its descendants are as illustrated in Figure 76.10. Thus, each coefficient in the subband QMF scheme we have looked at has four children with the exception of the *LL* band which has 3 children at the locations in *HL*, *LH*, and *HH* bands.

Definition 76.21 A coefficient is said to be an element of a zero-tree for threshold T if it, and all of its descendants, are insignificant with respect to T . A coefficient is a zero-tree root if it is not the descendant of a previously found zero-tree root (i.e., it is the coefficient at the coarsest scale for which it and its descendants are all insignificant with respect to T).

Definition 76.22 A coefficient is classified as an isolated zero if the coefficient under consideration is insignificant but its descendants are not all insignificant.

Definition 76.23 A coefficient is positive (negative) significant if it is not insignificant with respect to a threshold. If the value of the coefficient is greater (less) than zero, then it is positive (negative).

FIGURE 76.10 The relationship between coefficients at different levels of hierarchy in EZW.

The image is subband decomposed and then the coefficients are defined according to the above criteria. After the first pass, which is carried out with the highest threshold value, a list of significant coefficients is generated as well as the locations of zero-tree roots and isolated zeros. This allows the reconstruction of the signal at a coarse resolution. Further passes reduce the thresholds as defined in Definition 76.20. Only the insignificant coefficients are reevaluated, and the previously defined significant coefficients are treated as zeros. This allows us to build an increasingly finer resolution reconstruction. Adaptive arithmetic coding is used to actually encode the symbols that are generated in the subordinate and dominant passes. An example makes this process more clear.

Example 76.17*

Suppose the result of applying a three-level, two-dimensional subband decomposition to an 8×8 image produces the following decomposition:

63	-34	49	10	7	13	-12	7
-31	23	14	-13	3	4	6	-1
15	14	3	-12	3	-7	3	9
-9	-7	-14	8	4	-2	3	2
-5	9	-1	47	4	6	-2	2
3	0	-3	2	3	-2	0	4
2	-3	6	-4	3	6	3	6
5	11	5	6	0	3	-4	4

Because the maximum value is 63, then by Definition 76.20 the initial threshold is between 31.5 and 63. Let us choose, without loss of generality, $T_0 = 32$. Table 76.7 lists the coefficients and their classification based upon the selected threshold value. It has been reproduced from Shapiro.⁴¹

Comments:

1. The coefficient in the LL_3 has a value of $|63| > T_0$, so it is significant with respect to the threshold and positive. Hence, it is coded as POS. Similarly, HL_3 , which has a value of -34 , is encoded as NEG.
2. The coefficient in LH_3 has a value of $|-31| < T_0$, so it is insignificant. However, there is a coefficient that is significant among its children — 47 in LH_1 ; thus, this value is encoded as an isolated zero (IZ).

*Reproduced substantially from Shapiro.⁴¹

TABLE 76.7 Classification of Coefficient Values for EZW Compression

Comment	Subband	Coefficient Value	Symbol	Reconstruction Value
1	LL_3	63	POS	48
	HL_3	-34	NEG	-48
2	LH_3	-31	IZ	0
3	HH_3	23	ZTR	0
4	HL_2	49	POS	48
	HL_2	10	ZTR	0
	HL_2	14	ZTR	0
	HL_2	-13	ZTR	0
5	LH_2	15	ZTR	0
	LH_2	14	IZ	0
	LH_2	-9	ZTR	0
	LH_2	-7	ZTR	0
6	HL_1	7	Z	0
	HL_1	13	Z	0
	HL_1	3	Z	0
	HL_1	4	Z	0
7	LH_1	-1	Z	0
	LH_1	47	POS	48
	LH_1	-3	Z	0
	LH_1	2	Z	0

The encoding symbols are POS for coefficients that are positive and significant with respect to the threshold, NEG for significant and negative, IZ for isolated zero, ZTR for zero-tree root, and Z for zero.

3. The coefficient in the HH_3 subband has a value of $|-23| < T_0$, and all its descendants HH_2 and HH_1 are also insignificant with respect to T_0 . Thus, it is encoded as a zero-tree root (ZTR). Because all of the coefficients in HH_2 and HH_3 are part of the zero-tree, they are not examined any further.
4. This coefficient in the HL_2 subband and all its descendants are insignificant with respect to the threshold, so it is labeled ZTR. Note, however, that one of its children, -12 in HL_3 has a larger magnitude, so it violates the assumption that coefficients at finer resolutions have smaller magnitudes than their parents at coarser resolutions.
5. The coefficient 14 in LH_2 is insignificant with respect to T_0 but one of its children, -1, 47, -3, 2 in LH_3 is significant, so it is encoded as an isolated zero.
6. Because HL_1 has no descendants, the ZTR and IZ classes are merged into a single class Z. This means that the coefficient has no descendants and it is insignificant with respect to the threshold.
7. This coefficient is significant with respect to the threshold, so it is encoded as POS. For future passes, its value is set to zero.

The first subordinate pass refines the reconstruction values of the four significant coefficients that were found in the first dominant pass. Because the range of the first dominant pass was between [32, 64), the reconstruction value of 48 was used to represent the outputs. In the first subordinate pass, the range is divided into two parts, [32, 48) and [48, 64). The midpoints of these ranges are then used to reconstruct the coefficients that fall within the range. So, for instance, 63 gets reconstructed to 56, the midpoint of [48, 64), while 47 gets reconstructed to 40, the midpoint of [32, 48). Subsequent passes refine the ranges.

The second dominant pass is made with $T_1 = 16$. Recall that only those coefficients that were not significant in the first pass are considered in the second pass. Also, the significant coefficients from the previous pass(es) are set to zero for the current pass. Hence, each pass refines the reconstruction values from the previous pass and adds the less significant values to the data stream. Thus, decoding the first pass results in a very coarse decoded image that is successively refined as more coefficients are received.

EZW offers high data compression and precise control over the bit rate. Because of the use of SAQ, the process can stop exactly when the bit bucket is exhausted, and the image can be reconstructed from the coefficients transmitted up to that point.

The new JPEG standard, JPEG 2000,⁴² has moved away from DCT-based compression to wavelet-based compression. JPEG performs very well for compression ratios of about 20:1. For lower bit rates, the artifacts are very evident. JPEG 2000 uses subband coding followed by Embedded Block Coding with Optimized Truncation (EBCOT). The basic idea of EBCOT is similar to that of EZW, in that each coefficient is encoded at increasingly better resolution using multiple passes over the coefficient data set. However, the notion of zero-trees is abandoned in EBCOT because of the criterion for optimal truncation. It has been shown that optimal truncation and embedded coefficient coding do not work well together.

76.4 Conclusion

We have introduced a number of different lossless and lossy compression techniques in this chapter. However, we have barely scratched the surface of a rich and complex field ripe for research and innovation. Each of the techniques mentioned in this chapter has several variations that have not been described. The bibliographic references provided give the interested reader a good starting point into the world of compression.

77.1 Introduction

This chapter provides an introduction to the concepts of security and privacy in computer-communication systems. Definitions tend to vary widely from one book to another, as well as from one system to another and from one application to another. The definitions used here are intuitively motivated and generally consistent with common usage, without trying to be overly precise.

Security is loosely considered as the avoidance of bad things. With respect to computers and communications, it encompasses many different attributes, and often connotes three primary attributes: confidentiality, integrity, and availability, with respect to various information entities such as data, programs, access control parameters, cryptographic keys, and computational resources (including processing and memory). Confidentiality implies that information cannot be read or otherwise acquired except by those to whom such access is authorized. Integrity implies that content (including software and data — including that of users, applications, and systems) cannot be altered except under properly authorized circumstances. Availability implies that resources are available when desired (for example, despite accidents and intentional denial-of-service attacks). All three attributes must typically be maintained in the presence of malicious users and accidental misuse, and ideally also under certain types of system failures. Which of these is most important depends on the specific application environments, as do the particular characteristics of each attribute.

Secondary attributes include authenticity, non-repudiability, and accountability, among others. Authenticity of a user, file, or other computational entity implies that the apparent identity of that entity is genuine. Non-repudiability implies that the authenticity is sufficiently trustworthy that later claims to its falsehood cannot be substantiated. Accountability implies that, whenever necessary, it is possible to determine what has transpired, in terms of who did what operations on what resources at what time, to whatever requisite level of detail, with respect to activities of users, systems, networks, etc., particularly in times of perceived or actual crises resulting from accidents or intentional misuse.

Trustworthiness is the notion that a given system, application, network, or other computational entity is likely to satisfy its desired requirements. The concept is essentially meaningless in the absence of well-defined requirements because there is no basis for evaluation. Furthermore, a distinction needs to be made between trustworthiness and trust. Something may be said to be trusted for any of several reasons; for example, it may justifiably be trusted because it is trustworthy; alternatively, it may have to be trusted because you have no alternative (you must depend on it), even if it is not trustworthy.

Authorization is the act of granting permission, typically based on authenticated identities and requested needs, with respect to a security policy that determines how authorizations may be granted. A fundamental distinction is made between policy and mechanism: policy implies what must occur or what must not occur, while mechanism determines how it is done. One of the fundamental challenges of computer-communication security is establishing the policy unambiguously before carrying out design and implementation, and then ensuring that the use of the mechanisms satisfies the required policies. A system cannot meaningfully be said to be secure unless it satisfies a well-defined security policy, both statically in terms of configured systems and dynamically in operation.

Security mechanisms can exist at many different hierarchical layers — such as hardware, operating system kernels, network software, database management, and application software. Each such layer may have its own security policy. In this way, it becomes clear (for example) that operating-system security depends on hardware and software mechanisms such as authentication and access control. Furthermore, cryptographic confidentiality and integrity of networked communications typically depend on the security of the underlying storage, processing, and network mechanisms, particularly with respect to protecting keys and exposed unencrypted information. By making careful distinctions among different hierarchical layers of abstraction and different entities in distributed environments, it is possible to associate the proper policies with the appropriate mechanisms, and to avoid circular dependencies.

Granularity is an important concept in security. It is possible to specify an access-control policy according to arbitrary granularities, with respect to individual bits, bytes, words, packets, pages, files, hyperfiles, subsystems, systems, collections of related system, and indeed entire networks of systems, as desired. Access permissions may themselves be subdivided into individually protecting operations such as read, write, append-only, execute, and perhaps the ability to execute without reading or to do a blind append without reading or overwriting. Each functional layer or subsystem may have protections according to its own operations and resources. For example, operations on files, database entities, electronic mail, and network resources such as Web pages all tend to be different. Digital commerce and network-mobile objects add further security requirements as well. Ideally, each type of object has its own set of protections defined according to the permissible operations on those objects.

Vulnerabilities are rampant in most computer-communication systems, whether stand-alone, accessible by dial-up maintenance paths, or connected directly to the Internet or private networks. Exploitations of those vulnerabilities are also rampant, including penetrations by outsiders, misuse by insiders, insertion of malicious Trojan horses and personal-computer viruses, financial fraud, and other forms of computer crime, as well as many accidental problems. When exploited, vulnerabilities can lead to a wide range of consequences — for example, resulting from a lack of confidentiality, integrity, availability, authentication, accountability, or other aspect of security, or a lack of reliability. Merely installing firewalls, virus checkers, and misuse-detection systems is nowhere near enough, especially if those systems are poorly configured — as often seems to be the case. (For numerous examples of vulnerabilities, threats, exploitations, and risks, see Neumann [1995]. Avoiding vulnerabilities is a very difficult matter because it depends on having sufficiently precise requirements, sufficiently flawless designs, sufficiently correct implementations, sensible system operations and administration, and aware users. All of those require strict adherence to high principles.

Various principles have evolved over the years, and are commonly observed — at least in principle. These include (1) separation of concerns according to types of system functions, user roles, and usage modes; (2) minimization of granted privileges; (3) abstraction; (4) modularity with encapsulation, as in hiding of implementation detail and minimization of adverse interactions; and (5) avoiding dependence on security by obscurity — that is, in essence, a belief that hiding your head in the sand makes you more secure. An example that encompasses (1) and (2) is to avoid using superuser privileges for nonprivileged operations. Overall, good software engineering practice (which includes (3) and (4)) can contribute considerably to the extent to which a system avoids certain characteristic flaws. Security by obscurity (5) is the generally invalid assumption that your antagonists know less than you do and always will; relying exclusively on that assumption is very dangerous, although security ultimately depends to some extent on staying ahead of your attackers. However, security is greatly increased when subsystem and network operations are well encapsulated; for example, if distributed implementations and remote operations can be hidden from the invoker.

TABLE 77.1 Generally Accepted System Security Principles (GASSP): Pervasive Principles

1. *Accountability*: information security accountability and responsibility should be explicit.
2. *Awareness*: principles, standards, conventions, mechanisms (PSCM) and threats should be known to those legitimately needing to know.
3. *Ethics*: information distribution and information security administration should respect rights and legitimate interests of others.
4. *Multidisciplinary*: PSCM should pervasively address technical, administrative, organizational, operational, commercial, educational, and legal concerns.
5. *Proportionality*: controls and costs should be commensurate with value and criticality of information, and with probability, frequency, and severity of direct and indirect harm or loss.
6. *Integration*: PSCM should be coordinated and integrated with each other and with organizational implementation of policies and procedures, creating coherent security.
7. *Timeliness*: actions should be timely and coordinated to prevent or respond to security breaches.
8. *Reassessment*: security should periodically be reassessed and upgraded accordingly.
9. *Democracy*: security should be weighed against relevant rights of users and other affected individuals.
10. *Competency*: information security professionals should be competent to fulfill their respective tasks.

Source: From GASSP, June 1997.

Some pervasive principles have been collected together as the emerging Generally Accepted System Security Principles [GASSP 1997], inspired by the National Research Council study, *Computers at Risk* [Clark et al. 1990], as summarized in Table 77.1.

One of the most important problems in ensuring security at every externally visible layer in a hierarchy and in all systems throughout a highly distributed environment is that of ensuring adequate authentication. Identities of all users, subsystems, servers, network nodes, and any other entities that might otherwise be spoofed or subverted should be authenticated with a level of certainty commensurate with the nature of the application, the potential untrustworthiness of the entity, and the risks of compromise — unless it can be demonstrated that no significant compromises can result. Fixed (reusable) passwords are extremely dangerous, particularly when they routinely traverse unencrypted local or global networks and can be intercepted. Similarly, although it is appealing to enhance ease of use, the single-sign-on concept is dangerous, except possibly within areas of common trust and trustworthiness. This is just one more example of the risks involved in trade-offs between security and ease of use. One-time tokens of some sort (e.g., cryptographically generated) are becoming highly desirable for authenticating users, systems, and in some cases even subsystems — particularly in distributed systems in which some of the entities are of unknown trustworthiness. Cryptographically based authentication is discussed in [Chapter 79](#).

Privacy, and particularly electronic privacy, is an enormous problem area that is widely ignored. It is a socially motivated expectation that computer-communication systems will adequately enforce confidentiality against unauthorized people, and that authorized people will behave well enough. As is the case with trustworthiness, privacy is a meaningless concept in the absence of a well-defined policy defining the expectations that must be satisfied. Even then, many of the violations of typical privacy policies occur outside the confines of computers and communications, as results of actions of trusted insiders or untrustworthy outsiders.

Enforcement of privacy depends on system security, on adequate laws to discourage misuses that cannot otherwise be prevented, and on a society that is sufficiently orderly to follow the laws. Thus, privacy can be aided by computer-based controls, but has a substantial extrinsic component — it can be compromised externally by trusted people who are not trustworthy and by untrusted people who have been able to use whatever privileges they might have acquired or whatever security vulnerabilities they might have been able to exploit. Losses of privacy can have very serious consequences, although those consequences are not the subject of this chapter (see [Chapter 2](#)).

There are many techniques for enhancing security and reducing the risks associated with compromises of computer security and privacy. These techniques necessarily span a wide range, encompassing technological, administrative, and operational measures. Good system design and good software engineering practice can help considerably to increase security, but are by themselves inadequate. Considerable burden

must also be placed in system administration. In addition, laws and implied threats of legal actions are necessary to discourage misuse and improper user behavior.

Inference and aggregation are problems arising particularly in distributed computer systems and database systems. Aggregation of diverse information items that individually are not sensitive can often lead to highly harmful results. Inferences can sometimes be drawn from just two pieces of information, even if they are seemingly unrelated. The absence of certain information can also provide information that cannot be gleaned directly from stored data, as can the unusual presence of an encrypted message. Such gleanings are referred to as exploitations of out-of-band information channels. Some channels are called covert channels, because they can leak information that cannot be derived explicitly — for example, as a result of the behavior of exception conditions (covert storage channels) or execution time (covert timing channels). Inferences can often be drawn from bits of gleaned information relating to improperly encapsulated implementations, such as exposed cryptographic keys. For example, various approaches such as differential power analysis, noise injection, and exposing specific spots on a chip to a flashbulb have all resulted in the extraction of secret keys from hardware devices.

Identity theft is increasingly becoming a serious problem, seriously exacerbated by the widespread availability of personal information and extremely bad policies of using that information not merely for identification, but also for authentication.

77.2 Conclusions

Attaining adequate security is a challenge in identifying and avoiding potential vulnerabilities and threats (see Neumann [1995]), and understanding the real risks that those vulnerabilities and threats entail. Security measures should be adopted whenever they protect against significant risks and their overall cost is commensurate with the expected losses. The field of risk management attempts to quantify risks. However, a word of warning is in order: if the techniques used to model risks are themselves flawed, serious danger can result — the risks of risk management may themselves be devastating. See Section 7.10 of Neumann [1995].

77.3 Recommendations

Security is a weak-link phenomenon. Weak links can often be exploited by insiders, if not by outsiders, and with very bad consequences. The challenge of designing and implementing meaningfully secure systems and networks is to minimize the presence of weak links whose accidental and intentional compromise can cause unpreventable risks. Considerable experience with past flaws and their exploitations, observance of principles, use of good software engineering methodologies, and extensive peer review are all highly desirable, but never by themselves sufficient to increase the security of the resulting systems and networks. Ultimately, security and privacy both depend ubiquitously on the competence, experience, and knowledge of many people — including those who establish requirements, design, implement, administer, and use computer-communication systems. Unfortunately, given the weak security that exists today, many risks arise from the same attributes of those who seek to subvert those systems and networks.

78.1 Background

Since the advent of one of the first computer viruses on the IBM personal computer (PC) platform in 1986 the variety and complexity of malicious software has grown to encompass over 5000 viruses on IBM PC, Apple Macintosh, Commodore Amiga, Atari ST, and many other platforms. In addition to viruses a wide range of other disruptions such as Trojan horses, logic bombs, and e-mail bombs have been detected. In each case the software has been crafted with malicious intent ranging from system disruption to demonstration of the intelligence and creativity of the author.

The wide variety of malicious software is complemented by an extensive range of tools and methods designed to support unauthorized access to computer systems, misuse of telecommunications facilities and computer-based fraud. Behind this range of utilities lies a stratified and complex underculture: the computer underground. The underground embraces all age groups, motivations and nationalities, and its activities include software piracy, elite system hacking, pornographic bulletin boards, and virus exchange bulletin boards.

78.2 Culture of the Underground

An attempt to define the computer underground can produce a variety of descriptions from a number of sources. Many consider it a collection of friendless teenagers, who spend their time destroying people's data. To others, it is an elite society of computer gurus, whose expertise is an embarrassment to the legitimate bodies that continually try to extinguish their existence. However, the computer underground is really a collection of computer enthusiasts with as varied a collection of personalities as you would experience in any walk of life.

Not all members of the underground are computer anarchists; many use it as an environment in which to gather information and share ideas. However, many are in the following categories:

- *Hackers*, who try and break into computer systems for reasons such as gaining information or destroying data.
- *Malicious software writers*, who create software with a malicious intention. Viruses and Trojan horses are examples.
- *Phreakers*, who hack phones. This is done mainly to gain free phone calls, in order to support other activities such as hacking.

Some have described the inhabitants of the underground as information warriors; this is a too glamorous and inaccurate a term. It is true that many individuals' main cause is the freedom of information. These individuals may gain this information by breaking into a computer system, and extracting the stored information for distribution to any person who wants it. Many try and sell the information; these could be termed information brokers. Virus writers are certainly not information warriors, but may be information destroyers.

Thus, we have the person with the computer, surfing the net. An interesting site is stumbled across, with the electronic equivalent of a barbed-wire fence. Behind this fence there must be something interesting, otherwise, why so much security? The site is probed, in an attempt to challenge the security. Is this just a person's keen interest in the unknown, or is there a deeper malicious intent?

When security is breached, an assessment of the damage must be made. Was the availability of the system damaged? A virus could have destroyed vital files, crucial to the operation of the system. Has the integrity of data been compromised? An employee's salary could have been changed. Confidentiality lost? A company's new idea stolen. The cost of recovering from a security breach can be major: the time spent by an antivirus expert cleaning up machines after an infection, the time lost when employees could not work because their machines were inoperable. The cost mounts up. It is possible for a company dependent on its computer systems to go bankrupt after a security breach. It could also put peoples' lives at risk. The computer underground poses a significant threat to computer systems, of all descriptions, all over the world.

78.2.1 Stereotypes

The underground is a random collection of individuals, communicating over the Internet, bulletin boards, or occasionally face to face. Some individuals amalgamate to form a group. Groups sometimes compete with other groups, to prove they are the best. These competitions usually take the form of who can hack into the most computer systems. T-shirts even get printed to celebrate achievements.

A computer hacking group that did gain considerable recognition was the Legion of Doom (LoD). This group participated in a number of activities, including: obtaining money and property fraudulently from companies by altering computerized information, stealing computer source code from companies and individuals, altering routing information in computerized telephone switches to disrupt telecommunications, and theft or modification of information stored on individuals by credit bureaus. A member of LoD claims that curiosity was the biggest crime they ever committed!

Hacker groups do cause damage and disruption, wasting the resources of system administrators and law enforcement agencies worldwide. It has also been argued that hackers are responsible for closing security loopholes. Many hacker groups such as the Chaos Computer Club state that their members abide by a moral code.

78.2.2 Hacker

Simon Evans is a hypothetical example of a hacker with a broad level of computer expertise. Evans' history is one of persistent attempts to break into networks and systems; attempts which were often successful.

Evans' name first hit the press, when in 1980 a magazine wrote a cover story on an underground group. Evans had met the leader of this group a few years previously. Later in 1980, Evans and this hacker group

broke into a computer system at U.S. Leasing. Not content with simple computer system breakins, Evans illegally entered an office of a telecom company in 1981 and stole documents and manuals. Following a tip off, Evans's home was searched and he was arrested, along with his accomplice and the leader of the hacker group. Evans was placed on one year's probation.

During his probation period, Evans managed to gain physical access to some university computers and started using them for hacking purposes. A computer crime unit pursued Evans and he was sentenced to six months in a juvenile prison for breaking probation. In 1984 Evans got a job, working for Great American Merchandising. From this company, he started making unauthorized credit checks, he was reported, and went into hiding.

In 1985, Evans came out of hiding and enrolled at a computer learning center. He fell for a girl, from whose address he hacked a system at Santa Cruz Operation. The call was traced, and Evans and his girlfriend were arrested. The girlfriend was released and Evans received 3 years probation, during which he married his girlfriend. In 1988, a friend of Evans started talking to the FBI, who subsequently arrested Evans for breaking into Digital Equipment Corporation's systems and stealing software. Evans got a year at a Californian prison, he and his wife then separated.

During Evans's probation in 1992 the FBI started probing again, and Evans went into hiding. In 1994 the Californian Department of Motor Vehicles issued a warrant for Evans' arrest. During the same year, Evans was accused of breaking into a security expert's system in San Diego, and stealing a large amount of information. He left a voice message made by a computer generated voice. Throughout the message he bragged about his expertise, and threatened to kill the security expert with the aid of his friends.

Evans made a mistake, he stored the data he stole from the computer expert on the Well, an on-line conferencing system. This information was spotted, and the security expert was alerted, who then subsequently monitored Evans' activities. Evans was tracked down, arrested and charged with 23 offenses, with a possibility of up to 20 years in prison for each offense.

Although the character described is fictional, the events are based on a real hacker's exploits.

78.3 Techniques and Countermeasures

78.3.1 Malicious Software

Malicious software is specifically written to perform actions that are not desired by the user of a computer. These actions could be passive, displaying a harmless message on the screen, or aggressive, reformatting a hard disk.

The programming abilities required to produce malicious software need not be at genius level. Little experience is required to use the toolkits that are currently available. A number of malicious software authors have taught themselves how to program. Some produce complex programs, which take time to analyze and demonstrate original programming concepts. Much malicious software, however, shows signs of bad programming, and does not execute correctly. Despite the varying quality, malicious software has found its way onto computers worldwide. Malicious software falls into a number of categories.

78.3.1.1 Trojan Horse

This software pretends to be something it is not. For example, on a disk operating system (DOS) machine, when we type DIR the contents of the current working directory is displayed. If, however, the contents of the directory were deleted, we would be witnessing a Trojan horse in action. It is a program that has the same name as a legitimate piece of software, but when executed, may perform an unexpected malicious act. This malicious act may not occur immediately, but on certain external conditions, for example, the user pressing ctrl-alt-delete (*logic bomb*) or the time being two minutes past midnight (*time bomb*).

78.3.1.2 Trojan Mule

When a computer is waiting to be logged into, a log-in screen is displayed. A user identification and a password usually needs to be entered in order to gain access to the system. If a piece of software is run that

simulates the log-in screen, this would be a Trojan mule. A user would approach the computer, assume the screen was the genuine log-in screen, and enter their user identifier and password. The Trojan mule would record the data entered and terminate, usually informing the user that the log-in was incorrect. The effect of a Trojan mule is that users' passwords are captured by the person executing the Trojan mule.

78.3.1.3 Worm

A worm attacks computers that are connected by a network. A worm spreads by attacking a computer, then sending a copy of itself down the network looking for another machine to attack. An important difference exists between a worm and a virus (explained subsequently). A worm makes a copy of itself to spread, which is a standalone entity. A virus makes a copy of itself, but differs in that it needs to attach itself to a program, similar to a parasite attaching to a host. The most infamous example is the Internet worm which attacked computers connected to the Internet on November 2, 1988. It infected over 30% of Internet-connected computers and caused damage estimated at \$10–\$98 million.

78.3.1.4 E-Mail Bomb

The e-mail bomb is the electronic equivalent of a letter bomb. When the e-mail is read, an electronic bomb explodes. The result of the explosion may be degradation of system performance due to key system resources being used in the processing of the e-mail message; denial of service because the e-mail program does not filter out certain terminal control codes from e-mail messages, causing the terminal to hang; or something more serious due to the e-mail message containing embedded object code, which in turn contains malicious code (Trojan horse).

78.3.1.5 Malicious Scripts

These are constructed by the underground to aid an attack on a computer system. The script could take the form of a C program that takes advantage of a known vulnerability in an operating system. It could also be a simplification of a complex command sequence.

78.3.1.6 Viruses

Viruses have existed for some time and can cause a variety of annoyances to the user. They can produce amusing messages on a user's screen, delete files, and even corrupt the hard disk so that it needs reformatting. Whatever its actions, the virus interferes with the correct operation of the computer without the authorization of the owner.

Many have compared computer viruses to human viruses. Thus the virus writer becomes the equivalent of an enemy waging germ warfare. The most vulnerable computer to virus infection at the moment is the PC running MS-DOS. Viruses do exist that can infect Macintosh, and other types of machines using different operating systems, such as OS/2. Viruses that infect Unix machines are in existence; most are laboratory viruses but there are new reports of one being in the wild, i.e., existing on innocent users machines that have not deliberately installed the virus.

In order to distinguish one virus from another, they are given names by the antivirus industry. Naming conventions vary considerably between antivirus software vendors. A virus author may include a text string in the virus which gives an obvious name, however unprintable. The classic definition of a virus is as follows.

A virus is a self replicating program that can *infect* other programs, either by modifying them directly or by modifying the environment in which they operate. When an infected file is executed, this will cause virus code within the program to be run.

78.3.2 Boot Sector Viruses

A common form of PC virus is the boot sector virus. When a PC is booted a number of steps are followed. First, the power on self-test (POST) is executed, which tests the integrity of system memory and then

initializes the hardware. Information stored in nonvolatile memory is collected, and finally POST sets up the basic input output system (BIOS) address in the interrupt table.

The A: drive is then checked, to see if a disk is present in the drive. This can be seen and heard when the A: drive's motor is started and the light flashes. If a disk is present in the drive, the first sector is read into memory and executed. If no disk is found, then the first sector of the hard disk is read. This sector is known as the master boot sector (MBS). The MBS searches for a pointer to the DOS boot sector (DBS), which is loaded into memory, and control is passed to it.

At this point an opportunity exists for virus infection. A boot sector virus can infect the MBS or the DBS of a hard disk, or the boot sector of the floppy disk. Consider a virus on a floppy first. A floppy with a virus resident on its boot sector is inserted into the A: drive (the original boot sector of the floppy is usually stored elsewhere on the floppy). The machine is booted, and the virus in the boot sector is loaded into memory and executed. The virus searches out the MBS or DBS, depending on the virus' plan, and copies itself to that sector. As with a floppy, the virus usually stores the original MBS or DBS elsewhere on the disk. When the virus has completed execution, it can load the original boot sector and pass control to it, making the actions of the virus invisible to the user. It is important to note that all DOS formatted floppies have a boot sector, even if the floppy is not a system disk.

If the virus infected the MBS of the hard disk (similarly, when the DBS is infected), how does the virus work? The computer is booted from the hard disk, i.e., there's no floppy in the A: drive. The virus code in the MBS is loaded into memory and executed. The virus loads any other sectors that it needs to execute, then loads the original boot sector into memory. The virus is active in memory and can now monitor any floppy disk read/write activity. When an uninfected floppy is detected, it can infect its boot sector. This allows the virus to spread from disk to disk and thus computer to computer.

78.3.3 File Infector Viruses

A file infector virus is basically a program that when executed seeks out another program to infect. When the virus finds a suitable program (the host) it attaches a copy of itself and may alter the host in some way. These alterations ensure that when the host is executed, the attached virus will also be executed. The virus can then seek out another host to infect, and so the process continues. The virus may attach itself to a host program in a number of ways, the most common types are the following:

Overwriting: the virus places its code over the host, thus destroying the host (Figure 78.1). When the virus has finished executing, control is returned to the operating system.

Appending: the virus places its code at the end of the host (Figure 78.2). When the host is executed, a jump instruction is usually executed which passes control to the virus. This jump instruction is placed at the start of the host by the virus, the original instructions that were at the start are stored in the body of the virus. During the virus's execution, it replaces the host's original start instructions, and on completion it passes control to these instructions. This process makes the virus invisible to the user until it triggers.

Prepending: the virus places its code at the start of the host (Figure 78.3). When the host is executed, the virus is executed first, followed by the host.

FIGURE 78.1 Overwriting virus.

FIGURE 78.2 Appending virus.

FIGURE 78.3 Prepending virus.

78.3.4 Triggers and Payloads

A trigger is the condition that must be met in order for a virus to release its payload, which is the malicious part of the virus. Some viruses simply display a message on the screen, others slow the operation of the computer, the nastier ones delete or corrupt files or reformat the hard disk. The trigger conditions are also only limited by the writer's imagination. It may be that a certain date causes the virus to trigger, a popular day is Friday 13th, or it may be a certain key sequence, such as control-alt-delete.

78.3.5 Virus Techniques

Virus writers go to great lengths to hide the existence of their viruses. The longer a virus remains hidden, the further its potential spread. Once it is discovered, the virus' trail of infection comes to an end. Common concealment techniques include:

78.3.5.1 Polymorphism

Polymorphism is a progression from encryption (Figure 78.4). Virus writers started encrypting their viruses, so that when they were analyzed they appeared to be a collection of random bytes, rather than program instructions. Antivirus software was written that could decrypt and analyze these encrypted viruses. To combat this the writers developed polymorphic viruses.

Polymorphism is the virus' attempt at making itself unrecognizable. It does this by encrypting itself differently every time it infects a new host. The virus can use a different encryption algorithm, as well as a different encryption key when it infects a new host. The virus can now encrypt itself in thousands of different ways.

78.3.5.2 Stealth

Viruses reveal their existence in a number of ways. An obvious example is an increase in the file size, when an appending or prepending virus infects a host. A file could possibly increase from 1024 bytes long before infection to 1512 bytes after infection. This change could be revealed during a DOS DIR command.

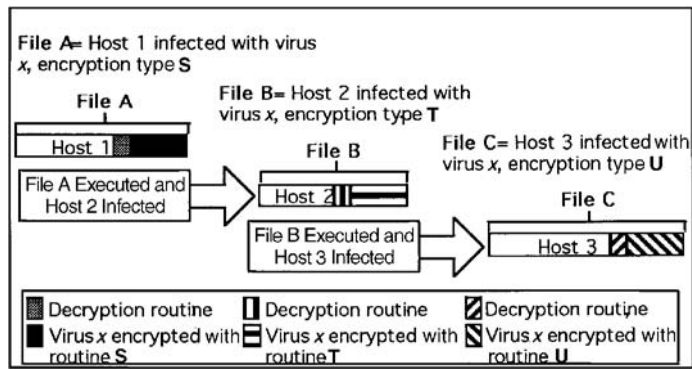

FIGURE 78.4 Polymorphic infection.

To combat this symptom of the virus' existence, the idea of stealth was created. As was mentioned earlier, the longer a virus remains hidden, the farther it spreads. Stealth can be described as a virus' attempt to hide its existence and activities from system services and/or virus detection software.

A virus, for example, to avoid advertising the increase in file size, would intercept the relevant system call and replace it with its own code. This code would take the file size of an infected file, subtract from it the size of the virus, and return the result, the original file size.

78.3.6 Is the Threat of Viruses Real?

Viruses are being written and released every day, in ever increasing numbers. Anyone with access to the Internet can download a virus, even the source code of the virus. These viruses can be run and can spread rapidly between machines. There are widely available electronic magazines such as *40-Hex* that deal with virus writing. They cover new techniques being developed, virus source code, and countermeasures to commercial antivirus software. The existence of magazines, books, and compact disk read-only memory (CD-ROM) information on viruses makes the task of virus construction considerably easier.

If someone has a knowledge of DOS and an understanding of assembly language then that person can write a virus. If someone can boot a PC, and run a file, then that person can create a virus using a toolkit. The costs to recover from a virus incident have been estimated as being as low as \$17 and as high as \$30,000.

78.3.7 Protection Measures

How can we stop a virus infecting a computer, and if infected, how can we get rid of it before it does any damage? Since prevention is better than cure, a wide range of antivirus software of varying effectiveness is available, commercially and as shareware. When the software has been purchased, follow the instructions. This usually involves checking the machine for viruses first, before installing the software. Antivirus software normally consists of one or more of the following utilities.

78.3.7.1 Scanner

Every virus (or file for that matter) is constructed from a number of bytes. A unique sequence of these bytes can be selected, which can be used to identify the virus. This sequence is known as the virus' signature. Therefore, any file containing these bytes may be infected with that virus. A scanner simply searches through files looking for this signature.

A scanner is the most common type of antivirus software in use, and is very effective. Unfortunately scanners occasionally produce *false positives*. That is, the antivirus product identifies a file as containing a virus, whereas in reality it is clean. This can occur by a legitimate file containing an identical sequence

of bytes to the virus' signature. By contrast, a *false negative* occurs when the antivirus software identifies a file as clean, when in fact it contains a virus.

The introduction of polymorphism techniques complicates the extraction of a signature, and stealth techniques underline the need to operate the scanner in a clean environment. This clean environment is a system booted from the so-called magic object (a write protected clean system diskette). Heuristic scanners have also been developed which analyze executable files to identify segments of code that are typical of a virus, such as code to enable a program to remain resident in memory or intercept interrupt vectors.

78.3.7.2 Integrity Checkers

Scanners can only identify viruses which have been analyzed and have had a signature extracted. An integrity checker can be used to combat unidentified viruses. This utility calculates a checksum for every file that the user chooses, and stores these checksums in a file. At frequent intervals, the integrity checker is run again on the selected files, and checksums are recalculated. These recalculated values can be compared with the values stored in the file. If any checksums differ then it may be a sign that a virus has infected that file. This may not be the case of course, because some programs legitimately alter files during the course of their execution, and this would result in a different checksum being calculated.

78.3.7.3 Behavior Blocker

This utility remains in memory while the computer is active. Its task is to alert the user to any suspicious activity. An example would be a program writing to a file. The drawback of this is that user intervention is required to confirm an action to be taken, which can be an annoyance that many prefer to live without.

Fortunately, as viruses increase, so do the number of people taking precautions. With antivirus precautions in place the chance of virus infection can be kept to a minimum.

78.3.8 Virus Construction Kits

These kits allow anyone to create a computer virus. There are a number of types available, offering different functionality. Some use a pull down menu interface (such as the Virus Creation Laboratory), others (such as PS-MPC) use a text configuration file to contain a description of the required virus. Using these tools, anyone can create a variety of viruses in a minimal amount of time.

78.3.8.1 Hacking

Hacking is the unauthorized access to a computer system. Computer is defined in the broadest sense, and a fine line exists between hacking and telephone phreaking [unauthorized access to telephone switch, private automated branch exchange (PABX) or voice mail]. Routers, bridges, and other network support systems also increasingly use sophisticated computer bases, and are thus open to deliberate attack.

This section provides a hacker's eye view of a target system, indicating the types of probes and data gathering typically undertaken, the forms of penetration attack mounted, and the means of concealing such attacks. An understanding of these techniques is key to the placement of effective countermeasures and auditing mechanisms.

78.3.8.2 Anatomy of a Hack

An attack can be divided into five broad stages:

1. *Intelligence*: initial information gathering on the target system from bulletin board information swaps, technical journals, and social engineering aimed at extracting key information from current or previous employees. Information collection also includes searching through discarded information (dumpster diving) or physical access to premises.
2. *Reconnaissance*: using a variety of initial probes and tests to check for target accessibility, security measures, and state of maintenance and upgrade.

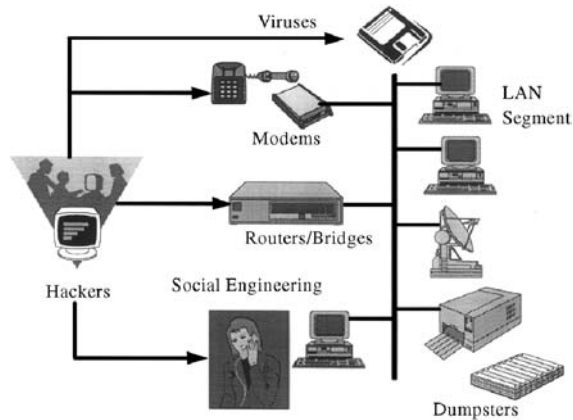

FIGURE 78.5 Possible attacks against IT systems.

3. *Penetration*: attacks to exploit known weaknesses or bugs in trusted utilities, the misconfiguration of systems, or the complete absence of security functionality.
4. *Camouflage*: modification of key system audit and accounting information to conceal access to the system, replacement of key system monitoring utilities.
5. *Advance*: subsequent penetration of interconnected systems or networks from the compromised system.

A typical hacking incident will contain all of these key elements. The view seen by a hacker attacking a target computer system is illustrated in Figure 78.5. There are many access routes which could be used.

78.3.8.3 Intelligence Gathering

A considerable amount of information is available on most commercial systems from a mix of public and semiopen sources. Examples range from monitoring posts on Usenet news for names, addresses, product information and technical jargon; probing databases held by centers such as the Internet Network Information Center (NIC); to the review of technical journals and professional papers. Information can be exchanged via hacker bulletin boards, shared by drop areas in anonymous FTP servers, or discussed on line in forums such as Internet Relay Chat (IRC).

Probably the most effective information gathering technique is known as social engineering. This basically consists of masquerade and impersonation to gain information or to trick the target into showing a chink in its security armor. Social engineering ranges from the shared drink in the local bar, to a phone call pretending to be the maintenance engineer, the boss, the security officer, or the baffled secretary who can't operate the system.

Techniques even include a brief spell as a casual employee in the target company. It is often surprising how much temporary staff, even cleaners, tend to be trusted. Physical access attacks include masquerading as legitimate employees (from another branch, perhaps) or maintenance engineers, to covert access using lockpicking techniques and tools (also available from bulletin boards).

Even if physical access to the interior of the building is impossible, access to discarded rubbish may be possible. So-called dumpster diving is a key part of a deliberate attack. Companies often discard key information including old system manuals, printouts with passwords/user codes, organization charts and telephone directories, company newsletters, etc. All this material lends credence to a social engineering attack, and may provide key information on system configuration which helps to identify exploitable vulnerabilities.

78.3.8.4 Reconnaissance

A wide variety of tools and techniques are available to probe for accessible systems on wide area networks (WAN) such as the Internet. Techniques include the following:

1. *Traceroute*: designed to send a series of Internet protocol (IP) packets with increasing time-to-live (TTL) values in order to determine the routing to the target, and to identify intermediate routers and Internet carriers which might be attacked.
2. *DNS dig tools*: designed to query the name-address translation services on the Internet domain name server (DNS) to retrieve a complete listing of all IP addresses within a specified domain. An example might be downloading a list of all MIL domain military systems.
3. *IP scanners*: designed to search a series of IP addresses for active systems. These operate by sending ICMP echo packets to each address in turn (or in random order) and awaiting a reply. These utilities can rapidly locate systems on class B and class C networks (with up to 65,534 and 254 hosts, respectively).
4. *Port scanners*: designed to search a specific system for transmission control protocol (TCP) and user datagram protocol (UDP) ports offering services. The port scanner will attempt to connect to each port in turn, verify whether the connection is accepted, and note which service is being offered. This can also include noting the version string which is sent by utilities such as Telnet (remote log in) and Sendmail [simple mail transfer protocol (SMTP) electronic mail] to check on possible vulnerabilities.
5. *RPCINFO*: designed to probe the portmapper on the remote system, which handles registration of remote procedure call (RPC) services. This allows the hacker to identify which RPC based services are being offered [such as the network filesystem (NFS) or network information system (NIS)].
6. *MOUNT*: designed to display the list of exported filesystems and associated security attributes, allowing the hacker to decide on the best target for NFS attacks.
7. *FINGER*: to check which users are active on the system (ruser is possible substitute), and to decide on busiest time and periods when no system administrator is logged on.

These probes allow an attacker to locate systems, identify which services are offered, gain some idea of the system usage patterns, and decide on an attack strategy.

78.3.8.5 Penetration

Once the hacker has gathered this key information, then exploitation of security weaknesses begins. If obvious configuration errors show up (such as a world exported NFS filesystem) or access via the anonymous file transfer protocol (FTP) or trivial file transfer protocol (TFTP) to the full filesystem, then this penetration is rapid. Otherwise the hacker has four courses of action:

1. Try to guess user code and passwords. Common default accounts such as ENGINEER, BIN, SYS, MAINT, GUEST, DIAG, ROOT, FIELD may have weak or default passwords. The hacker may make use of services such as FTP or rexec which do not log failed log-in attempts. Utilities such as *fbomb* use seed lists of common passwords to mount the attack.
2. Try to exploit vulnerabilities in network services such as Sendmail to gain access to the system. Key to the attack is a wide range of attack scripts available on the boards for swapping and trading, together with active participation in full disclosure security discussion lists such as INFOHAX and BUGTRAQ, which openly reveal the details of security holes.
3. Try to exploit weaknesses in the network protocols themselves such as the IP spoofing attack discussed subsequently.
4. Try to break into the network provider's system or network in order to capture user codes and passwords passed in clear across the provider's network. Once captured they can be used to break into the target system; failing which someone on the boards may be able to trade an account for other information.

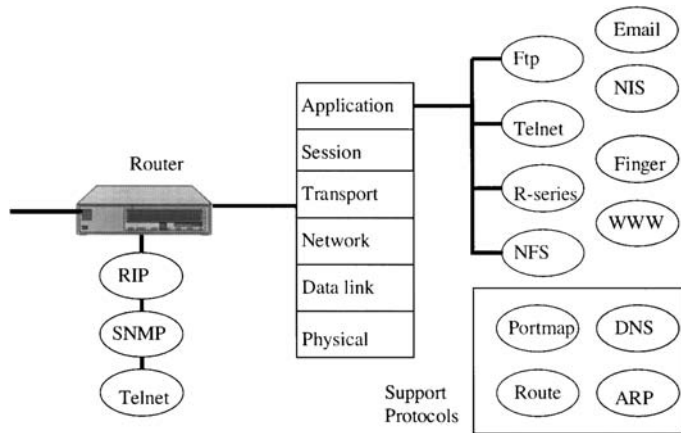

FIGURE 78.6 Network view of system services.

The proliferation of network services offered by systems, and the increasing intelligence of routers can assist the attacker. Figure 78.6 illustrates the range of services offered to the network by a typical Unix system. While many protocols are supported, each must be adequately secured to prevent system penetration.

78.3.8.6 Vulnerabilities and Exploitation

The increasing complexity and dynamicity of modern software is one of the key sources of software vulnerabilities. As an example, the Unix operating system now consists of over 2.8 million lines of C code, an estimated 67% of which execute with full privilege. With this size of code base there is a high likelihood of code errors which can open a window for remote exploitation via a network, or local exploitation by a user with an unprivileged account on the local system.

The main source of vulnerabilities are the assumptions made by system programmers about the operating environment of the software, these include:

- *Race conditions*: in which system software competes for access to a shared object. Unix-based operating systems do not support atomic transactions, and as such operations can be interrupted allowing malicious tampering with system resources. Race conditions are responsible for vulnerabilities in utilities such as `expreserve`, `passwd`, and `mail`. They have been widely exploited by the group known as the 8-legged groove machine (8lgm).
- *Buffer overruns*: allowing data inputs to overflow storage buffers and overwrite key memory areas. This form of attack was used by the Internet worm of November 1988 to overrun a buffer in the `fingerd` daemon causing the return stack frame to be corrupted, leading to a root privileged shell being run. Similar forms of attack were used against World Wide Web (WWW) servers.
- *Security responsibilities*: in which one component of a security system assumes the other is responsible for implementing access control or authentication, an example being the Berkeley Unix line printer daemon, which assumed that the front end utility (`lpr`) carried out security checks. This allowed an attacker to connect directly to the line printer and bypass security checks.
- *Argument checking*: utilities which do not fully validate the arguments they are invoked with, allowing illegal access to trusted files. An example was the failure of the TFTP daemon in AIX to check for inclusion of “.” components in a filename. This allowed access outside a secure directory area.
- *Privilege bracketing*: privileged utilities which fail to correctly contain their privilege, and in particular allow users to run commands in a privileged subshell via shell escapes.

Examples of vulnerabilities in the past have included:

- An argument to the log-in command which indicated that authentication had already been carried out by a graphical front end *logintool* and that no further password checks were needed.
- An argument to the log-in command which allowed direct log in with root privileges, or allowed key system files (such as */etc/passwd*) to be modified so that they are owned by the unprivileged user logging in.
- A sequence of commands to the sendmail mail program via the SMTP which allowed arbitrary commands to be run with system privileges. This was a new manifestation of an old bug from 1988. The new bug allowed a hacker to cause a mail message to be bounced by the target system and automatically returned to the sender address. This address was a program which would take the mail message as standard input.
- Dynamic library facilities added to newer operating systems allowed an attacker to trick privileged setuid programs into running a Trojanized version of the system library.
- Bugs in the FTP server which allowed a user to begin anonymous (unprivileged) log in, overwrite the buffer containing the user information with the information for a privileged account, and then complete the log-in process. Since the server still believed this was an anonymous log in, no password was requested.

Vulnerabilities often manifest in other forms and on other operating systems. An example is the *expresserve* bug in the editor recovery software, which was first fixed by Berkeley, then fixed by Sun Microsystems, and finally in a slightly modified form by AT&T.

Penetration scripts circulate widely in the security and hacker community. These scripts effectively deskill hacking, allowing even novices to attack and compromise operating system security. The hacker threat is dynamic and rapidly evolving, new vulnerabilities are discovered, vendors promulgate patches, system administrators upgrade, hackers try again. A single operating system release had 1200 fielded patches, 35 of which were security critical. It is difficult, if not impossible, for system administrators to track patch releases and maintain a secure up-to-date operating system configuration. On a network as large and diverse as the Internet (6.5 million systems, 30 million users in 1995), hackers will always find a vulnerable target which is not correctly configured or upgraded.

78.3.8.7 Automated Penetration Tools

The task of verifying the security of a system configuration is complex. Security problems originate from insecure manufacturer default configurations; configurations drift as administrators upgrade and maintain the system; vulnerabilities and bugs in software. Tools have been developed to assist in this task, allowing the following:

- Checking of filesystem security settings and configuration files for obvious errors: these include the Computer Oracle & Password System (COPS), Tiger, and Security Profile Inspector (SPI).
- Verifying that operating system utilities are up to date and correctly patched: this is a function included in Tiger and in SPI which use checksum checks on utility files to verify patch installation, and in SATAN and the Internet Security Scanner (ISS) which directly probe for vulnerabilities in network servers.
- Monitoring system configuration to check for malicious alteration of key utilities: this is based on the use of integrity checkers generating checksums of software such as Tripwire.

These tools are extremely powerful, but represent a two-edged sword. Remote probe utilities such as SATAN can be used directly by hackers to scan remote systems for known vulnerabilities. The use of automated attack tools is allowing hackers to screen hundreds of systems within seconds. Initial probes were based on TFTP attack, but now cover a much wider range of protocols including NFS. The NFSBUG security tool allows rapid checking and exploitation of vulnerabilities including mounting of world accessible partitions, forgery of credentials, and exploitation of implementation errors.

78.3.8.8 Camouflage

After system penetration, hackers will attempt to conceal their presence on the system by altering system log files, audit trails, and key commands. Initial tools such as *cloak* work by altering log files such as *utmp* and *wtmp*, which record system log ins, and altering the system accounting trail.

Second-generation concealment techniques also modified key system utilities such as *ps*, *ls*, *netstat*, and *who* which report information on system state to the administrator. An example is the *rootkit* set of utilities which provides C source code replacements for many key utilities. Once rootkit is installed, the hacker becomes effectively invisible.

Hidden file techniques can also be used to conceal information (using the hidden attribute in DOS, the invisible attribute on the Macintosh, or the “.” prefix on Unix), together with more sophisticated concealment techniques based on steganographic methods such as concealing data in bit-mapped images.

78.3.8.9 Advance

Once hackers are active on a system there are a number of additional attacks open to them, including the following:

- Exploiting system configuration errors and vulnerabilities to gain additional privilege, such as breaking into the bin, sys, daemon, and root accounts
- Using Trojanized utilities such as telnet to record passwords used to access remote systems
- Implanting trapdoors, which allow easy access to hackers with knowledge of a special password
- Monitoring traffic on the local area network to gather passwords and access credentials passed in clear
- Exhaustive password file dictionary attacks

These attacks aim at breaking into systems on the same network or on networks accessed by users on the local system. Typically, a small network sniffer (such as *sunsniff*) would be run on the compromised system; this would monitor all TCP-based connections collecting the first 128 bytes of traffic on each virtual circuit in the hope of collecting passwords and user codes. These sniffers log information in hidden files for later recovery.

Vulnerabilities and system configuration errors may also allow the compromise of a privileged account, and subsequent alteration of key utilities such as telnet or FTP may demand passwords from users. These modified utilities can store information for later retrieval. The system log-in utility can be modified to add a simple trapdoor allowing privileged access even if the system administrator has revoked the compromised account originally used for access.

Systems within the same organization often trust each other through the use of explicit trust relationships. A typical example is the r-series protocols from Berkeley which allow a system administrator or user to specify a list of systems which are trusted to log in to corresponding user accounts on the local system without specifying a password. This is very powerful for simplifying administration but very dangerous once a system in the organization is penetrated. The growth of these trust relations over time has been likened to the growth of ivy on old oak trees.

Finally, older systems are susceptible to password cracking style attacks. In these attacks the hacker will take advantage of the one-way encryption algorithm used in Unix to hash plain text passwords to cipher text. This is done by exhaustively encrypting each word in a standard dictionary and then comparing the encrypted version against the stored password cipher text. If the two versions match, then the word can be used as the password for that account. Sophisticated tools are available for both the hacker (to attack accounts) and the system administrator (to proactively check for weak passwords). An example is the crack tool which allows for rule-based transformation of dictionary words to mimic common substitutions, such as replacing I by l or O by 0.

78.3.8.10 Countermeasures

Four major categories of countermeasure are available to counter the hacker threat, they are as follows:

- Firewalls: designed to provide security barriers to prevent unauthorized access to internal systems within an organization from an untrusted network.
- Audit and intrusion detection: designed to provide effective on-line monitoring of systems for unauthorized access.
- Configuration management: to ensure that systems are correctly configured and maintained.
- Community action: to jointly monitor hacker activities and take appropriate action.

78.3.8.10.1 Firewall/Gateway Systems

Firewall systems aim to defend internal systems against unauthorized access from an untrusted network.

The firewall consists of two main components:

1. Screening or choke router is designed to prevent external access to an internal system other than the bastion host, in addition to restricting incoming protocols to a safer subset such as telnet, FTP and SMTP.
2. Bastion host or firewall authenticates and validates each external access attempt based on a pre-defined access control list. The bastion host also acts as a proxy by connecting legitimate external users to services on internal systems. Finally, the bastion host will also conceal the structure of the internal network by rewriting outgoing mail addresses and force all outgoing internal connections to be routed through the firewall proxy.

Firewalls are now being evaluated and certified under both the U.S. Trusted Computer Security Evaluation Criteria (TCSEC) and U.K. IT security evaluation criteria (ITSEC). A firewall is an effective barrier defense against external penetration, and if deployed internally within organizations it can also provide protection against insider threats. To be effective a firewall has to be supplemented by strong cryptographic authentication mechanisms based on challenge-response style mechanisms or one-time pads. Without such mechanisms user accounts and passwords will still be carrier unencrypted over Internet provider networks.

78.3.8.10.2 Audit and Intrusion Detection Mechanisms

Initial barrier defenses can be supplemented by effective monitoring of networks and systems. Traffic flow analysis can provide an indication of which systems are accessing the organization. Firewall products offer extensive logging of connection attempts, both failed and successful. Intrusion detection systems are being developed which permit user activity profiles to be constructed and allow deviation from established profiles of behavior to be flagged. Examples include the NIDES tool developed at SRI, and the Haystack tool from the U.S. Department of Energy. Key problems with intrusion detection are identifying effective behavior metrics and the processing of heterogeneous audit trails in a wide variety of vendor formats.

78.3.8.10.3 Configuration Management

The security of end systems can be improved through strict configuration management, and the use of a variety of proactive configuration checking tools such as COPS, Tiger, and SPI. These tools provide a means for rapidly checking filesystem security settings, verifying patch states, and correcting for the more obvious security blunders. Vendor specific tools such as Asset on the Sun platform are also available. The use of these tools should complement a policy that unnecessary functionality should be disabled on system installation.

78.3.8.10.4 Community Action

One of the most effective counters to hacker activity is community action. This takes two main forms: first, collectively reacting to security incidents; second, collectively investigating computer crime. Since the Internet worm of 1988, a series of incident response teams have been set up to deal with network

intrusions. An example (and the first of its kind) was the Computer Emergency Response Team (CERT) set up by Carnegie-Mellon University. The CERT provides support to the Internet constituency, providing the following:

- Point of contact for system administrators believing that their system has been compromised
- Means of disseminating security advice and alerts
- Lobbying body for pressuring vendors to fix security problems rapidly
- Central repository of knowledge on the nature of the hacker threat

CERT produces an extensive range of security alerts and advisories giving information on security problems, available fixes, and vendor contact points. The incident response teams work together in a forum known as the Forum for Incident Response and Security Teams (FIRST) to exchange information and techniques. The FIRST group provides a worldwide community of concerned security professionals. FIRST maintains a WWW archive site at www.first.org, which carries advisories and security advice.

The second form of community action is cooperation among law enforcement agencies to investigate computer crime. Most countries in the world now have some form of computer abuse legislation, an example being the Computer Misuse Act in the U.K. The form of legislation varies considerably in its coverage, definition of abuse, extraterritorial extent, and its available penalties. For example, the U.K. act defines three categories of offense:

1. Unauthorized access to computer systems, carrying up to 6 months in prison or a fine
2. Unauthorized access to computer systems with intent to facilitate other criminal acts, such as collecting information from a computer to perpetrate a fraud, carrying up to 5 years in prison
3. Unauthorized modification of data held on a computer system, again with a maximum 5-year penalty

The U.K. act has extraterritorial scope in that a crime is committed if a U.K. system is penetrated or if the penetration attempt originates from the U.K. Clifford Stoll's experiences of attempting to investigate and track a hacker (related in *The Cuckoo's Egg*) clearly indicated the problem of persuading law enforcement agencies in the U.S., Canada, and Europe to work together to track an intruder. In the modern computer world, an attacker can go indirectly through Columbia, China, Nicaragua, and Brazil, making tracking and enforcement a world problem.

Interpol has established a computer crime working group which is attempting to build links between European police forces (including the former Soviet Union), in order to facilitate investigation, share experiences, and unify computer crime legislation.

78.3.8.11 Phreaking

In contrast to hacking, phreaking is the penetration and misuse of telephone systems. Since the replacement of older crossbar and Strowger switches by digital exchanges, this has become a very nebulous distinction.

Phreaking was born out of the early days of analog switches in which exchanges carried signaling information (such as the number dialed by a subscriber) in-band as part of the voice channel. Signaling information was passed by a series of dual-tone multifrequency (DTMF) codes. The U.S. telephone carriers making use of an international standard Consultative Committee of International Telephony and Telegraphy-5 (CCITT-5), which uses combinations of 700-, 900-, 1100-, 1300-, and 1500-Hz tones to signal line state and number dialed. There was little to prevent a phreaker from generating comparable tones via a PC sound card or a simple oscillator (or box).

In particular, U.S. carriers used a single 2600-Hz tone to signal to trunk equipment that a local call had finished, and that the trunk equipment should be placed in idle mode awaiting the next call. A hacker could inject a 2600-Hz tone, reset the trunk line, and then dial the number required in CCITT-5 format. This technique also allowed the phreaker to evade call billing, and thus proved quite popular with hackers needing to access remote computer systems or bulletin boards.

78.3.8.11.1 Colored Boxing

The history of phone phreaking revolved around 2600 Hz. Early stories include a famous phreaker named Captain Crunch, who discovered that a whistle in a breakfast cereal packet generated exactly the correct frequency, to a blind phone phreaker whose perfect pitch allowed him to whistle up the 2600-Hz carrier. A whole spectrum of boxes were built (with plans swapped on the boards) to generate tone sets such as CCITT-5 (a blue box) or the 2200-Hz pulses generated by U.S. coin boxes to signal insertion of coins (a red box) or a combination of both (a silver box). Instructions range from building lineman's handsets (to tap local loops), to ways of avoiding billing by simulating an on-hook condition while making calls, and to ways of disrupting telephone service by current pulses injected on telephone lines.

The move from in-band signaling to common carrier signaling is reducing the risk of boxing attacks. Common carrier signaling carries signaling information for a cluster of calls on a separate digital circuit rather than in-band where it may be susceptible to attack. Older switching equipment in developing countries, and in specialist networks (such as 1-800) are still being targeted.

78.3.8.11.2 War Dialers

The worlds of hacking and phone phreaking come together in the war dialer. A war dialer is a device designed to exhaustively scan a range of numbers on a specific telephone exchange looking for modems, fax machines, and interesting line characteristics. War dialers were also capable of randomizing the list of numbers to be searched (to avoid automated detection mechanisms), to automatically log line states, and to automatically capture the log-in screen presented by a remote computer system. While U.S. telecom charging policies often meant that local calls were free (encouraging a bulletin board culture), to use long distance meant the use of phone phreaking to avoid call billing.

War dialers such as Toneloc and Phonetag offered an effective way of screening over 2000 lines per night. Boards regularly carried the detailed results of these scans for each area code in the U.S.

78.3.8.11.3 Modems

A war dial scan was likely to detect many modems with various levels of security, ranging from unprotected to challenge-response authentication. A popular defensive technique was the use of a dial-back facility, in which the user was identified to the modem, which would then ring the user back on a predefined number. If the modem used the same incoming line to initiate dial-back, a hacker could generate a simulated dial tone to trick the modem into believing that the line had been dropped and that dial-back could begin. The identification of modems also led to a range of other problems:

- Publicly accessible network gateways, which allowed an authorized user to access WAN functionality by dialing in: This led to system intrusion over the Internet which could not be traced back beyond the public dial in.
- Diagnostic modems for computer systems, for PABXs, and for PTT trunk switches: This opened the door to direct attacks on the digital switches with weak password security.

The details of such switches are widely exchanged in the underground (particularly the Unix-based 5-ESS switch from AT&T) with considerable knowledge of the methods for reconfiguration of switches to change quality of service on lines, or to compromise subscriber information. Subscriber information such as the reverse mapping between subscriber number and name/address has been openly sold by phreakers.

78.3.8.11.4 Phone Loops

Phone loops refer to a linked pair of subscriber circuits used for testing purposes. Callers dialing both circuits will be automatically interconnected. Numbers for phone loops were widely swapped among phreakers to provide a convenient forum for phreaker/hacker conferences.

78.3.8.11.5 PABX Penetration

Private automatic branch exchanges are open to a range of attacks including weak security on diagnostic modem lines and misconfiguration of switches. These systems are now a common target providing a

convenient springboard for long-distance attacks. An example might be an attacker who calls into the PABX and then uses private wire circuits belonging to the firm to call out to countries overseas. Direct inward system access (DISA) facilities provide a rich facility set for legitimate company workers outside the office, including call diversion, conferencing, message pickup, etc. If misconfigured these facilities can compromise the security of the company and permit call fraud.

78.3.8.11.6 Cellular Phones

Cellular phone technology is still in its infancy in many countries with many analog cellular systems in common usage. Analog cellular phones are vulnerable in a number of areas:

- Call interception: no encryption or scrambling of the call is carried out, calls can therefore be directly monitored by an attacker with a VHF/UHF scanner. U.S. scanners are modified to exclude the cellular phone band, but the techniques for reversing the modification are openly exchanged.
- Signaling interception: signaling information for calls is also carried in clear including the telephone number/electronic serial number (ESN) pair used to authenticate the subscriber. This raises the risk of this information being intercepted and replayed for fraudulent use.
- Reprogramming: commercial phones are controlled by firmware in ROM (or flash ROM) and can be reprogrammed with appropriate interface hardware or access to the manufacturers security code.

Three forms of attack have been described: the simple reprogramming of a cellular phone to an ESN captured on-air or by interrogating a cellular phone; the tumbler, in which a telephone number/ESN pair is randomly generated; and the vampire, in which a modified phone rekeys itself with an ESN intercepted directly over the air.

The use of modified cellular phones provides a linkage between the phreaker community and organized crime. In particular, lucrative businesses have been set up in allowing immigrants to call home at minimal cost on stolen cellular phones or telephone credit cards. Newer digital networks such as GSM are encrypted and not open to the same form of direct interception attack.

78.3.8.11.7 Carding

The final category of malicious attack is aimed at the forgery of credit and telephone card information. A key desire is to make free phone calls to support hacking activities. Four techniques have been used:

1. Reading the magnetic stripe on the back of a credit card using a commercial stripe reader. This stripe can then be duplicated and affixed to a blank card or legitimate card.
2. Generating random credit card numbers for a chosen bank with a valid checksum digit. These numbers will pass the simple off-line authentication checks used by vendors for low-value purchases.
3. Using telephone card services to validate a series of randomly generated telephone card numbers generated by modem.
4. Compromising a credit card number in transit over an untrusted network, such as the Internet.

The last category is a growing problem with the increasing range of commercial agencies now attempting to carry out business on the Internet. The introduction of secure electronic funds transfer systems is key to supporting the growth of electronic commerce on the Internet.

78.4 The Future

78.4.1 Computer Security

The level of technical sophistication of computer systems, telecomm switches, router and network infrastructure continues to grow. With increasing complexity comes increasing vulnerability. The focus of hacker attacks has moved with improving security measures, as the attackers seek to find a weak point in system defenses. Common carrier signaling is more secure than in-band, but the digital switches are vulnerable.

Firewalls protect end systems but the network infrastructure can be attacked. Security is improving over time, but the level of technical attack sophistication continues to rise.

78.4.2 National Information Infrastructure

The U.S. vision of the information superhighways is leading to growing internetworking and a move toward ubiquitous computing. This move is increasing our use of and dependence on networks. Security will become a key issue on these networks, not just protection against casual penetration but also against deliberate motivated attack by organized crime, terrorists, or anarchists: the beginning of information warfare. The organization of effective coordinated defenses against threats against our infrastructure will be one of the key challenges.

The Access Control Matrix • Implementation Approaches
• Access Control Policies • Administration of Authorization

79.4 Auditing and Intrusion Detection

Intrusion Detection Systems • Audit Control Issues

79.5 Conclusion

79.1 Introduction

An important requirement of any information management system is to protect information against improper disclosure or modification (known as confidentiality and integrity, respectively). Three mutually supportive technologies are used to achieve this goal. Authentication, access control, and audit together provide the foundation for information and system security as follows. *Authentication* establishes the identity of one party to another. Most commonly, authentication establishes the identity of a user to some part of the system typically by means of a password. More generally, authentication can be computer-to-computer or process-to-process and mutual in both directions. *Access control* determines what one party will allow another to do with respect to resources and objects mediated by the former. Access control usually requires authentication as a prerequisite. The *audit* process gathers data about activity in the system and analyzes it to discover security violations or diagnose their cause. Analysis can occur off line after the fact or it can occur on line more or less in real time. In the latter case, the process is usually called *intrusion detection*. This chapter discusses the scope and characteristics of these security controls.

Figure 79.1 is a logical picture of these security services and their interactions. Access control constrains what a user can do directly as well as what programs executing on behalf of the user are allowed to do. Access control is concerned with limiting the activity of legitimate users who have been successfully authenticated. It is enforced by a reference monitor, which mediates every attempted access by a user (or program executing on behalf of that user) to objects in the system. The reference monitor consults an authorization database to determine if the user attempting to do an operation is actually authorized to perform that operation. Authorizations in this database are administered and maintained by a security administrator.

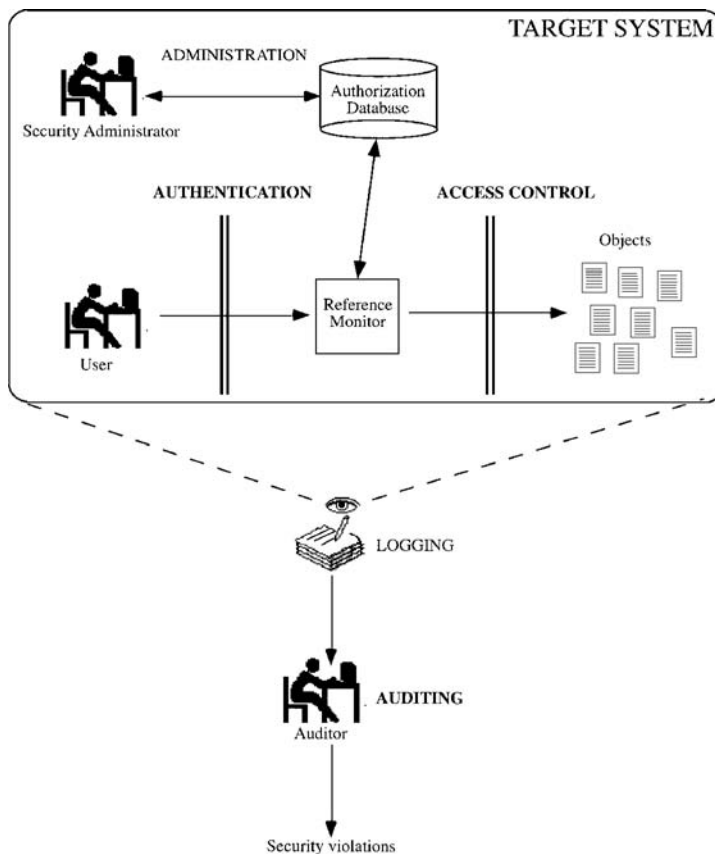

FIGURE 79.1 Access control and other security services.

The administrator sets these authorizations on the basis of the security policy of the organization. Users may also be able to modify some portion of the authorization database, for instance, to set permissions for their personal files. Auditing monitors and keeps a record of relevant activity in the system.

Figure 79.1 is a logical picture and should not be interpreted literally. For instance, as we will see later, the authorization database is often stored with the objects being protected by the reference monitor rather than in a physically separate area. The picture is also somewhat idealized in that the separation between authentication, access control, auditing, and administration services may not always be so clear cut. This separation is considered highly desirable but is not always faithfully implemented in every system.

It is important to make a clear distinction between authentication and access control. Correctly establishing the identity of the user is the responsibility of the authentication service. Access control assumes that identity of the user has been successfully verified prior to enforcement of access control via a reference monitor. The effectiveness of the access control rests on a proper user identification and on the correctness of the authorizations governing the reference monitor.

It is also important to understand that access control is not a complete solution for securing a system. It must be coupled with auditing. Audit controls concern a posteriori analysis of all of the requests and activities of users in the system. Auditing requires the recording of all user requests and activities for their later analysis. Audit controls are useful both as a deterrent against misbehavior and as a means to analyze the users' behavior in using the system to find out about possible attempted or actual violations. Auditing can also be useful for determining possible flaws in the security system. Finally, auditing is essential to ensure that authorized users do not misuse their privileges: in other words, to hold users accountable for

their actions. Note that effective auditing requires that good authentication be in place; otherwise it is not possible to reliably attribute activity to individual users. Effective auditing also requires good access control; otherwise the audit records can themselves be modified by an attacker.

These three technologies are interrelated and mutually supportive. In the following sections, we discuss, respectively, authentication, access control, and auditing and intrusion detection.

79.2 Authentication

Authentication is in many ways the most primary security service on which other security services depend. Without good authentication, there is little point in focusing attention on strong access control or strong intrusion detection. The reader is surely familiar with the process of signing on to a computer system by providing an identifier and a password. In this most familiar form, authentication establishes the identity of a human user to a computer. In a networked environment, authentication becomes more difficult. An attacker who observes network traffic can replay authentication protocols to masquerade as a legitimate user.

More generally, authentication establishes the identity of one computer to another. Often, authentication is required to be performed in both directions. This is certainly true when two computers are engaged in communication as peers. Even in a client–server situation mutual authentication is useful. Similarly, authentication of a computer to a user is also useful to prevent against spoofing attacks in which one computer masquerades as another (perhaps to capture user identifiers and passwords).

Often we need a combination of user-to-computer and computer-to-computer authentication. Roughly speaking, user-to-computer authentication is required to establish identity of the user to a workstation and computer-to-computer authentication is required for establishing the identity of the workstation acting on behalf of the user to a server on the system (and vice versa). In distributed systems, authentication must be maintained through the life of a conversation between two computers. Authentication needs to be integrated into each packet of data that is communicated. Integrity of the contents of each packet, and perhaps confidentiality of contents, also must be ensured.

Our focus in this chapter is on user-to-computer authentication. User-to-computer authentication can be based on one or more of the following:

- Something the user knows, such as a password
- Something the user possesses, such as a credit-card sized cryptographic token or smart card
- Something the user is, exhibited in a biometric signature such as a fingerprint or voice print

We now discuss these in turn.

79.2.1 Authentication by Passwords

Password-based authentication is the most common technique, but it has significant problems. A well-known vulnerability of passwords is that they can be guessed, especially because users are prone to selecting weak passwords. A password can be snooped by simply observing a user keying it in. Users often need to provide their password when someone else is in a position to observe it as it is keyed in. Such compromise can occur without the user even being aware of it. It is also hard for users to remember too many passwords, especially for services that are rarely used. Nevertheless, because of low cost and low technology requirements, passwords are likely to be around for some time to come.

An intrinsic problem with passwords is that they can be shared, which breaks down accountability in the system. It is all too easy for a user to give their password to another user. Sometimes poor system design actually encourages password sharing because there may be no other convenient means of delegating permissions of one user to another (even though the security policy allows the delegation).

Password management is required to prod users to regularly change their passwords, to select good ones, and to protect them with care. Excessive password management makes adversaries of users and security administrators, which can be counterproductive. Many systems can configure a maximum lifetime for a

password. Interestingly, many systems also have a minimum lifetime for a password. This has come about to prevent users from reusing a previous password when prompted to change their password after its maximum life has expired. The system keeps a history of, say, eight most recently used passwords for each user. When asked to change the current password the user can change it eight times to flush the history and then resume reuse of the same password. The response is to disallow frequent changes to a user's password!

Passwords are often used to generate cryptographic keys, which are further used for encryption or other cryptographic transformations. Encrypting data with keys derived from passwords is vulnerable to so-called dictionary attacks. Suppose the attacker has access to known plaintext, that is, the attacker knows the encrypted and plaintext versions of data that were encrypted using a key derived from a user's password. Instead of trying all possible keys to find the right one, the attacker instead tries keys generated from a list of, say, 20,000 likely passwords (known as a dictionary). The former search is usually computationally infeasible, whereas the latter can be accomplished in a matter of hours using commonplace workstations. These attacks have been frequently demonstrated and are a very real threat.

Operating systems typically store a user's password by using it as a key to some cryptographic transformation. Access to the so-called encrypted passwords provides the attacker the necessary known plaintext for a dictionary attack. The Unix system actually makes these encrypted passwords available in a publicly readable file. Recent versions of Unix are increasingly using shadow passwords by which these data are stored in files private to the authentication system. In networked systems, known plaintext is often visible in the network authentications protocols.

Poor passwords can be detected by off-line dictionary attacks conducted by the security administrators. Proactive password checking can be applied when a user changes his or her password. This can be achieved by looking up a large dictionary. Such dictionaries can be very big (tens of megabytes) and may need to be replicated at multiple locations. They can themselves pose a security hazard. Statistical techniques for proactive password checking have been proposed as an alternative [Davies and Ganesan 1993].

Selecting random passwords for users is not user friendly and also poses a password distribution problem. Some systems generate pronounceable passwords for users because these are easier to remember. In principle this is a sound idea but some of the earlier recommended methods for generating pronounceable passwords have been shown to be insecure [Ganesan and Davies 1994]. It is also possible to generate a sequence of one-time passwords that are used one-by-one in sequence without ever being reused. Human beings are not expected to remember these and must instead write them down or store them on laptop hard disks or removable media.

79.2.2 Token-Based Authentication

A token is a credit-card size device that the user carries around. Each token has a unique private cryptographic key stored within it, used to establish the token's identity via a challenge-response handshake. The party establishing the authentication issues a challenge to which a response is computed using the token's private key. The challenge is keyed into the token by the user and the response displayed by the token is again keyed by the user into the workstation to be communicated to the authenticating party. Alternately, the workstation can be equipped with a reader that can directly interact with the token, eliminating the need for the user to key in the challenge and response. Sometimes the challenge is implicitly taken to be the current time, so only the response needs to be returned (this assumes appropriately accurate synchronization of clocks).

The private key should never leave the token. Attempts to break the token open to recover the key should cause the key to be destroyed. Achieving this in the face of a determined adversary is a difficult task. Use of the token itself requires authentication; otherwise the token can be surreptitiously used by an intruder or stolen and used prior to discovery of the theft. User-to-token authentication is usually based on passwords in the form of a personal identification number (PIN).

Token-based authentication is much stronger than password-based authentication and is often called strong as opposed to weak authentication. However, it is the token that is authenticated rather than the

user. The token can be shared with other users by providing the PIN, and so it is vulnerable to loss of accountability. Of course, only one user at a time can physically possess the token.

Tokens can use secret key or public key cryptosystems. With secret key systems the computer authenticating the token needs to know the secret key that is embedded in the token. This presents the usual key distribution problem for secret key cryptography. With public key cryptography, a token can be authenticated by a computer that has had no prior contact with the user's token. The public key used to verify the response to a challenge can be obtained with public key certificates. Public key-based tokens have scalability advantages that in the long run should make them the dominant technique for authentication in large systems. However, the computational and bandwidth requirements are generally greater for public vs. secret key systems. Token-based authentication is a technical reality today, but it still lacks major market penetration and does cost money.

79.2.3 Biometric Authentication

Biometric authentication has been used for some time for high-end applications. The biometric signature should be different every time, for example, voice-print check of a different challenge phrase on each occasion. Alternately, the biometric signature should require an active input, for example, dynamics of handwritten signatures. Simply repeating the same phrase every time or using a fixed signature such as a fingerprint is vulnerable to replay attacks. Biometric authentication often requires cumbersome equipment, which is best suited for fixed installations such as entry into a building or room.

Technically the best combination would be user-to-token biometric authentication, followed by mutual cryptographic authentication between the token and system services. This combination may emerge sooner than one might imagine. Deployment of such technology on a large scale is certain to raise social and political debate. Unforgeable biometric authentication could result in significant loss of privacy for individuals. Some of the privacy issues may have technical solutions, whereas others may be inherently impossible.

79.2.4 Authentication in Distributed Systems

In distributed systems, authentication is required repeatedly as the user uses multiple services. Each service needs authentication, and we might want mutual authentication in each case. In practice, this process starts with a user supplying a password to the workstation, which can then act on the user's behalf. This password should never be disclosed in plaintext on the network. Typically, the password is converted to a cryptographic key, which is then used to perform challenge-response authentication with servers in the system. To minimize exposure of the user password, and the long-term key derived from it, the password is converted into a short-term key, which is retained on the workstation, while the long-term user secrets are discarded. In effect these systems use the desktop workstation as a token for authentication with the rest of the network. Trojan horse software in the workstation can, of course, compromise the user's long-term secrets.

The basic principles just outlined have been implemented in actual systems in an amazing variety of ways. Many of the early implementations are susceptible to dictionary attacks. Now that the general nature and ease of a dictionary attack are understood we are seeing systems that avoid these attacks or at least attempt to make them more difficult. For details on actual systems, we refer the reader to Kaufman et al. [1995], Neuman [1994], and Woo and Lam [1992].

79.3 Access Control

In this section we describe access control. We introduce the concept of an access matrix and discuss implementation alternatives. Then we explain discretionary, mandatory, and role-based access control policies. Finally, we discuss issues in administration of authorizations.

79.3.1 The Access Control Matrix

Security practitioners have developed a number of abstractions over the years in dealing with access control. Perhaps the most fundamental of these is the realization that all resources controlled by a computer system can be represented by data stored in objects (e.g., files). Therefore, protection of objects is the crucial requirement, which in turn facilitates protection of other resources controlled via the computer system. (Of course, these resources must also be physically protected so they cannot be manipulated, directly bypassing the access controls of the computer system.)

Activity in the system is initiated by entities known as subjects. Subjects are typically users or programs executing on behalf of users. A user may sign on to the system as different subjects on different occasions, depending on the privileges the user wishes to exercise in a given session. For example, a user working on two different projects may sign on for the purpose of working on one project or the other. We then have two subjects corresponding to this user, depending on the project the user is currently working on.

A subtle point that is often overlooked is that subjects can themselves be objects. A subject can create additional subjects in order to accomplish its task. The children subjects may be executing on various computers in a network. The parent subject will usually be able to suspend or terminate its children as appropriate. The fact that subjects can be objects corresponds to the observation that the initiator of one operation can be the target of another. (In network parlance, subjects are often called initiators, and objects are called targets.)

The subject-object distinction is basic to access control. Subjects initiate actions or operations on objects. These actions are permitted or denied in accord with the authorizations established in the system. Authorization is expressed in terms of access rights or access modes. The meaning of access rights depends on the object in question. For files, the typical access rights are read, write, execute, and own. The meaning of the first three of these is self-evident. Ownership is concerned with controlling who can change the access permissions for the file. An object such as a bank account may have access rights inquiry, credit and debit corresponding to the basic operations that can be performed on an account. These operations would be implemented by application programs, whereas for a file the operations would typically be provided by the operating system.

The access matrix is a conceptual model that specifies the rights that each subject possesses for each object. There is a row in this matrix for each subject and a column for each object. Each cell of the matrix specifies the access authorized for the subject in the row to the object in the column. The task of access control is to ensure that only those operations authorized by the access matrix actually get executed. This is achieved by means of a reference monitor, which is responsible for mediating all attempted operations by subjects on objects. Note that the access matrix model clearly separates the problem of authentication from that of authorization.

An example of an access matrix is shown in Figure 79.2, where the rights R and W denote read and write, respectively, and the other rights are as previously discussed. The subjects shown here are John, Alice, and Bob. There are four files and two accounts. This matrix specifies that, for example, John is the owner of file 3 and can read and write that file, but John has no access to file 2 or file 4. The precise meaning of ownership varies from one system to another. Usually the owner of a file is authorized to grant other users access to the file as well as revoke access. Because John owns file 1, he can give Alice the R right and Bob the R and W rights, as shown in Figure 79.2. John can later revoke one or more of these rights at his discretion.

	File 1	File 2	File 3	File 4	Account 1	Account 2
John	Own R W		Own R W		Inquiry Credit	
Alice	R	Own R W	W	R	Inquiry Debit	Inquiry Credit
Bob	R W	R		Own R W		Inquiry Debit

FIGURE 79.2 An access matrix.

The access rights for the accounts illustrate how access can be controlled in terms of abstract operations implemented by application programs. The inquiry operation is similar to read in that it retrieves information but does not change it. Both the credit and debit operations will involve reading the previous account balance, adjusting it as appropriate, and writing it back. The programs that implement these operations require read and write access to the account data. Users, however, are not allowed to read and write the account object directly. They can manipulate account objects only indirectly via application programs, which implement the debit and credit operations.

Also note that there is no own right for accounts. Objects such as bank accounts do not really have an owner who can determine the access of other subjects to the account. Clearly the user who establishes the account at the bank should not be the one to decide who can access the account. Within the bank different officials can access the account on the basis of their job functions in the organization.

79.3.2 Implementation Approaches

In a large system, the access matrix will be enormous in size, and most of its cells are likely to be empty. Accordingly, the access matrix is very rarely implemented as a matrix. We now discuss some common approaches to implementing the access matrix in practical systems.

79.3.2.1 Access Control Lists

A popular approach to implementing the access matrix is by means of access control lists (ACLs). Each object is associated with an ACL, indicating for each subject in the system the accesses the subject is authorized to execute on the object. This approach corresponds to storing the matrix by columns. ACLs corresponding to the access matrix of Figure 79.2 are shown in Figure 79.3. Essentially, the access matrix column for file 1 is stored in association with File 1, and so on.

By looking at an object's ACL, it is easy to determine which modes of access subjects are currently authorized for that object. In other words, ACLs provide for convenient access review with respect to an object. It is also easy to revoke all access to an object by replacing the existing ACL with an empty one. On the other hand, determining all of the accesses that a subject has is difficult in an ACL-based system. It is necessary to examine the ACL of every object in the system to do access review with respect to a subject. Similarly, if all accesses of a subject need to be revoked all ACLs must be visited one by one. (In practice,

FIGURE 79.3 Access control lists for files in Figure 79.2.

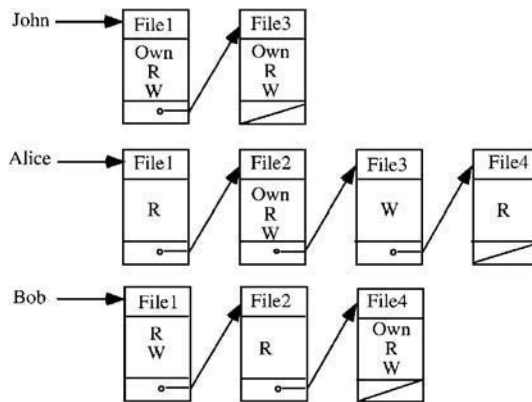

FIGURE 79.4 Capability lists for files in Figure 79.2.

revocation of all accesses of a subject is often done by deleting the user account corresponding to that subject. This is acceptable if a user is leaving an organization. However, if a user is reassigned within the organization it would be more convenient to retain the account and change its privileges to reflect the changed assignment of the user.)

Many systems allow group names to occur in ACLs. For example, an entry such as (ISSE, R) can authorize all members of the ISSE group to read a file. Several popular operating systems, such as Unix and VMS, implement an abbreviated form of ACLs in which a small number, often only one or two, of group names can occur in the ACL. Individual subject names are not allowed. With this approach, the ACL has a small fixed size so it can be stored using a few bits associated with the file. At the other extreme, there are a number of access control packages that allow complicated rules in ACLs to limit when and how the access can be invoked. These rules can be applied to individual users or to all users who match a pattern defined in terms of user names or other user attributes.

79.3.2.2 Capabilities

Capabilities are a dual approach to ACLs. Each subject is associated with a list, called the capability list, indicating for each object in the system the accesses the subject is authorized to execute on the object. This approach corresponds to storing the access matrix by rows. Figure 79.4 shows capability lists for the files in Figure 79.2. In a capability list approach, it is easy to review all accesses that a subject is authorized to perform by simply examining the subject's capability list. However, determination of all subjects who can access a particular object requires examination of each and every subject's capability list. A number of capability-based computer systems were developed in the 1970s but did not prove to be commercially successful. Modern operating systems typically take the ACL-based approach.

It is possible to combine ACLs and capabilities. Possession of a capability is sufficient for a subject to obtain access authorized by that capability. In a distributed system, this approach has the advantage that repeated authentication of the subject is not required. This allows a subject to be authenticated once, obtain its capabilities, and then present these capabilities to obtain services from various servers in the system. Each server may further use ACLs to provide finer grained access control.

79.3.2.3 Authorization Relations

We have seen that ACL- and capability-based approaches have dual advantages and disadvantages with respect to access review. There are representations of the access matrix that do not favor one aspect of access review over the other. For example, the access matrix can be represented by an authorization relation (or table), as shown in Figure 79.5. Each row, or tuple, of this table specifies one access right of a subject to an object. Thus, John's accesses to file 1 require three rows. If this table is sorted by subject, we get the

Subject	Access mode	Object
John	Own	File 1
John	R	File 1
John	W	File 1
John	Own	File 3
John	R	File 3
John	W	File 3
Alice	R	File 1
Alice	Own	File 2
Alice	R	File 2
Alice	W	File 2
Alice	W	File 3
Alice	R	File 4
Bob	R	File 1
Bob	W	File 1
Bob	R	File 2
Bob	Own	File 4
Bob	R	File 4
Bob	W	File 4

FIGURE 79.5 Authorization relation for files in Figure 79.2.

effect of capability lists. If it is sorted by object, we get the effect of ACLs. Relational database management systems typically use such a representation.

79.3.3 Access Control Policies

In access control systems, a distinction is generally made between policies and mechanisms. Policies are high-level guidelines that determine how accesses are controlled and access decisions are determined. Mechanisms are low-level software and hardware functions that can be configured to implement a policy. Security researchers have sought to develop access control mechanisms that are largely independent of the policy for which they could be used. This is a desirable goal to allow reuse of mechanisms to serve a variety of security purposes. Often, the same mechanisms can be used in support of secrecy, integrity, or availability objectives. On the other hand, sometimes the policy alternatives are so many and diverse that system implementors feel compelled to choose one in preference to the others.

In general, there do not exist policies that are better than others. Rather there exist policies that ensure more protection than others. However, not all systems have the same protection requirements. Policies suitable for a given system may not be suitable for another. For instance, very strict access control policies, which are crucial to some systems, may be inappropriate for environments where users require greater flexibility. The choice of access control policy depends on the particular characteristics of the environment to be protected.

We will now discuss three different policies that commonly occur in computer systems as follows:

- Classic discretionary policies
- Classic mandatory policies
- The emerging role-based policies

We have added the qualifier classic to the first two of these to reflect the fact that these have been recognized by security researchers and practitioners for a long time. However, in recent years there is increasing consensus that there are legitimate policies that have aspects of both of these. Role-based policies are an example of this fact.

It should be noted that access control policies are not necessarily exclusive. Different policies can be combined to provide a more suitable protection system. This is indicated in Figure 79.6. Each of the

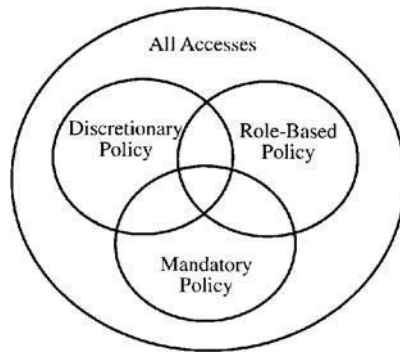

FIGURE 79.6 Multiple access control policies.

three inner circles represents a policy that allows a subset of all possible accesses. When the policies are combined, only the intersection of their accesses is allowed. Such a combination of policies is relatively straightforward so long as there are no conflicts where one policy asserts that a particular access *must* be allowed while another one prohibits it. Such conflicts between policies need to be reconciled by negotiations at an appropriate level of management.

79.3.3.1 Classic Discretionary Policies

Discretionary protection policies govern the access of users to the information on the basis of the user's identity and authorizations (or rules) that specify, for each user (or group of users) and each object in the system, the access modes (e.g., read, write, or execute) the user is allowed on the object. Each request of a user to access an object is checked against the specified authorizations. If there exists an authorization stating that the user can access the object in the specific mode, the access is granted, otherwise it is denied.

The flexibility of discretionary policies makes them suitable for a variety of systems and applications. For these reasons, they have been widely used in a variety of implementations, especially in the commercial and industrial environments.

However, discretionary access control policies have the drawback that they do not provide real assurance on the flow of information in a system. It is easy to bypass the access restrictions stated through the authorizations. For example, a user who is able to read data can pass it to other users not authorized to read it without the cognizance of the owner. The reason is that discretionary policies do not impose any restriction on the usage of information by a user once the user has read it, i.e., dissemination of information is not controlled. By contrast, dissemination of information is controlled in mandatory systems by preventing flow of information from high-level objects to low-level objects.

Discretionary access control policies based on explicitly specified authorization are said to be closed in that the default decision of the reference monitor is denial. Similar policies, called open policies, could also be applied by specifying denials instead of permissions. In this case, for each user and each object of the system, the access modes the user is forbidden on the object are specified. Each access request by a user is checked against the specified (negative) authorizations and granted only if no authorizations denying the access exist. The use of positive and negative authorizations can be combined, allowing the specification of both the accesses to be authorized as well as the accesses to be denied to the users. The interaction of positive and negative authorizations can become extremely complicated [Bertino et al. 1993].

79.3.3.2 Classic Mandatory Policies

Mandatory policies govern access on the basis of classification of subjects and objects in the system. Each user and each object in the system is assigned a security level. The security level associated with an object reflects the sensitivity of the information contained in the object, i.e., the potential damage that could result from unauthorized disclosure of the information. The security level associated with a user,

FIGURE 79.7 Controlling information flow for secrecy.

also called clearance, reflects the user's trustworthiness not to disclose sensitive information to users not cleared to see it. In the simplest case, the security level is an element of a hierarchical ordered set. In the military and civilian government arenas, the hierarchical set generally consists of top secret (TS), secret (S), confidential (C), and unclassified (U), where $TS > S > C > U$. Each security level is said to dominate itself and all others below it in this hierarchy.

Access to an object by a subject is granted only if some relationship (depending on the type of access) is satisfied between the security levels associated with the two. In particular, the following two principles are required to hold:

Read down: A subject's clearance must dominate the security level of the object being read.

Write up: A subject's clearance must be dominated by the security level of the object being written.

Satisfaction of these principles prevents information in high-level objects (i.e., more sensitive) to flow to objects at lower levels. The effect of these rules is illustrated in Figure 79.7. In such a system, information can flow only upward or within the same security class.

It is important to understand the relationship between users and subjects in this context. Let us say that the human user Jane is cleared to S and assume she always signs on to the system as an S subject (i.e., a subject with clearance S). Jane's subjects are prevented from reading TS objects by the read-down rule. The write-up rule, however, has two aspects that seem at first sight contrary to expectation:

- First, Jane's S subjects can write a TS object (even though they cannot read it). In particular, they can overwrite existing TS data and therefore destroy it. Because of this integrity concern, many systems for mandatory access control do not allow write up but limit writing to the same level as the subject. At the same time, write up does allow Jane's S subjects to send electronic mail to TS subjects and can have its benefits.
- Second, Jane's S subjects cannot write C or U data. This means, for example, that Jane can never send electronic mail to C or U users. This is contrary to what happens in the paper world, where S users can write memos to C and U users. This seeming contradiction is easily eliminated by allowing Jane to sign on to the system as a C or U subject as appropriate. During these sessions, she can send electronic mail to C or U and C subjects.

In other words, a user can sign on to the system as a subject at any level dominated by the user's clearance. Why then bother to impose the write-up rule? The main reason is to prevent malicious software from leaking secrets downward from S to U. Users are trusted not to leak such information, but the programs they execute do not merit the same degree of trust. For example, when Jane signs on to the system at U level, her subjects cannot read S objects and thereby cannot leak data from S to U. The write-up rule also prevents users from inadvertently leaking information from high to low.

In addition to hierarchical security levels, categories (e.g., Crypto, NATO, Nuclear) can also be associated with objects and subjects. In this case, the classification labels associated with each subject and each object

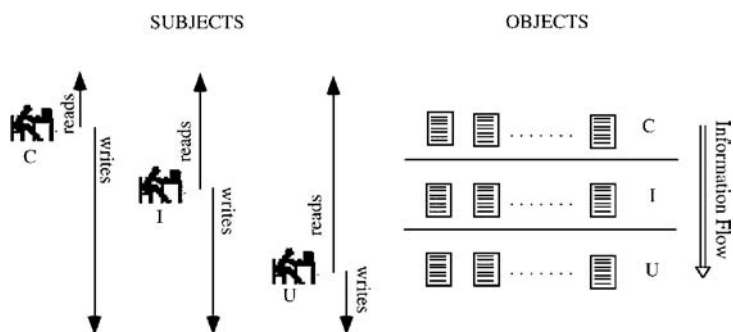

FIGURE 79.8 Controlling information flow for integrity.

consist of a pair composed of a security level and a set of categories. The set of categories associated with a user reflect the specific areas in which the user operates. The set of categories associated with an object reflect the area to which information contained in objects are referred. The consideration of categories provides a finer grained security classification. In military parlance, categories enforce restriction on the basis of the need-to-know principle, i.e., a subject should be given only those accesses that are required to carry out the subject's responsibilities.

Mandatory access control can as well be applied for the protection of information integrity. For example, the integrity levels could be crucial (C), important (I), and unknown (U). The integrity level associated with an object reflects the degree of trust that can be placed in the information stored in the object and the potential damage that could result from unauthorized modification of the information. The integrity level associated with a user reflects the user's trustworthiness for inserting, modifying, or deleting data and programs at that level. Principles similar to those stated for secrecy are required to hold, as follows:

Read up: A subject's integrity level must be dominated by the integrity level of the object being read.

Write down: A subject's integrity level must dominate the integrity level of the object being written.

Satisfaction of these principles safeguard integrity by preventing information stored in low objects (and therefore less reliable) to flow to high objects. This is illustrated in Figure 79.8. Controlling information flow in this manner is but one aspect of achieving integrity. Integrity in general requires additional mechanisms, as discussed in Castano et al. [1994] and Sandhu [1994].

Note that the only difference between Figure 79.7 and Figure 79.8 is the direction of information flow: bottom to top in the former case and top to bottom in the latter. In other words, both cases are concerned with one-directional information flow. The essence of classical mandatory controls is one-directional information flow in a lattice of security labels. For further discussion on this topic, see Sandhu [1993].

79.3.3.3 Role-Based Policies

The discretionary and mandatory policies previously discussed have been recognized in official standards, notably, the Orange Book of the U.S. Department of Defense. A good introduction to the Orange Book and its evaluation procedures is given in Chokhani [1992].

There has been a strong feeling among security researchers and practitioners that many practical requirements are not covered by these classic discretionary and mandatory policies. Mandatory policies rise from rigid environments, such as those of the military. Discretionary policies rise from cooperative yet autonomous requirements, such as those of academic researchers. Neither requirement satisfies the needs of most commercial enterprises. Orange Book discretionary policy is too weak for effective control of information assets, whereas Orange Book mandatory policy is focused on the U.S. Government policy for confidentiality of classified information. (In practice the military often finds Orange Book mandatory policies to be too rigid and subverts them.)

FIGURE 79.9 A role inheritance hierarchy.

Several alternatives to classic discretionary and mandatory policies have been proposed. These policies allow the specification of authorizations to be granted to users (or groups) on objects as in the discretionary approach, together with the possibility of specifying restrictions (as in the mandatory approach) on the assignment or on the use of such authorizations. One of the promising avenues that is receiving growing attention is that of role-based access control [Ferraiolo and Kuhn 1992, Sandhu et al. 1996].

Role-based policies regulate the access of users to the information on the basis of the activities the users execute in the system. Role-based policies require the identification of roles in the system. A role can be defined as a set of actions and responsibilities associated with a particular working activity. Then, instead of specifying all of the accesses each user is allowed to execute, access authorizations on objects are specified for roles. Users are given authorizations to adopt roles. A recent study by the National Institute of Standards and Technology (NIST) confirms that roles are a useful approach for many commercial and government organizations [Ferraiolo and Kuhn 1992].

The user playing a role is allowed to execute all accesses for which the role is authorized. In general, a user can take on different roles on different occasions. Also, the same role can be played by several users, perhaps simultaneously. Some proposals for role-based access control allow a user to exercise multiple roles at the same time. Other proposals limit the user to only one role at a time or recognize that some roles can be jointly exercised, whereas others must be adopted in exclusion to one another. As yet there are no standards in this arena, and so it is likely that different approaches will be pursued in different systems.

The role-based approach has several advantages. Some of these are discussed in the following:

- *Authorization management:* Role-based policies benefit from a logical independence in specifying user authorizations by breaking this task into two parts, one that assigns users to roles and one that assigns access rights for objects to roles. This greatly simplifies security management. For instance, suppose a user's responsibilities change, say, due to a promotion. The user's current roles can be taken away and new roles assigned as appropriate for the new responsibilities. If all authorization is directly between users and objects, it becomes necessary to revoke all existing access rights of the user and assign new ones. This is a cumbersome and time-consuming task.
- *Hierarchical roles:* In many applications, there is a natural hierarchy of roles based on the familiar principles of generalization and specialization. An example is shown in Figure 79.9. Here the roles of hardware and software engineer are specializations of the engineer role. A user assigned to the role of software engineer (or hardware engineer) will also inherit privileges and permissions assigned to the more general role of engineer. The role of supervising engineer similarly inherits privileges and permissions from both software-engineer and hardware-engineer roles. Hierarchical roles further simplify authorization management.
- *Least privilege:* Roles allow a user to sign on with the least privilege required for the particular task at hand. Users authorized to powerful roles do not need to exercise them until those privileges are actually needed. This minimizes the danger of damage due to inadvertent errors or by intruders masquerading as legitimate users.

- *Separation of duties*: Separation of duties refers to the principle that no users should be given enough privileges to misuse the system on their own. For example, the person authorizing a paycheck should not also be the one who can prepare them. Separation of duties can be enforced either statically (by defining conflicting roles, i.e., roles that cannot be executed by the same user) or dynamically (by enforcing the control at access time). An example of dynamic separation of duty is the two-person rule. The first user to execute a two-person operation can be any authorized user, whereas the second user can be any authorized user different from the first.
- *Object classes*: Role-based policies provides a classification of users according to the activities they execute. Analogously, a classification should be provided for objects. For example, generally a clerk will need to have access to the bank accounts, and a secretary will have access to the letters and memos (or some subset of them). Objects could be classified according to their type (e.g., letters, manuals) or to their application area (e.g., commercial letters, advertising letters). Access authorizations of roles should then be on the basis of object classes, not specific objects. For example, a secretary can be given the authorization to read and write the entire class of letters instead of being given explicit authorization for each single letter. This approach has the advantage of making authorization administration much easier and better controlled. Moreover, the accesses authorized on each object are automatically determined according to the type of the object without need of specifying authorizations on each object creation.

79.3.4 Administration of Authorization

Administrative policies determine who is authorized to modify the allowed accesses. This is one of the most important, and least understood, aspects of access controls.

In mandatory access control, the allowed accesses are determined entirely on the basis of the security classification of subjects and objects. Security levels are assigned to users by the security administrator. Security levels of objects are determined by the system on the basis of the levels of the users creating them. The security administrator is typically the only one who can change security levels of subjects or objects. The administrative policy is therefore very simple.

Discretionary access control permits a wide range of administrative policies. Some of these are described as follows:

- *Centralized*: A single authorizer (or group) is allowed to grant and revoke authorizations to the users.
- *Hierarchical*: A central authorizer is responsible for assigning administrative responsibilities to other administrators. The administrators can then grant and revoke access authorizations to the users of the system. Hierarchical administration can be applied, for example, according to the organization chart.
- *Cooperative*: Special authorizations on given resources cannot be granted by a single authorizer but needs cooperation of several authorizers.
- *Ownership*: Users are considered owners of the objects they create. The owner can grant and revoke access rights for other users to that object.
- *Decentralized*: In decentralized administration, the owner of an object can also grant other users the privilege of administering authorizations on the object.

Within each of these there are many possible variations.

Role-based access control has a similar wide range of possible administrative policies. In this case, roles can also be used to manage and control the administrative mechanisms.

Delegation of administrative authority is an important area in which existing access control systems are deficient. In large distributed systems, centralized administration of access rights is infeasible. Some existing systems allow administrative authority for a specified subset of the objects to be delegated by the central security administrator to other security administrators. For example, authority to administer

objects in a particular region can be granted to the regional security administrator. This allows delegation of administrative authority in a selective piecemeal manner. However, there is a dimension of selectivity that is largely ignored in existing systems. For instance, it may be desirable that the regional security administrator be limited to granting access to these objects only to employees who work in that region. Control over the regional administrators can be centrally administered, but they can have considerable autonomy within their regions. This process of delegation can be repeated within each region to set up subregions, and so on.

79.4 Auditing and Intrusion Detection

Auditing consists of examination of the history of events in a system to determine whether and how security violations have occurred or been attempted. Auditing requires registration or logging of users' requests and activities for later examination. Audit data are recorded in an *audit trail* or *audit log*. The nature and format of these data vary from system to system.

Information that should be recorded for each event includes the subject requesting the access, the object to be accessed, the operation requested, the time of the request, perhaps the location from which the requested originated, the response of the access control system, the amount of resources [central processing unit (CPU) time, input/output (I/O), memory, etc.] used, and whether the operation succeeded or, if not, the reason for the failure, and so on.

In particular, actions requested by privileged users, such as the system and the security administrators, should be logged. First, this serves as a deterrent against misuse of powerful privileges by the administrators as well as a means for detecting operations that must be controlled (the old problem of guarding the guardian). Second, it allows control of penetrations in which the attacker gains a privileged status.

Audit data can become voluminous very quickly and searching for security violations in such a mass of data is a difficult task. Of course, audit data cannot reveal all violations because some may not be apparent in even a very careful analysis of audit records. Sophisticated penetrators can spread out their activities over a relatively long period of time, thus making detection more difficult. In some cases, audit analysis is executed only if violations are suspected or their effects are visible because the system shows an anomalous or erroneous behavior, such as continuous insufficient memory, slow processing, or nonaccessibility of certain files. Even in this case, often only a limited amount of audit data, namely, those that may be connected with the suspected violation, are examined. Sometimes the first clue to a security violation is some real-world event which indicates that information has been compromised. That may happen long after the computer penetration occurred. Similarly, security violations may result in Trojan horses or viruses being implanted whose activity may not be triggered until long after the original event.

79.4.1 Intrusion Detection Systems

Recent research has focused on the development of automated tools to help or even to carry out auditing controls. Automated tools can be used to screen and reduce audit data that need to be reviewed by humans. These tools can also organize audit data to produce summaries and measures needed in the analysis. This data reduction process can, for instance, produce short summaries of user behaviors, anomalous events, or security incidents. The auditors can then go over summaries instead of examining each single event recorded. Another class of automated tools is represented by the so-called *intrusion detection systems*. The purpose of these tools is not only to automate audit data acquisition and reduction but also its analysis. Some of the more ambitious efforts attempt to perform intrusion detection in real time.

Intrusion detection systems can be classified as *passive* or *active*. Passive systems, generally operating off line, analyze the audit data and bring possible intrusions or violations to the attention of the auditor, who then takes appropriate actions (see [Figure 79.10](#)). Active systems analyze audit data in real time. Besides bringing violations to the attention of the auditor, these systems may take an immediate protective response on the system (see [Figure 79.11](#)). The protective response can be executed *ex post facto*, after the violation has occurred, or preemptively, to avoid the violation being perpetrated to completion.

FIGURE 79.10 Passive intrusion detection.

FIGURE 79.11 Active intrusion detection.

This latter possibility depends on the ability of the system to foresee violations. Protective responses include killing the suspected process, disconnecting the user, disabling privileges, or disabling user accounts. The response may be determined in total autonomy by the intrusion detection system or through interactions with the auditors.

Different approaches have been proposed for building intrusion detection systems. No single approach can be considered satisfactory with respect to different kinds of penetrations and violations that can occur. Each approach is appropriate for detecting a specific subset of violations. Moreover, each approach presents some pros and cons determined by the violations that can or cannot be controlled and by the amount and complexity of information necessary for its application. We now discuss the main intrusion detection approaches that have been attempted.

79.4.1.1 Threshold-Based Approach

The threshold-based approach is based on the assumption that the exploitation of system vulnerabilities involves abnormal use of the system itself. For instance, an attempt to break into a system can require trying several user accounts and passwords. An attempt to discover protected information can imply several, often denied, browsing operations through protected directories. A process infected by a virus can require an abnormal amount of memory or CPU resources.

Threshold-based systems typically control occurrences of specific events over a given period of time with respect to predefined allowable thresholds established by the security officer. For instance, more than three unsuccessful attempts to log in to a given account with the wrong password may indicate an attempt to penetrate that account. Multiple unsuccessful attempts to log in the system, using different accounts, concentrated in a short period of time, may suggest an attempt to break in.

Thresholds can also be established with respect to authorized operations to detect improper use of resources. For instance, a threshold can specify that print requests totaling more than a certain number of pages a day coming from the administrative office is to be considered suspicious. This misuse can be symptomatic of different kinds of violations such as the relatively benign misuse of the resource for personal use or a more serious attempt to print out working data for disclosure to the competition.

The threshold-based approach is limited by the fact that many violations occur without implying overuse of system resources. A further drawback of this approach is that it requires prior knowledge of how violations are reflected in terms of abnormal system use. Determining such connections and establishing appropriate thresholds are not always possible.

79.4.1.2 Anomaly-Based Approach

Like threshold-based controls, anomaly-based controls are based on the assumption that violations involve abnormal use of the system. However, whereas threshold-based systems define abnormal use with respect to prespecified fixed acceptable thresholds, anomaly-based systems define abnormal use as a use that is significantly different from that normally observed. In this approach, the intrusion detection system observes the behavior of the users in the target system and define profiles, i.e., statistical measures, reflecting the normal behavior of the users. Profiles can be defined with respect to different aspects to be controlled such as the number of events in a user session, the time elapsed between events in a user session, and the amount of resources consumed over a certain period of time or during execution of certain programs.

Construction of profiles from raw audit data is guided by rules that can be specified with respect to single users, objects, or actions as well as to classes of these. For instance, rules can state that profiles should be defined with respect to the number of pages printed every day by each user in the administration office, the number of resources per session and per day consumed by each user, the time elapsed between two log-in sessions for each single user, and some habit measures such as the time and the location from which a user generally logs in and the time the connections last. As users operate in the system, the intrusion detection system learns their behaviors with respect to the different profiles, thus defining what is normal and adapting the profiles to changes. Whenever a significant deviation occurs for a profile, an alarm is raised.

Statistical models that can be used include the *operational model*, the *mean and standard deviation model*, and *time series model*. With the operational model, an anomaly is raised when an observation exceeds a given acceptable threshold. This is similar to the threshold-based approach. With the mean and standard deviation model, an anomaly occurs when the observation falls outside an allowed confidence interval around the mean. For instance, an alarm can be raised if the CPU time consumed during a session for a user falls much below or above the CPU time generally consumed by the same user. With the time series model, an anomaly is raised when an event occurs at a given time at which the probability of its occurring is too low. For instance, a remote night-hour log-in request by a user who has never connected off hours or from outside the building may be considered suspicious.

The main advantage of the anomaly detection approach is that it does not require any a priori knowledge of the target system or of possible flaws from which the system may suffer. However, like the threshold-based approach, it can detect only violations that involve anomalous use. Moreover, some legitimate users may have a very erratic behavior (e.g., logging on and off at different hours or from different locations, varying their activity daily). For such users, no normal behavior can be actually established and misuse by them as well as by masqueraders exploiting their accounts would go undetected. The approach is also vulnerable from insiders who, knowing that behavior profiles are being defined, may either behave in a *bad* way from the beginning or slowly vary their behavior, going from *good* to *bad*, thus convincing the system that the bad behavior is normal.

79.4.1.3 Rule-Based Approach

In the rule-based approach, rules are used to analyze audit data for suspicious behavior independently from users' behavioral patterns. Rules describe what is suspicious on the basis of known past intrusions or known system vulnerabilities. This approach is generally enforced by means of expert systems encoding

knowledge of the security experts about past intrusions in terms of sequences of events or observable properties characterizing violations.

For instance, a rule can specify that a sequence of browsing operations (e.g., **cd**, **ls**, and **more** commands in a Unix environment) coming off hours from a remote location may be symptomatic of an intrusion. Rules can also identify suspicious sequences of actions. For example, withdrawal of a large amount of money from an account and its deposit back a few days later may be considered suspicious.

The rule-based approach can detect violations that do not necessarily imply abnormal use of resources. Its main limitation is that the expert knowledge encoded in the rules encompasses only known system vulnerabilities and attack scenarios or suspicious events. The system can therefore be penetrated by attackers employing new techniques.

79.4.1.4 Model-Based Reasoning Approach

The model-based reasoning approach is based on the definition, by the security officers, of models of proscribed intrusion activities [Garvey and Lunt 1991]. Proscribed activities are expressed by means of sequences of user behaviors (single events or observable measures), called scenarios.

Each component of a scenario is therefore a high-level observation on the system and does not necessarily correspond to an audit record (which contains information at a lower level of specification). From these high-level specifications, the intrusion detection system generates, on the basis of specified rules, the corresponding sequences of actions at the level of the audit records. Each audit record produced on the observation of the system is controlled against the specified scenarios to determine if a violation is being carried out. Audit data reduction and analysis can be modeled in such a way that only events relevant to specific scenarios corresponding to intrusions probably being carried out are examined. When the probability of a given scenario being followed passes a specified threshold, an alarm is raised informing the auditor of the suspected violation.

The basis of this approach is essentially the same as the rule-based approach, the main difference being the way in which controls are specified. Whereas in the rule-based approach the security officer must explicitly specify the control rules in terms of the audit data, in the model-based approach the security officer specifies the scenario only in terms of high-level observable properties. This constitutes the main advantage of this approach, which allows the security officer to reason in terms of high-level abstractions rather than audit records. It is the task of the system to translate the scenarios into corresponding rules governing data reduction and analysis.

Like the rule-based approach, this approach can control only violations whose perpetration scenario (i.e., actions necessary to fulfill them) are known. By contrast, violations exploiting unknown vulnerabilities or not yet tried violations cannot be detected.

79.4.1.5 State Transition-Based Approach

In the state transition-based approach, a violation is modeled as a sequence of actions starting from an initial state to a final compromised state [Ilgun et al. 1995]. A state is a snapshot of the target system representing the values of all volatile, semipermanent, and permanent memory locations. Between the initial and the final states there are a number of intermediate states and corresponding transitions. State transitions correspond to key actions necessary to carry out the violation. Actions do not necessarily correspond to commands issued by users but, instead, refer to how state changes within the system are achieved. A single command may produce multiple actions. Each state is characterized as a set of assertions evaluating whether certain conditions are verified in the system. For instance, assertions can check whether a user is the owner of an object or has some privileges on it, whether the user who caused the last two transitions is the same user, or whether the file to which an action is referred is a particular file. Actions corresponding to state transitions are accesses to files (e.g., read, write, or execute operations), or actions modifying the permissions associated with files (e.g., changes of owners or authorizations), or some of the files' characteristics (e.g., rename operations).

As the users operate in the system, state transitions caused by them are determined. Whenever a state transition causes a final compromised state to be reached, an alarm is raised. The state transition-based

approach can also be applied in a real-time active system to prevent users from executing operations that would cause a transition to a compromised state.

The state transition-based approach is based on the same concepts as the rule-based approach and therefore suffers from the same limitations, i.e., only violations whose scenarios are known can be detected. Moreover, it can be used to control only those violations that produce visible changes to the system state. Like the model-based approach, the state transition-based approach provides the advantage of requiring only high-level specifications, leaving the system the task of mapping state transitions into audit records and producing the corresponding control rules. Moreover, because a state transition can be matched by different operations at the audit record level, a single state transition specification can be used to represent different variations of a violation scenario (i.e., involving different operations but causing the same effects on the system).

79.4.1.6 Other Approaches

Other approaches have been proposed to complement authentication and access control to prevent violations from happening or to detect their occurrence.

One approach consists of preventing, rather than detecting, intrusions. In this class are tester programs that evaluate the system for common weaknesses often exploited by intruders and password checker programs that prevent users from choosing weak or obvious passwords (which may represent an easy target for intruders).

Another approach consists of substituting known bugged commands, generally used as trap doors by intruders, with programs that simulate the commands' execution while sending an alarm to the attention of the auditor. Other trap programs for intruders are represented by fake user accounts with *magic* passwords that raise an alarm when they are used.

Other approaches aim at detecting or preventing execution of Trojan horses and viruses. Solutions adopted for this include integrity checking tools that search for unauthorized changes to files and mechanisms controlling program executions against specifications of allowable program behavior in terms of operations and data flows.

Yet another intrusion detection approach is represented by the so-called keystroke latencies control. The idea behind the approach is that the elapsed time between keystrokes for regularly typed strings is quite consistent for each user. Keystroke latencies control can be used to cope against masqueraders. Moreover, they can also be used for authentication by controlling the time elapsed between the keystrokes when typing the password.

More recent research has interested intrusion detection at the network level [Mukherjee et al. 1994]. Analysis is performed on network traffic instead of on commands (or their corresponding low-level operations) issued on a system. Anomalies can then be determined, for example, on the basis of the probability of the occurrence of the monitored connections being too low or on the basis of the behavior of the connections. In particular, traffic is controlled against profiles of expected traffic specified in terms of expected paths (i.e., connections between systems) and service profiles.

79.4.2 Audit Control Issues

There are several issues that must be considered when employing intrusion detection techniques to identify security violations. These issues arise independently of the specific intrusion detection approach being utilized.

The task of generating audit records can be left to either the target system being monitored or the intrusion detection system. In the former case, the audit information generated by the system may need to be converted to a form understandable by the intrusion detection system. Many operating systems and database systems provide some audit information. However, this information often is not appropriate for security controls because it may contain data not relevant for detecting intrusions and omits details needed for identifying violations. Moreover, the audit mechanism of the target system may itself be vulnerable to

a penetrator who might be able to bypass auditing or modify the audit log. Thus, a stronger and more appropriate audit trail might be required for effective intrusion detection.

Another important issue that must be addressed is the retention of audit data. Because the quantity of audit data generated every day can be enormous, policies must be specified that determine when historical data can be discarded.

Audit events can be recorded at different granularity. Events can be recorded at the system command level, at the level of each system call, at the application level, at the network level, or at the level of each keystroke. Auditing at the application and command levels has the advantage of producing high-level traces, which can be more easily correlated, especially by humans (who would get lost in low-level details). However, the actual effect of the execution of a command or application on the system may not be reflected in the audit records and therefore cannot be analyzed. Moreover, auditing at such a high level can be circumvented by users exploiting alias mechanisms or by directly issuing lower level commands. Recording at lower levels overcomes this drawback at the price of maintaining a greater number of audit records (a single user command may correspond to several low-level operations) whose examination by humans (or automated tools) therefore becomes more complicated.

Different approaches can be taken with respect to the time at which the audit data are recorded and, in the case of real-time analysis, evaluated. For instance, the information that a user has requested execution of a process can be passed to the intrusion detection system at the time the execution is required or at the time it is completed. The former approach has the advantage of allowing timely detection and, therefore, a prompt response to stop the violation. The latter approach has the advantage of providing more complete information about the event being monitored (information on resources used or time elapsed can be provided only after the process has completed) and therefore allows more complete analysis.

Audit data recording or analysis can be carried out indiscriminately or selectively, namely, on specific events, such as events concerning specific subjects, objects, or operations, or occurring at a particular time or in a particular situation. For instance, audit analysis can be performed only on operations on objects containing sensitive information, on actions executed off hours (nights and weekends) or from remote locations, on actions denied by the access control mechanisms, or on actions required by mistrusted users.

Different approaches can be taken with respect to the time at which audit control should be performed. Real-time intrusion detection systems enforce control in real time, i.e., analyze each event at the time of its occurrence. Real-time analysis of data brings the great advantage of timely detection of violations. However, because of the great amount of data to analyze and the analysis to be performed, real-time controls are generally performed only on selected data, leaving a more thorough analysis to be performed off line. Approaches that can be taken include the following:

- *Period driven:* Audit control is executed periodically. For example, every night the audit data produced during the working day are examined.
- *Session driven:* Audit control on a user's session is performed when a close session command is issued.
- *Event driven:* Audit control is executed upon occurrence of certain events. For instance, if a user attempts to enter a protected directory, audit over the user's previous and/or subsequent actions is initiated.
- *Request driven:* Audit control is executed upon the explicit request of the security officer.

The intrusion detection system may reside either on the target computer system or on a separate machine. This latter solution is generally preferable because it does not impact the target systems performance and protects audit information and control from attacks perpetrated on the target system. On the other hand, audit data must be communicated to the intrusion detection machine, which itself could be a source of vulnerability.

A major issue in employing an intrusion detection system is privacy. Monitoring user behavior, even if intended for defensive purposes, introduces a sort of Big Brother situation where a centralized monitor is watching everybody's behavior. This may be considered an invasion of individual privacy. It also raises

concerns that audited information may be used improperly, for example, as a means for controlling employee performance.

79.5 Conclusion

Authentication, access control, and audit and intrusion detection together provide the foundations for building systems that can store and process information with confidentiality and integrity. Authentication is the primary security service. Access control builds directly on it. By and large, access control assumes authentication has been successfully accomplished. Strong authentication supports good auditing because operations can then be traced to the user who caused them to occur. There is a mutual interdependence between these three technologies, which can be often ignored by security practitioners and researchers. We need a coordinated approach that combines the strong points of each of these technologies rather than treating these as separate independent disciplines.

Operating Systems

Operating systems provide the software interface between the computer and its applications. This section covers the analysis, design, performance, and special challenges for operating systems in distributed and highly parallel computing environments. Much recent attention in operating system design is given to systems that control embedded computers, such as those found in vehicles. Also persistent are the particular challenges for synchronizing communication among simultaneously executing processes, managing scarce memory resources efficiently, and designing file systems that can handle massively large data sets.

80.1 Introduction

In brief, an **operating system** is the set of programs that control a computer. Some operating systems you may have heard of are Unix (including SCO UNIX, Linux, Solaris, Irix, and FreeBSD); the Microsoft family (MS-DOS, MS-Windows, Windows/NT, Windows 2000, and Windows XP); IBM operating systems (MVS, VM, CP, OS/2); MacOS; Mach; and VMS. Some of these (Mach and Unix) have been implemented on a wide variety of computers, but most are specific to a particular architecture, such as the Digital Vax (VMS), the Intel 8086 and successors (the Microsoft family, OS/2), the Motorola 68000 and successors (MacOS), and the IBM 360 and successors (MVS, VM, CP).

Controlling the computer involves software at several levels. We distinguish kernel services, library services, and application-level services, all of which are part of the operating system. These services can be pictured as in [Figure 80.1](#). Applications are run by processes, which are linked together with libraries that perform standard services such as formatting output or presenting information on a display. The kernel supports the processes by providing a path to the peripheral devices. It responds to service calls from the processes and interrupts from the devices.

This chapter discusses how operating systems have evolved, often in response to architectural advances. It then examines the goals and organizing principles of current operating systems. Many books describe operating systems concepts [4–6,17–19] and specific operating systems [1,2,9–11].

80.2 Historical Perspective

Operating systems have undergone enormous changes over the years. The changes have been driven primarily by hardware facilities and their cost, and secondarily by the applications that users have wanted to run on the computers.

FIGURE 80.1 Operating system services.

80.2.1 Open Shop Organization

The earliest computers were massive, extremely expensive, and difficult to use. Users would sign up for blocks of time during which they were allowed “hands-on” exclusive use of the computer. The user would repeatedly load a program into the computer through a device such as a card reader, watch the results, and then decide what to do next.

A typical session on the IBM 1620, a computer in use around 1960, involved several steps in order to compile and execute a program. First, the user would load the first pass of the Fortran compiler.

This operation involved clearing main store by typing a cryptic instruction on the console typewriter; putting the compiler, a 10-inch stack of punched cards, in the card reader; placing the program to be compiled after the compiler in the card reader; and then pressing the “load” button on the reader. The output would be a set of punched cards called “intermediate output.” If there were any compilation errors, a light would flash on the console, and error messages would appear on the console typewriter. If everything had gone well so far, the next step would be to load the second pass of the Fortran compiler just like the first pass, putting the intermediate output in the card reader as well. If the second pass succeeded, the output was a second set of punched cards called the “executable deck.” The third step was to shuffle the executable deck slightly, load it along with a massive subroutine library (another 10 inches of cards), and observe the program as it ran.

The facilities for observing the results were limited: console lights, output on a typewriter, punched cards, and line-printer output. Frequently, the output was wrong. Debugging often took the form of peeking directly into main store and even patching the executable program using console switches. If there was not enough time to finish, a frustrated user might get a line-printer dump of main store to puzzle over at leisure. If the user finished before the end of the allotted time, the machine might sit idle until the next reserved block of time.

The IBM 1620 was quite small, slow, and expensive by our standards. It came in three models, ranging from 20K to 60K digits of memory (each digit was represented by 4 bits). Memory was built from magnetic cores, which required approximately 10 microseconds for a read or a write. The machine cost hundreds of thousands of dollars and was physically fairly large, covering about 20 square feet.

80.2.2 Operator-Driven Shop Organization

The economics of massive mainframe computers made idle time very expensive. In an effort to avoid such idleness, installation managers instituted several modifications to the open shop mechanism just outlined. An **operator** was hired to perform the repetitive tasks of loading jobs, starting the computer, and collecting the output. The operator was often much faster than ordinary users at such chores as mounting cards and magnetic tapes, so the setup time between job steps was reduced. If the program failed, the operator could have the computer produce a dump. It was no longer feasible for users to inspect main store or patch

programs directly. Instead, users would submit their runs, and the operator would run them as soon as possible. Each user was charged only for the amount of time the job required.

The operator often reduced setup time by batching similar job steps. For example, the operator could run the first pass of the Fortran compiler for several jobs, save all the intermediate output, then load the second pass and run it across all the intermediate output that had been collected. In addition, the operator could run jobs out of order, perhaps charging more for giving some jobs priority over others. Jobs that were known to require a long time could be delayed until night. The operator could always stop a job that was taking too long.

The operator-driven shop organization prevented users from fiddling with console switches to debug and patch their programs. This stage of operating system development introduced the long-lived tradition of the users' room, which had long tables often overflowing with oversized fan-fold paper and a quietly desperate group of users debugging their programs until late at night.

80.2.3 Offline Loading

The next stage of development was to automate the mechanical aspects of the operator's job. First, input to jobs was collected **offline** by a separate computer (sometimes called a "satellite") whose only task was the transfer from cards to tape. Once the tape was full, the operator mounted it on the main computer. Reading jobs from tape is much faster than reading cards, so less time was occupied with input/output. When the computer finished the jobs on one tape, the operator would mount the next one. Similarly, output was generated onto tape, an activity that is much faster than punching cards. This output tape was converted to line-printer listings offline.

A small **resident monitor** program, which remained in main store while jobs were executing, reset the machine after each job was completed and loaded the next one. Conventions were established for control cards to separate jobs and specify their requirements. These conventions were the beginnings of command languages. For example, one convention was to place an asterisk in the first column of control cards, to distinguish them from data cards. The compilation job we just described could be specified in cards that looked like this:

```
*JOB SMITH           The user's name is Smith.
*  PASS CHESTNUT     Password so others can't use Smith's account
*  OPTION TIME=60    Limit of 60 seconds
*  OPTION DUMP=YES   Produce a dump if any step fails.
*STEP FORT1         Run the first pass of the Fortran compiler.
*  OUTPUT TAPE1     Put the intermediate code on tape 1.
*  INPUT FOLLOWS    Input to the compiler comes on the next cards.
...                Fortran program
*STEP FORT2         Run the second pass of the Fortran compiler.
*  OUTPUT TAPE2     Put the executable deck on scratch tape 2.
*  INPUT TAPE1      Input comes from scratch tape 1.
*STEP LINK          Link the executable with the Fortran library.
*  INPUT TAPE2      First input is the executable.
*  INPUT TAPELIB    Second input is a tape with the library.
*  OUTPUT TAPE1    Put load image on scratch tape 1.
*STEP TAPE1        Run whatever is on scratch tape 1.
*  OUTPUT TAPEOUT  Put output on the standard output tape.
*  INPUT FOLLOWS   Input to the program comes on the next cards.
...                Data
```

The resident monitor had several duties, including:

- Interpret the command language
- Perform rudimentary accounting
- Provide device-independent input and output by substituting tapes for cards and line printers

This last duty is an early example of information hiding and abstraction: programmers would direct output to cards or line printers but, in fact, the output would go elsewhere. Programs called subroutines provided by the resident monitor for input/output to both logical devices (cards, printers) and physical devices (actual tape drives).

The early operating systems for the IBM 360 series of computer used this style of control. Large IBM 360 installations could cost millions of dollars, so it was important not to let the computer sit idle.

80.2.4 Spooling Systems

Computer architecture advanced throughout the 1960s. (We survey computer architecture in [Section II](#).) Input/output units were designed to run at the same time the computer was computing. They generated an interrupt when they finished reading or writing a record instead of requiring the resident monitor to track their progress. As mentioned, an interrupt causes the computer to save some critical information (such as the current program counter) and to branch to a location specific to the kind of interrupt. Device-service routines, known as **device drivers**, were added to the resident monitor to deal with these interrupts.

Drums and, later, disks were introduced as a secondary storage medium. Now the computer could be computing one job while reading another onto the drum and printing the results of a third from the drum. Unlike a tape, a drum allows programs to be stored anywhere, so there was no need for the computer to execute jobs in the same order in which they were entered. A primitive **scheduler** was added to the resident monitor to sort jobs based on priority and amount of time needed, both specified on control cards. The operator was retained to perform several tasks:

- Mount data tapes needed by jobs (specified on control cards, which caused request messages to appear on the console typewriter).
- Decide which priority jobs to run and which to hold.
- Restart the resident monitor when it failed or was inadvertently destroyed by the running job.

This mode of running a computer was known as a **spooling system**, and its resident monitor was the start of modern operating systems. (The word “spool” originally stood for “simultaneous peripheral operations on line,” but it is easier to picture a spool of thread, where new jobs are wound on the outside, and old ones are extracted from the inside.) One of the first spooling systems was HASP (the Houston Automatic Spooling Program), an add-on to OS/360 for the IBM 360 computer family.

80.2.5 Batch Multiprogramming

Spooling systems did not make efficient use of all the hardware resources. The currently running job might not need the entire main store. A job performing input/output causes the computer to wait until the input/output finishes. The next software improvement, which occurred in the early 1960s, was the introduction of **multiprogramming**, a scheme in which more than one job is active simultaneously.

Under multiprogramming, while one job waits for an input/output operation to complete, another can compute. With luck, no time at all is wasted waiting for input/output. The more simultaneous jobs, the better. However, a **compute-bound** job (one that performs little input/output but much computation) can easily prevent **input/output-bound** jobs (those that perform mostly input/output) from making progress. Competition for the time resource and policies for allocating it are the main theme of [Chapter 82](#).

Multiprogramming also introduces competition for memory. The number of jobs that can be accommodated at one time depends on the size of main store and the hardware available for subdividing that space. In addition, jobs must be secured against inadvertent or malicious interference or inspection by other jobs. It is more critical now that the resident monitor not be destroyed by errant programs, because not one but many jobs suffer if it breaks. In [Chapter 85](#), we examine policies for memory allocation and how each of them provides security.

The form of multiprogramming we have been describing is often called **batch multiprogramming** because jobs are grouped into batches: those that need small memory, those that need customized tape

mounts, those that need long execution, etc. Each batch might have different priorities and fee structures. Some batches (such as large-memory, long-execution jobs) can be scheduled for particular times (such as weekends or late at night). Generally, only one job from any batch can run at any one time.

Each job is divided into discrete steps. Because job steps are independent, the resident monitor can separate them and apply policy decisions to each step independently. Each step might have its own time, memory, and input/output requirements. In fact, two separate steps of the same job can be performed at the same time if they do not depend on each other. The term **process** was introduced in the late 1960s to mean the entity that performs a single job step. The operating system (as the resident monitor may now be called) represents each process by a data structure sometimes called a **process descriptor**, **process control block**, or **context block**. The process control block includes billing information (owner, time used), scheduling information, and the resources the job step needs. While it is running, a process may request assistance from the kernel by submitting a service call across the **process interface**. Executing programs are no longer allowed to control devices directly; otherwise, they could make conflicting use of devices and prevent the kernel from doing its work. Instead, processes must use service calls to access devices, and the kernel has complete control of the **device interface**.

Allocating resources to processes is not a trivial task. A process might require resources (such as tape drives) at various stages in its execution. If a resource is not available, the scheduler might block the process from continuing until later. The scheduler must take care not to block any process forever.

Along with batch multiprogramming came new ideas for structuring the operating system. The kernel of the operating system is composed of routines that manage central store, CPU time, devices, and other resources. It responds both to requests from processes and to interrupts from devices. In fact, the kernel runs only when it is invoked either from above, by a process, or below, by a device. If no process is ready to run and no device needs attention, the computer sits idle.

Various activities within the kernel share data, but they must not be interrupted when the data is in an inconsistent state. Mechanisms for **concurrency control** were developed to ensure that these activities do not interfere with each other. [Chapter 84](#) introduces the mutual-exclusion and synchronization problems associated with concurrency control and surveys the solutions that have been found for these problems. The MVS operating system for the IBM 360 family was one of the first to use batch multiprogramming.

80.2.6 Interactive Multiprogramming

The next step in the development of operating systems was the introduction of **interactive multiprogramming**, also called **timesharing**. The principal user-oriented input/output device changed in the late 1960s from cards or tape to an interactive terminal. Instead of packaging all the data that a program might need before it starts running, the interactive user is able to supply input as the program wants it. The data can depend on what the program has produced thus far. Among the first terminals were teletypes, which produced output on paper at perhaps ten characters per second. Later terminals were called “glass teletypes” because they displayed characters on a television screen, substituting electronics for mechanical components. Like a regular teletype, they could not back up to modify data sitting earlier on the screen. Shortly thereafter, terminals gained cursor addressability, which meant that programs could show entire “pages” of information and change any character anywhere on a page.

Interactive computing caused a revolution in the way computers were used. Instead of being treated as number crunchers, computers became information manipulators. Interactive text editors allowed users to construct data files online. These files could represent programs, documents, or data. As terminals improved, so did the text editors, changing from line- or character-oriented interfaces to full-screen interfaces.

Instead of representing a job as a series of steps, interactive multiprogramming identifies a **session** that lasts from initial connection (“login”) to the point at which that connection is broken (“logout”). During login, the user typically gives two forms of identification: a user name and a password. The password is not echoed at the terminal, or is at least blackened by overstriking garbage, to avoid disclosing it to onlookers. This data is converted into a **user identifier** that is associated with all the processes that run on behalf of this

user and all the files he or she creates. This identifier helps the kernel decide whom to bill for services and whether to permit various actions such as modifying files. (We discuss files in [Chapter 86](#) and protection in [Chapter 89](#).)

During a session, the user imagines that the resources of the entire computer are devoted to this terminal, although many sessions may be active simultaneously for many users. Typically, one process is created at login time to serve the user. That first process, which is usually a command interpreter, may start others as needed to accomplish individual steps.

Users need to save information from session to session. Magnetic tape is too unwieldy for this purpose. Disk storage became the medium of choice for data storage, both short term (temporary files used to connect steps in a computation), medium term (from session to session), and long-term (from year to year). Issues of disk space allocation and backup strategies needed to be addressed to provide this facility.

Interactive computing was sometimes added into an existing batch multiprogramming environment. For example, TSO (“timesharing option”) was an add-on to the OS/360 operating system. The EXEC-8 operating system for Univac computers also included an interactive component.

Later operating systems were designed from the outset to support interactive use, with batch facilities added when necessary. TOPS-10 and Tenex (for the Digital PDP-10), and almost all operating systems developed since 1975, including Unix (first on the Digital PDP-11), MS-DOS (Intel 8086), OS/2 (Intel 286 family [10]), VMS (Digital VAX [9]), and all their descendents, were primarily designed for interactive use.

80.2.7 Graphical User Interfaces (GUIs)

As computers became less expensive, the time cost of switching from one process to another (which happens frequently in interactive computing) became insignificant. Idle time also became unimportant. Instead, the goal became helping users get their work done efficiently. This goal led to new software developments, enabled by improved hardware.

Graphics terminals, first introduced in the mid-1970s, have led to the video monitors that are now ubiquitous and inexpensive. These monitors allow individual control of multicolored pixels; a high-quality monitor (along with its video controller) can display millions of pixels in an enormous range of colors. Pointing devices, particularly the mouse, were developed in the late 1970s. Software links them to the display so that a visible cursor reacts to physical movements of the pointing device. These hardware advances have led to **graphical user interfaces** (GUIs), discussed in [Chapter 48](#).

The earliest GUIs were just rectangular regions of the display that contained, effectively, a cursor-addressable glass teletype. These regions are called “windows.” The best-known windowing packages were those pioneered by MacOS [15] and the later ones introduced by MS-Windows, OS/2 [10] and X Windows (for UNIX, VMS, and other operating systems [12]). Each has developed from simple rectangular models of a terminal to significantly more complex displays.

Programs interact with the hardware by invoking routines in libraries that know how to communicate with the display manager, which itself knows how to place bits on the screen. The early libraries were fairly low-level and difficult to use; toolkits (in the X Windows environment), especially ones with a fairly small interpreted language (such as Tcl/Tk [13] or Visual Basic), have eased the task of building good GUIs. Early operating systems that supported graphical interfaces, such as MacOS and MS-Windows, provided interactive computing but not multiprogramming. Modern operating systems all provide multiprogramming as well as interaction, allowing the user to start several activities and to switch attention to whichever one is currently most interesting.

80.2.8 Distributed Computing

At the same time that displays were improving, networks of computers were being developed. A network requires not only hardware to physically connect machines, but also protocols to use that hardware effectively, operating system support to make those protocols available to processes, and applications that make use of these protocols. [Chapter 87](#) through [Chapter 89](#) are devoted to the issues raised by networks.

Computers can be connected together by a variety of devices. The spectrum ranges from tight coupling, where several computers share main storage, to very loose coupling, where a number of computers belong to the same international network and can send one another messages.

The ability to send messages between computers opened new opportunities for operating systems. Individual machines become part of a larger whole and, in some ways, the operating system begins to span networks of machines. Cooperation between machines takes many forms.

- Each machine may offer **network services** to others, such as accepting mail, providing information on who is currently logged in, telling what time it is (quite important in keeping clocks synchronized), allowing users to access machines remotely, and transferring files.
- Machines within the same **site** (typically, those under a single administrative control) may **share file systems** in order to reduce the amount of disk space needed and to allow users to have accounts on multiple machines. Novell nets (MS-DOS), the Sun and Andrew network file systems (UNIX), and the Microsoft File-Sharing Protocol (Windows XP) are examples of such arrangements. Shared file systems are an essential component of a **networked operating system**.
- Once users have accounts on several machines, they want to associate graphical windows with sessions on different machines. The machine on which the display is located is called a **thin client** of the machine on which the processes are running. Thin clients have been available from the outset for X Windows; they are also available under Windows 2000 and successors.
- Users want to execute computationally intensive algorithms on many machines in parallel. **Middleware**, usually implemented as a library to be linked into distributed applications, makes it easier to build such applications. PVM [7] and MPI [14] are examples of such middleware.
- Standardized ways of presenting data across site boundaries developed rapidly. The File-Transfer Protocol (**ftp**) service was developed in the early 1970s as a way of transferring files between machines connected on a network. In the early 1990s, the **gopher** service was developed to create a uniform interface for accessing information across the Internet. Information is more general than just files; it can be a request to run a program or to access a database. Each machine that wishes to can provide a server that responds to connections from any site and communicate a menu of available information. This service was superseded in 1995 by the **World Wide Web**, which supports a GUI to gopher, ftp, and hypertext (documents with links internally and to other documents, often at other sites, and including text, pictures, video, audio, and remote execution of packaged commands).

Of course, all these forms of cooperation introduce security concerns. Each site has a responsibility to maintain security if for no other reason than to prevent malicious users across the network from using the site as a breeding ground for nasty activity attacking other sites. Security issues are discussed in [Chapter 77](#) through [Chapter 79](#).

80.3 Goals of an Operating System

During the evolution of operating systems, their purposes have also evolved. At present, operating systems have three major goals:

1. Hide details of hardware by creating abstractions.
2. Manage resources.
3. Provide a pleasant and effective user interface.

We address each of these goals in turn.

80.3.1 Abstracting Reality

We distinguish between the **physical** world of devices, instructions, memory, and time, and the **virtual** world that is the result of abstractions built by the operating system. An **abstraction** is software (often

implemented as a subroutine or as a library of subroutines) that hides lower-level details and provides a set of higher-level functions. Programs that use abstraction can safely ignore the lower-level (physical) details; they need only deal with the higher-level (virtual) structures.

Why is abstraction important in operating systems? First, the code needed to control peripheral devices is often not standardized; it can vary from brand to brand, and it certainly varies between, say, disks and tape drives and keyboards. Input/output devices are extremely difficult to program efficiently and correctly. Abstracting devices with a uniform interface makes programs easier to write and to modify (e.g., to use a different device). Operating systems provide subroutines called **device drivers** that perform input/output operations on behalf of programs. The operations are provided at a much higher level than the device itself provides. For example, a program may wish to write a particular block on a disk. Low-level methods involve sending commands directly to the disk to seek to the right block and then undertake memory-to-disk data transfer. When the transfer is complete, the disk interrupts the running program. A low-level program needs to know the format of disk commands, which vary from manufacturer to manufacturer and must deal with interrupts. In contrast, a program using a high-level routine in the operating system might only need to specify the memory location of the data block and where it belongs on the disk; all the rest of the machinery is hidden.

Second, the operating system introduces new functions as it abstracts the hardware. In particular, operating systems introduce the “file” abstraction. Programs do not need to deal with disks at all; they can use high-level routines to read and write disk files (instead of disk blocks) without needing to design storage layouts, worry about disk geometry, or allocate free disk blocks.

Third, the operating system transforms the computer hardware into multiple virtual computers, each belonging to a different process. Each process views the hardware through the lens of abstraction; memory, time, and other resources are all tailored to the needs of the process. Processes see only as much memory as they need, and that memory does not contain the other processes (or the operating system) at all. They think that they have all the CPU cycles on the machine, although other processes and the operating system itself are competing for those cycles. Service calls allow processes to start other processes and to communicate with other processes, either by sending messages or by sharing memory.

Fourth, the operating system can enforce security through abstraction. The operating system must secure both itself and its processes against accidental or malicious interference. Certain instructions of the machine, notably those that halt the machine and those that perform input and output, are moved out of the reach of processes. Memory is partitioned so that processes cannot access each other’s memory. Time is partitioned so that even a run-away process will not prevent others from making progress.

For security and reliability, it is wise to structure an operating system so that processes must use the operating system’s abstractions instead of dealing with the physical hardware. This restriction can be enforced by the hardware, which provides several **processor states**. Most architectures provide at least two states: the **privileged state** and the **non-privileged state**.

Processes always run in non-privileged state. Instructions such as those that perform input/output and those that change processor state cause traps when executed in non-privileged state. Traps save the current execution context (perhaps on a stack), force the processor to jump to the operating system, and enter the privileged state. Once the operating system has finished servicing the trap or interrupt, it returns control to the same process or perhaps to a different one, resetting the computer into non-privileged state.

The core of the operating system runs in privileged state. All instructions have their usual, physical meanings in this state. The part of the operating system that always runs in privileged state is the **kernel** of the operating system. It only runs when a process has caused a trap or when a peripheral device has generated an interrupt. Traps do not necessarily represent errors; usually, they are service calls. Interrupts often indicate that a device has finished servicing a request and is ready for more work. The clock interrupts at a regular rate in order to let the kernel make scheduling decisions.

If the operating system makes use of this dichotomy of states, the abstractions that the operating system provides are presented to processes as **service calls**, which are like new CPU instructions. A program can perform high-level operations (such as reading a file) with a single service call. Executing the service call generates a trap, which causes a switch to the privileged state of the kernel. The advantage of the

service-call design over a procedure-call design is that it allows access to kernel operations and data only through well-defined entry points.

Not all operating systems make use of non-privileged state. MS-DOS, for example, runs all applications in privileged state. Service calls are essentially subroutine calls. Although the operating system provides device and file abstractions, processes may interact directly with disks and other devices. One advantage of this choice is that device drivers can be loaded after the operating system starts; they do not need special privilege. One disadvantage is that viruses can thrive because nothing prevents a program from placing data anywhere it wishes.

80.3.2 Managing Resources

An operating system is not only an abstractor of information, but also an allocator that controls how processes (the active agents) can access resources (passive entities).

A **resource** is a commodity necessary to get work done. The computer's hardware provides a number of low-level resources. Working programs need to reside somewhere in main store (the computer's memory), must execute instructions, and need some way to accept data and present results. These needs are related to the fundamental resources of **memory**, **CPU time**, and **input/output**. The operating system abstracts these resources to allow them to be shared.

In addition to these physical resources, the operating system creates virtual, abstract resources. For example, **files** are able to store data. They abstract the details of disk storage. **Pseudo-files** (i.e., objects that appear to be data files on disk but are in fact stored elsewhere) can also represent devices, processes, communication ports, and even data on other computers. **Sockets** are process-to-process communication channels that can cross machine boundaries, allowing communication through networks such as the Internet. Sockets abstract the details of transmission media and network protocols.

Still higher-level resources can be built on top of abstractions. A **database** is a collection of information, stored in one or more files with structure intended for easy access. A **mailbox** is a file with particular semantics. A **remote file**, located on another machine but accessed as if it were on this machine, is built on both file and network abstractions.

The resource needs of processes often interfere with each other. Resource managers in the operating system include policies that try to be fair in giving resources to the processes and allow as much computation to proceed as possible. These goals often conflict.

Each resource has its own manager, typically in the kernel. The memory manager allocates regions of main memory for processes. Modern operating systems use address translation hardware that maps between a process's **virtual addresses** and the underlying **physical addresses**. Only the currently active part of a process's virtual space needs to be physically resident; the rest is kept on backing store (usually a disk) and brought in on demand. The virtual spaces of processes do not usually overlap, although some operating systems also provide **light-weight processes** that share a single virtual space. The memory manager includes policies that determine how much physical memory to grant to each process and which region of physical memory to swap out to make room for other memory that must be swapped in. For more information on virtual memory, see [Chapter 85](#).

The CPU-time manager is called the **scheduler**. Schedulers usually implement a preemptive policy that forces the processes to take turns running. Schedulers categorize processes according to whether they are currently runnable (they may not be if they are waiting for other resources) and their priority.

The file manager mediates process requests such as creating, reading, and writing files. It validates access based on the identity of the user running the process and the permissions associated with the file. The file manager also prevents conflicting accesses to the same file by multiple processes. It translates input/output requests into device accesses, usually to a disk, but often to networks (for remote files) or other devices (for pseudo-files).

The device managers convert standard-format requests into the particular commands appropriate for individual devices, which vary widely among device types and manufacturers. Device managers may also maintain caches of data in memory to reduce the frequency of access to physical devices.

Although we usually treat processes as autonomous agents, it is often helpful to remember that they act on behalf of a higher authority: the human **users** who are physically interacting with the computer. Each process is usually “owned” by a particular user. Many users may be competing for resources on the same machine. Even a single user can often make effective use of multiple processes.

Each user application is performed by a process. When a user wants to compose a letter, a process runs the program that converts keystrokes into changes in the document. When the user mails that letter electronically, a process runs a program that knows how to send documents to mailboxes.

To service requests effectively, the operating system must satisfy two conflicting goals:

1. To let each process have whatever resources it wants
2. To be fair in distributing resources among the processes

If the active processes cannot all fit in memory, for example, it is impossible to satisfy the first goal without violating the second. If there is more than one process, it is impossible on a single CPU to give all processes as much time as they want; CPU time must be shared.

To satisfy the computer’s owner, the operating system must also satisfy a different set of goals:

1. To make sure the resources are used as much as possible
2. To complete as much work as possible

These latter goals were once more important than they are now. When computers were all expensive mainframes, it seemed wasteful to let any time pass without a process using it, or to let any memory sit unoccupied by a process, or to let a tape drive sit idle. The measure of success of an operating system was how much work (measured in “jobs”) could be finished and how heavily resources were used. Computers are now far less expensive; we no longer worry if computers sit idle, although we still prefer efficient use of resources.

80.3.3 User Interface

We have seen how operating systems are creators of abstractions and allocators of resources. Both of these aspects center on the needs of programmers and the processes that execute programs. But many users are not programmers and are uninterested in the process abstraction and in the interplay between processes and the operating system. They do not care about service calls, interrupts, and devices. Instead, they are interested in what might be termed the “look and feel” of the operating system.

The user interacts with the operating system through the **user interface**. Human–computer interaction is covered in detail in [Section V](#) of this Handbook. Here we will only point out some highlights.

The hardware for user interfaces has seen rapid change over the past 50 years, ranging over plugging wires into a plugboard (e.g., IBM 610, 1957), punching cards and reading printouts (IBM 1620, 1959), remote teletype (DEC PDP-10, 1967), monochrome glass teletypes (around 1973), monochrome graphics terminals with pointing devices (Xerox PARC’s Alto computer, around 1974), color video CRTs (around 1980), and LCD displays (late 1980s).

User-interface software has steadily changed as well. Interactive text editors (WYLBUR and TECO, around 1975) replaced punched paper cards. Interactive command languages replaced job-control languages. Programming environments integrating editing, compiling, and debugging were introduced as early as 1980 (Smalltalk) and are still in heavy use (MetroWerks Code Warrior; Microsoft Visual Studio). Data entry moved from line-oriented to forms-based (by 1980) to Web-based (1995). Many user interfaces are now navigated without needing a keyboard at all; the user clicks a mouse to move to the next step in a process. Voice-activated commands are also gaining in popularity.

The “look and feel” of an operating system is affected by many components of the user interface. Some of the most important are the process launcher (a command interpreter, a menu-driven GUI, or clickable of icons); the file system (including remote files); online help; and application integration (such as ability to insert pictures in text files).

80.4 Implementing an Operating System

As mentioned, the core of the operating system is the **kernel**, a control program that functions in privileged state, reacting to interrupts from external devices and to service requests and traps from processes. In general, the kernel is a permanent resident of the computer. It creates and terminates processes and responds to their requests for service.

80.4.1 Processes

Each process is represented in the kernel by a collection of data called the **process descriptor**. A process descriptor includes such information as:

- Processor state: stored values of the program counter and registers, needed to resume execution of the process.
- Scheduling statistics, needed to determine when to resume the process and how much time to let it run.
- Memory allocation, both in main memory and backing store (disk), needed to accomplish memory management.
- Other resources held, such as locks or semaphores, needed to manage contention for such resources.
- Open files and pseudo-files (devices, communication ports), needed to interpret service requests for input and output.
- Accounting statistics, needed to bill users and determine hardware usage levels.
- Privileges, needed to determine if activities such as opening files and executing potentially dangerous service calls should be allowed.
- Scheduling state: running, ready, waiting for input/output or some other resource, such as memory.

The process descriptors can be saved in an array, in which case each process can be identified by the index of its descriptor in that array. Other structures are possible, of course, but the concept of **process number** is across operating systems. Some of the information in the process descriptor can be bulky, such as the page tables. Page tables for idle processes can be stored on disk to save space in main memory.

Resuming a process, that is, switching control from the kernel back to the process, is a form of **context switching**. It requires that the processor move from privileged to unprivileged state, that the registers and program counter of the process be restored, and that the address-translation hardware be set up to accomplish the correct mappings for this process. Switching back to the kernel is also a context switch; it can happen when the process tries to execute a privileged instruction (including the service call instruction) or when a device generates an interrupt.

Hardware is designed to switch context rapidly. For example, the hardware may maintain two sets of registers and address translation data, one for each privilege level. Context switches into the kernel just require moving to the kernel's set of registers. Resuming the most recently running process is also fast. Resuming a different process requires that the kernel load all the information for the new process into the second set of registers; this activity takes longer. For that reason, a **process switch** is often more expensive than two context switches.

80.4.2 Virtual Machines

Although most operating systems try to present to processes an enhanced and simplified view of the hardware, some take a different tack. They make the process interface look just like the hardware interface, except that the size of memory and the types, numbers, and sizes of input/output devices may be more or less than the physical resources. However, a process is allowed to use all the machine instructions, even the privileged ones.

Under this organization, the process interface is called a **virtual machine** because it looks just like the underlying machine. The kernel of such an operating system is called a **virtualizing kernel**. Each virtual machine runs its own ordinary operating system.

We examine virtual operating systems in some detail because they elucidate the interplay of traps, context switches, processor states, and the fact that a process at one level is just a data structure at a lower level. Virtualizing kernels were first developed (IBM VM, early 1970s) to allow operating system designers to experiment with new versions of an operating system on machines that were too expensive to dedicate to such experimentation. More importantly, virtualizing kernels allow multiple operating systems to run simultaneously on the same machine to satisfy a wide variety of users.

This idea is still valuable. The Wine program emulates the Win32 environment (used by Windows XP) as it runs as a process under UNIX, allowing a Unix user who has Windows programs to run them at the same time as other applications. Mach emulates Unix and can accept modules that emulate other operating systems as well. This emulation is at the library-routine level; service calls are converted to messages directed to a UNIX-emulator process that provides all the services. The NT [3] and OS/2 [10] operating systems for Intel computers also provide for virtual machines running other operating systems.

In a true virtualizing kernel, the hardware executes most instructions (such as arithmetic and data motion) directly. However, privileged instructions, such as the halt instruction, are just too dangerous to let processes use directly. Instead, the virtualizing kernel must run all processes in non-privileged state to prevent them from accidentally or maliciously interfering with each other and with the kernel itself.

To let each process P imagine it has control of processor states, the kernel keeps track of the virtual processor state of each P , that is, the processor state of the virtual machine that the kernel emulates on behalf of P . This information is stored in P 's context block inside the kernel. All privileged instructions executed by P cause traps to the kernel, which then emulates the behavior of the hardware on behalf of P .

- If P is in virtual non-privileged state, the kernel emulates a trap for P . This emulation puts P in virtual privileged state, although it is still running in physical non-privileged state. The program counter for P is reset to the proper trap address within P 's virtual space.
- If P is in virtual privileged state, the kernel emulates the action of the instruction itself. For example, it terminates P on a halt instruction, and it executes input/output instructions interpretively.

Some dangerous instructions are particularly difficult to emulate. Input/output can be very tricky. Address translation also becomes quite complex. A good test of a virtualizing kernel is to let one of its processes be another virtualizing kernel. For example, consider Figure 80.2, in which there are two levels

FIGURE 80.2 Emulating a service call.

of virtualizing kernel, V_1 and V_2 , above which sits an ordinary operating system kernel, **OS**, above which a compiler is running.

The compiler executes a single service call (marked “*”) at time 1. As far as the compiler is concerned, **OS** performs the service and lets the compiler continue (marked “c”) at time 29. The dashed line at the level of the compiler indicates the compiler’s perception that no activity below its level takes place during the interval.

From the point of view of **OS**, a trap occurs at time 8 (marked by a dot on the control-flow line). This trap appears to come directly from the compiler, as shown by the dashed line connecting the compiler at time 1 and the **OS** at time 8. **OS** services the trap (marked “s”). For simplicity, we assume that it needs to perform only one privileged instruction (marked “p”) to service the trap, which it executes at time 9. Lower levels of software (which **OS** cannot distinguish from hardware) emulate this instruction, allowing **OS** to continue at time 21. It then switches context back to the compiler (marked “b”) at time 22. The dashed line from **OS** at time 22 to the compiler at time 29 shows the effect of this context switch.

The situation is more complicated from the point of view of V_2 . At time 4, it receives a trap that tells it that its client has executed a privileged instruction while in virtual non-privileged state. V_2 therefore reflects this trap at time 5 (marked “r”) back to **OS**. Later, at time 12, V_2 receives a second trap, this time because its client has executed a privileged instruction in virtual privileged state. V_2 services this trap by emulating the instruction itself at time 13. By time 17, the underlying levels allow it to continue, and at time 18 it switches context back to **OS**. The last trap occurs at time 25, when its client has attempted to perform a context switch (which is privileged) when in virtual privileged state. V_2 services this trap by changing its client to virtual non-privileged state and switching back to the client at time 26.

V_1 has the busiest schedule of all. It reflects traps that arrive at time 2, 10, and 23. (The trap at time 23 comes from the context-switch instruction executed by **OS**.) It also emulates instructions for its client when traps occur at times 5, 14, 19, and 27.

This example demonstrates the principle that each software level is just a data structure as far as its supporting level is concerned. It also shows how a single privileged instruction in the compiler becomes two privileged instructions in **OS**, which becomes four in V_2 and eight in V_1 . In general, a single privileged instruction at one level might require many instructions at its supporting level to emulate it.

80.4.3 Components of the Kernel

Originally, operating systems were written as a single large program encompassing hundreds of thousands of lines of assembly-language instructions. Two trends have made the job of implementing operating systems less difficult. First, high-level languages have made programming much easier. For example, more than 99% of the Linux variant of Unix is written in C. Complex algorithms can be expressed in a structured, readable fashion; code can be partitioned into modules that interact with each other in a well-defined manner, and compile-time typechecking catches most programming errors. Only a few parts of the kernel, such as those that switch context or modify execution priority, need to be written in assembly language.

Second, the discipline of structured programming has suggested a layered approach to designing the kernel. Each layer provides abstractions needed by the layers above it. For example, the kernel can be organized as follows:

- Context- and process-switch services (lowest layer)
- Device drivers
- Resource managers for memory and time
- File system support
- Service call interpreter (highest layer)

For example, the MS-DOS operating system provides three levels: (1) device drivers (the BIOS section of the kernel), (2) a file manager, and (3) an interactive command interpreter. It supports only one process and provides no security, so there is no need for context-switch services. Because service calls do not need to cross protection boundaries, they are implemented as subroutine calls.

The concept of layering allows the kernel to be small, because much of the work of the operating system need not operate in a protected and hardware-privileged environment. When all the layers listed above are privileged, the organization is called a **macrokernel**. UNIX is often implemented as a macrokernel.

If the kernel only contains code for process creation, inter-process communication, the mechanisms for memory management and scheduling, and the lowest level of device control, the result is a **microkernel**, also called a “communication kernel.” Mechanisms are distinct from policies, which can be outside the kernel. Policies decide which resources should be allocated in cases of conflict, whereas mechanisms carry out those decisions. Mach [16] and QNX [8] follow the microkernel approach. In this organization, services such as the file system and policy modules for scheduling and memory are relegated to processes. These processes are often referred to as **servers**; the ordinary processes that need those services are called their **clients**. The microkernel itself acts as a client of the policy servers. Servers need to be trusted by their clients, and sometimes they need to execute with some degree of hardware privilege (for example, if they access devices).

The microkernel approach has some distinct advantages:

- It imposes uniformity on the requests that a process might make. Processes need not distinguish between kernel-level and process-level services because all are provided via messages to servers.
- It allows easier addition of new services, even while the operating system is running, as well as multiple services that cover the same set of needs, so that individual users (and their agent processes) can choose whichever seems best. For example, different file organizations for diskettes are possible; instead of having many file-level modules in the kernel, there can be many file-level servers accessible to processes.
- It allows an operating system to span many machines in a natural way. As long as inter-process communication works across machines, it is generally immaterial to a client where its server is located.
- Services can be provided by teams of servers, any one of which can help any client. This organization relieves the load on popular servers, although it often requires a degree of coordination among the servers on the same team.

A microkernel also has some disadvantages. It is generally slower to build and send a message, accept and decode the reply (taking about 100 μ s), than to make a single service call (taking about 1 μ s). However, other aspects of service tend to dominate the cost, allowing microkernels to be similar in speed to macrokernels. Keeping track of which server resides on which machine can be complex. This complexity may be reflected in the user interface. The perceived complexity of an operating system has a large effect on its acceptance by the user community.

Recently, people have begun to speak of **nanokernels**, which support only devices and communication ports. They sit at the bottom level of the microkernel, providing services for the other parts of the microkernel, such as memory management. All the competing executions supported by the nanokernel are called **threads**, to distinguish them from **processes**. Threads all share kernel memory, and they explicitly yield control in order to let other threads continue. They synchronize with each other by means of primitive locks or more complex semaphores. For more information on processes and threads, see [chapters 93 and 97](#).

Although the trend toward microkernels is unmistakable, macrokernels are likely to remain popular for the foreseeable future.

80.5 Research Issues and Summary

Operating systems have developed enormously in the past 45 years. Modern operating systems generally have three goals: (1) to hide details of hardware by creating abstractions, (2) to allocate resources to processes, and (3) to provide an effective user interface. Operating systems generally accomplish these goals by running processes in low privilege and providing service calls that invoke the operating system kernel in

high privilege state. The recent trend has been toward increasingly integrated graphical user interfaces that encompass the activities of multiple processes on networks of computers. These increasingly sophisticated application programs are supported by increasingly small operating system kernels.

Current research issues revolve mostly around networked operating systems, including network protocols, distributed shared memory, distributed file systems, mobile computing, and distributed application support. There is also active research in kernel structuring, file systems, and virtual memory.

Defining Terms

The following terms may have more general definitions than shown here, and often have other narrow technical definitions. This list indicates how the terms have been used in this chapter.

Abstraction: An interface that hides lower-level details and provides a set of higher-level functions.

Batch multiprogramming: Grouping jobs into batches based on characteristics such as memory requirements.

Client: A process that requests services by sending messages to server processes.

Command interpreter: A program (usually not in the kernel) that interprets user requests and starts computations to fulfill those requests.

Commands: Instructions in a job-control language.

Compute-bound: A process that performs little input/output but needs significant execution time.

Concurrency control: Means to mediate conflicting needs of simultaneously executing threads.

Context block: Process descriptor.

Context switching: The action of directing the hardware to execute in a different context (kernel or process) from the current context.

Database: A collection of files for storing related information.

Device driver: An operating-system module (usually in the kernel) that deals directly with a device.

Device interface: The means by which devices are controlled.

File: A named, long-term repository for data.

ftp: The file-transfer protocol service.

Gopher: A network service that connects information providers to their users.

Graphical user interface: Interactive program that makes use of a graphic display and a mouse.

Input/output: A resource: ability to interact with peripheral devices.

Input/output-bound: A process that spends most of its time waiting for input/output.

Integrated application: An application that agrees on data formats with other applications so they can use each other's outputs.

Interactive multiprogramming: Multiprogramming in which each user deals interactively with the computer.

Job: A set of computational steps packaged to be run as a unit.

Job-control language: A way of specifying the resource requirements of various steps in a job.

Kernel: The privileged core of an operating system, responding to service calls from processes and interrupts from devices.

Lightweight process: A thread.

Macrokernel: A large operating-system core that provides a wide range of services.

Mailbox: A file for saving messages between users.

Memory: A resource: ability to store programs and data.

Microkernel: A small privileged operating-system core that provides process scheduling, memory management, and communication services.

Middleware: Program that provides high-level communication facilities to allow distributed computation.

Multiprogramming: Scheduling several competing processes to run at essentially the same time.

Nanokernel: A very small privileged operating-system core that provides simple process scheduling and communication services.

Network services: Services available through the network, such as mail and file transfer.

Network service: A facility offered by one computer to other computers connected to it by a network.

Networked operating system: An operating system that uses a network for sharing files and other resources.

Non-privileged state: An execution context that does not allow sensitive hardware instructions to be executed, such as the halt instruction and input/output instructions.

Offline: Handled on a different computer.

Operating system: A set of programs that controls a computer.

Operator: An employee who performs the repetitive tasks of loading and unloading jobs.

Physical: The material upon which abstractions are built.

Physical address: A location in physical memory.

Pipeline: A facility that allows one process to send a stream of information to another process.

Privileged state: An execution context that allows all hardware instructions to be executed.

Process: A program being executed; an execution context that is allocated resources such as memory, time, and files.

Process control block: Process descriptor.

Process descriptor: A data structure in the kernel that represents a process.

Process interface: The set of service calls available to processes.

Process number: An identifier that represents a process by acting as an index into the array of process descriptors.

Process switch: The action of directing the hardware to run a different process from the one that was previously running.

Processor state: Privileged or non-privileged state.

Pseudo-file: An object that appears to be a file on the disk but is actually some other form of data.

Remote file: A file on another computer that appears to be on the user's computer.

Resident monitor: A precursor to kernels; a program that remains in main store during the execution of a job to handle simple requests and to start the next job.

Resource: A commodity necessary to get work done.

Scheduler: An operating system module that manages the time resource.

Server: A process that responds to requests from clients via messages.

Service call: The means by which a process requests service from the kernel, usually implemented by a trap instruction.

Session: The period during which a user interacts with a computer.

Shared file system: Files residing on one computer that can be accessed from other computers.

Site: The set of computers, usually networked, under a single administrative control.

Socket: An abstraction for communication between two processes, not necessarily on the same machine.

Spooling system: Storing newly arrived jobs on disk until they can be run, and storing the output of old jobs on disk until it can be printed.

Thin client: A program that runs on one computer that allows the user to interact with a session on a second computer.

Thread: An execution context that is independently scheduled, but shares a single address space with other threads.

Time: A resource: ability to execute instructions.

Timesharing: Interactive multiprogramming.

User: A human being physically interacting with a computer.

User identifier: A number or string that is associated with a particular user.

User interface: The facilities provided to let the user interact with the computer.

Virtual: The result of abstraction; the opposite of physical.

Virtual address: An address in memory as seen by a process, mapped by hardware to some physical address.

- Virtual machine:** An abstraction produced by a virtualizing kernel, similar in every respect but performance to the underlying hardware.
- Virtualizing kernel:** A kernel that abstracts the hardware to multiple copies that have the same behavior (except for performance) of the underlying hardware.
- World Wide Web:** A network service that allows users to share multimedia information.

81.1 Introduction

Disciplined concurrent programming can improve the structure and performance of computer programs on both uniprocessor and multiprocessor systems. As a result, support for *threads*, or lightweight processes, has become a common element of new operating systems and programming languages.

A thread is a sequential stream of instruction execution. A thread differs from the more traditional notion of a heavyweight process in that it separates the notion of execution from the other state needed to run a program (e.g., an address space). A single thread executes a portion of a program, while cooperating with other threads that are concurrently executing the same program. Much of what is normally kept on a per-heavyweight-process basis can be maintained in common for all threads in a single program, yielding dramatic reductions in the overhead and complexity of a concurrent program.

Concurrent programming has a long history. The operation of programs that must handle real-world concurrency (e.g., operating systems, database systems, and network file servers) can be complex and difficult to understand. Dijkstra [1968] and Hoare [1974, 1978] showed that these programs can be simplified when structured as cooperating sequential threads that communicate at discrete points within the program. The basic idea is to represent a single task, such as fetching a particular file block, within a single thread of control, and to rely on the thread management system to multiplex concurrent activities onto the available processor. In this way, the programmer can consider each function being performed by the system separately, and simply rely on automatic scheduling mechanisms to best assign available processing power.

In the uniprocessor world, the principal motivations for concurrent programming have been improved program structure and performance. Multiprocessors offer an opportunity to use concurrency in parallel

programs to improve performance, as well as structure. Moderately increasing a uniprocessor's power can require substantial additional design effort, as well as faster and more expensive hardware components. But, once a mechanism for interprocessor communication has been added to a uniprocessor design, the system's peak processing power can be increased by simply adding more processors. A shared-memory multiprocessor is one such design in which processors are connected by a bus to a common memory.

Multiprocessors lose their advantage if this processing power is not effectively utilized. If there are enough independent sequential jobs to keep all of the processors busy, then the potential of a multiprocessor can be easily realized: each job can be placed on a separate processor. However, if there are fewer jobs than processors, or if the goal is to execute single applications more quickly, then the machine's potential can only be achieved if individual programs can be parallelized in a cost-effective manner. Three factors contribute to the cost of using parallelism in a program:

- **Thread overhead:** The work, in terms of processor cycles, required to create and control a thread must be appreciably less than the work performed by that thread on behalf of the program. Otherwise, it is more efficient to do the work sequentially, rather than use a separate thread on another processor.
- **Communication overhead:** Again in terms of processor cycles, the cost of sharing information between threads must be less than the cost of simply computing the information in the context of each thread.
- **Programming overhead:** A less tangible metric than the previous two, programming overhead reflects the amount of human effort required to construct an efficient parallel program.

High overhead in any of these areas makes it hard to build efficient parallel programs. Costly threads can only be used infrequently. Similarly, if arranging communication between threads is slow, then the application must be structured so that little interthread communication is required. Finally, if managing parallelism is tedious or difficult, then the programmer may find it wise to sacrifice some speedup for a simpler implementation. Few algorithms parallelize well when constrained by high thread, communication, and programming costs, although many can flourish when these costs are low.

Low overhead in these three areas is the responsibility of the thread management system, which bridges the gap between the physical processors (the suppliers of parallelism) and an application (its consumer). In this chapter, we discuss the issues that arise in designing a thread management system to support low-overhead parallel programming for shared-memory multiprocessors. In the next section, we describe the functionality found in thread management systems. [Section 81.3](#) discusses a number of thread design issues. In [Section 81.4](#), we survey three systems for shared-memory multiprocessors, Windows NT [Custer 1993], Presto [Bershad et al. 1988], and Multilisp [Halstead 1985], focusing our attention on how they have addressed the issues raised in this chapter.

81.2 Thread Management Concepts

81.2.1 Address Spaces, Threads, and Multiprocessing

An address space is the set of memory locations that can be generated and accessed directly by a program. Address space limitations are enforced in hardware to prevent incorrect or malicious programs in one address space from corrupting data structures in others. Threads provide concurrency within a program, while address spaces provide failure isolation between programs. These are orthogonal concepts, but the interaction between thread management and address space management defines the extent to which data sharing and multiprocessing are supported.

The simplest operating systems, generally those for older style personal computers, support only a single thread and a single-address space per machine. A single-address space is simpler and faster since it allows all data in memory to be accessed uniformly. Separate address spaces are not needed on dedicated systems

to protect against malicious users; software errors can crash the system but at least are localized to one user, one machine.

Even single-user systems can have concurrency, however. More sophisticated systems, such as Xerox's Pilot [Redell et al. 1980], provide only one address space per machine, but support multiple threads within that single-address space. Because any thread can access any memory location, Pilot provides a compiler with strong type-checking to decrease the likelihood that one thread will corrupt the data structures of another.

Other operating systems, such as Unix, provide support for multiple-address spaces per machine, but only one thread per address space. The combination of a Unix address space with one thread is called a Unix *process*; a process is used to execute a program. Since each process is restricted from accessing data that belongs to other processes, many different programs can run at the same time on one machine, with errors confined to the address space in which they occur. Processes are able to cooperate by sending messages back and forth via the operating system. Passing data through the operating system is slow, however; only parallel programs that require infrequent communication can be written using threads in disjoint address spaces.

Instead of using messages to share data, processes running on a shared-memory multiprocessor can communicate directly through the shared memory. Some Unix systems allow memory regions to be set up as shared between processes; any data in the shared region can be accessed by more than one process without having to send a message by way of the operating system. The Sequent Symmetry's DYNIX [Sequent 1988] and Encore's UMAX [Encore 1986] are operating systems that provide support for multiprocessing based on shared memory between Unix processes.

More sophisticated operating systems for shared-memory multiprocessors, such as Microsoft's Windows NT and Carnegie Mellon University's Mach operating system [Tevanian et al. 1987] support multiple-address spaces *and* multiple threads within each address space. Threads in the same address space communicate directly with one another using shared memory; threads communicate across address space boundaries using messages. The cost of creating new threads is significantly less than that of creating whole address spaces, since threads in the same address space can share per-program resources. Figure 81.1 illustrates the various ways in which threads and address spaces can be organized by an operating system.

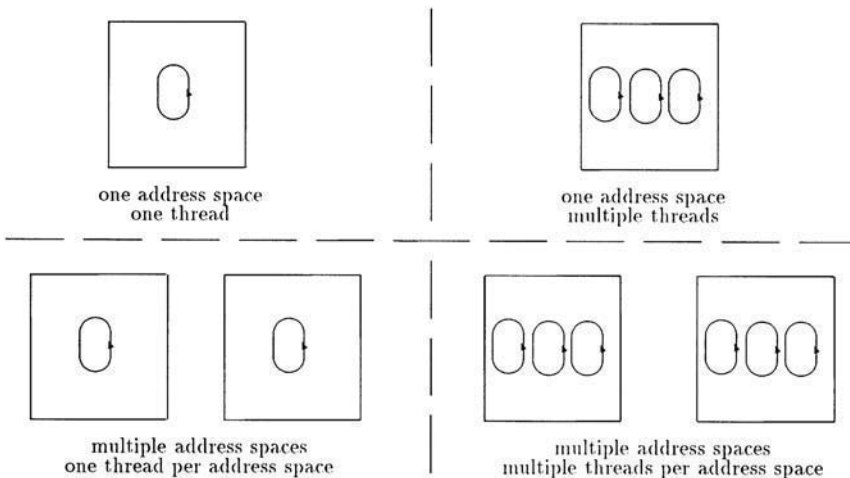

FIGURE 81.1 Threads and address spaces. MS-DOS is an example of a one address space, one thread system. A Java run-time engine is an example of one address space with multiple threads. The Unix operating system is an example of multiple address spaces, with one thread per address space. Windows NT is an example of a system that has multiple address spaces and multiple threads per address space.

81.2.2 Basic Thread Functionality

At its most basic level, a thread consists of a program counter (PC), a set of registers, and a stack of procedure activation records containing variables local to each procedure. A thread also needs a control block to hold state information used by the thread management system: a thread can be *running* on a processor, *ready-to-run* but waiting for a processor to become available, *blocked* waiting for some other thread to communicate with it, or *finished*. Threads that are ready-to-run are kept on a *ready-list* until they are picked up by an idle processor for execution. There are four basic thread operations:

- **Spawn:** A thread can create or spawn another thread, providing a procedure and arguments to be run in the context of a new thread. The spawning thread allocates and initializes the new thread's control block and places the thread on the ready-list.
- **Block:** When a thread needs to wait for an event, it may block (saving its PC and registers) and relinquish its processor to run another thread.
- **Unblock:** Eventually, the event for which a blocked thread is waiting occurs. The blocked thread is marked as ready-to-run and placed back on the ready-list.
- **Finish:** When a thread completes (usually by returning from its initial procedure), its control block and stack are deallocated, and its processor becomes available to run another thread.

When threads can communicate with one another through shared memory, *synchronization* is necessary to ensure that threads do not interfere with each other and corrupt common data structures. For example, if two threads each try to add an element to a doubly linked list at the same time, one or the other element may be lost, or the list could be left in an inconsistent state. *Locks* can solve this problem by providing mutually exclusive access to a data structure or region of code. A lock is acquired by a thread before it accesses a shared data structure; if the lock is held by another thread, the requesting thread blocks until the lock is released. (The code that a thread executes while holding a lock is called a *critical section*.) By serializing accesses, the programmer can ensure that threads only see and modify a data structure when it is in a consistent state.

When a program's work is split among multiple threads, one thread may store a result read by another thread. For correctness, the reading thread must block until the result has been written. This data dependency is an example of a more general synchronization object, the *condition variable*, which allows a thread to block until an arbitrary condition has been satisfied. The thread that makes the condition true is responsible for unblocking the waiting thread.

One special form of a condition variable is a *barrier*, which is used to synchronize a set of threads at a specific point in the program. In the case of a barrier, the arbitrary condition is: Have all threads reached the barrier? If not, a thread blocks when it reaches the barrier. When the final thread reaches the barrier, it satisfies the condition and *raises* the barrier, unblocking the other threads.

If a thread needs to compute the result of a procedure in parallel, it can first spawn a thread to execute the procedure. Later, when the result is needed, the thread can perform a *join* to wait for the procedure to finish and return its result. In this case, the condition is: Has a given thread finished? This technique is useful for increasing parallelism, since the synchronization between the caller and the callee takes place when the procedure's result is needed, rather than when the procedure is called.

Locks, barriers, and condition variables can all be built using the basic block and unblock operations. Alternatively, a thread can choose to *spin-wait* by repeatedly polling until an anticipated event occurs, rather than relinquishing the processor to another thread by blocking. Although spin-waiting wastes processor time, it can be an important performance optimization when the expected waiting time is less than the time it takes to block and unblock a thread. For example, spin-waiting is useful for guarding critical sections that contain only a few instructions.

81.3 Issues in Thread Management

This section considers the issues that arise in designing and implementing a thread management system as they relate to the programmer, the operating system, and the performance of parallel programs.

81.3.1 Programmer Issues

81.3.1.1 Programming Models

The flexibility to adapt to different programming models is an important attribute of thread systems. Parallelism can be expressed in many ways, each requiring a different interface to the thread system and making different demands on the performance of the underlying implementation. At the same time, a thread system that strives for generality in handling multiple models is likely to be well suited to none.

One general principle is that the programmer should choose the most restrictive form of synchronization that provides acceptable performance for the problem at hand. For coordinating access to shared data, messages are a more restrictive, and for many kinds of parallel programs, are a more appropriate form of synchronization than locks and condition variables. Threads share information by explicitly sending and receiving messages to one another, as if they were in separate address spaces, except that the thread system uses shared memory to efficiently implement message passing.

There are some cases where explicit control of concurrency may not be necessary for good parallel performance. For instance, some programs can be structured around a single instruction multiple data (SIMD) model of parallelism. With SIMD, each processor executes the same instruction in lockstep, but on different data locations. Because there is only one program counter, the programmer need not explicitly synchronize the activity of different processors on shared data, thus eliminating a major source of confusion and errors.

Perhaps the simplest programmer interface to the thread system is none at all: the compiler is completely responsible for detecting and exploiting parallelism in the application. The programmer can then write in a sequential language; the compiler will make the transformation into a parallel program. Nevertheless, the compiled program must still use some kind of underlying thread system, even if the programmer does not. Of course, there are many kinds of parallelism that are difficult for a compiler to detect, so automatic transformation has a limited range of use.

81.3.1.2 Language Support

Threads can be integrated into a programming language; they can exist outside the language as a set of subroutines that explicitly manage parallelism; or they can exist both within and outside the language, with the compiler and programmer managing threads together.

Language support for threads is like language support for object-oriented programming or garbage collection: it can be a mixed blessing. On one hand, the compiler can be made responsible for common bookkeeping operations, reducing programming errors. For example, locks can automatically be acquired and released when passing through critical sections. Further, the types of the arguments passed to a spawned procedure can be checked against the expected types for that procedure. This is difficult to do without compiler support.

On the other hand, language support for threads increases the complexity of the compiler, an important factor if a multiprocessor is to support more than one programming language. Further, the concurrency abstractions provided by a single parallel programming language may not do quite what the programmer wants or needs, making it necessary to express solutions in ways that are unnatural or inefficient.

A reasonable way of getting most of the benefits of language support without many of the disadvantages is to define both a language and a procedural interface to the thread management system. Common operations can be handled transparently by the compiler, but the programmer can directly call the basic thread management routines when the standard language support proves insufficient.

81.3.1.3 Granularity of Concurrency

The frequency with which a parallel program invokes thread management operations determines its *granularity*. A *fine-grained* parallel program creates a large number of threads, or uses threads that frequently block and unblock, or both. Thread management cost is the major obstacle to fine-grained parallelism. For a parallel program to be efficient, the ratio of thread management overhead to useful computation must be small. If thread management is expensive, then only *coarse-grained* parallelism can be exploited.

More efficient threads allow programs to be finer grained, which benefits both structure and performance. First, a program can be written to match the structure of the problem at hand, rather than the performance characteristics of the hardware on which the problem is being solved. Just as a singlethreaded environment on a uniprocessor can prevent the programmer from composing a program to reflect the problem's logical concurrency, a coarse-grained environment can be similarly restrictive. For example, in a parallel discrete-event simulation, physical objects in the simulated system are most naturally represented by threads that simulate physical interactions by sending messages back and forth to one another; this representation is not feasible if thread operations are too expensive.

Performance is the other advantage of fine-grained parallelism. In general, the greater the length of the ready-list, the more likely it is that a parallel program will be able to keep all of the available processors busy. When a thread blocks, its processor can immediately run another thread provided one is on the ready-list. With few threads though, as in a coarse-grained program, processors idle while threads do I/O or synchronize with one another.

The performance of a fine-grained parallel program is less sensitive to changes in the number of processors available to an application. For example, consider one phase of a coarse-grained parallel program that does 50 CPU-min worth of work. If the program creates five threads on a five processor machine, the phase finishes in just 10 min. But, if the program runs with only four processors, then the execution time of the phase *doubles* to 20 min: 10 min with four processors active followed by 10 min with one processor active. (Preemptive scheduling, which could be used to address this problem, has a number of serious drawbacks, which are discussed subsequently.) If the program had originally been written to use 50 threads, rather than 5, then the phase could have finished in only 13 min, a reasonable degradation in performance.

Of course, one could argue that the programmer erred in writing a program that was dependent on having exactly five processors. The program should have been parameterized by the number of processors available when it starts. But, even so, good performance cannot be ensured if that number can vary, as it can on a multiprogrammed multiprocessor. We consider further the issues of multiprogramming in the next section.

81.3.2 Operating System Issues

81.3.2.1 Multiprogramming

Multiprogramming on a uniprocessor improves system performance by taking advantage of the natural concurrency between computation and I/O. While one program waits for an I/O request, the processor can be running some other program. Because the processor and I/O devices are kept busy simultaneously, more jobs can be completed per unit time than if the system ran only one program at a time.

A multiprogrammed multiprocessor has an analogous advantage. Ideally, periods of low parallelism in one job can be overlapped with periods of high parallelism in another job. Further, multiprogramming allows the power of a multiprocessor to be used by a collection of simultaneously running jobs, none of which by itself has enough parallelism to fully utilize the multiprocessor.

81.3.2.2 Processor Scheduling

Processor scheduling can be characterized by whether physical processors are assigned directly to threads or are first assigned to jobs and then to threads within those jobs. The first approach, called *one-level* scheduling, makes no distinction between threads in the same job and threads in different jobs. Processors are shared across all runnable threads on the system so that all threads make progress at relatively the same rate. In this case, threads from all jobs are placed on one ready-list that supplies all processors, as shown in [Figure 81.2](#). Although this scheme makes sense for a uniprocessor operating system, it has some unpleasant performance implications on a multiprocessor.

The most serious problem with one-level scheduling occurs when the number of runnable threads exceeds the number of physical processors, because preemptive scheduling is necessary to allocate processor time to threads in a fair manner. With preemption, a processor can be taken away from one thread and given to another at any time. In a sequential program, preemption has a well-defined effect: the program

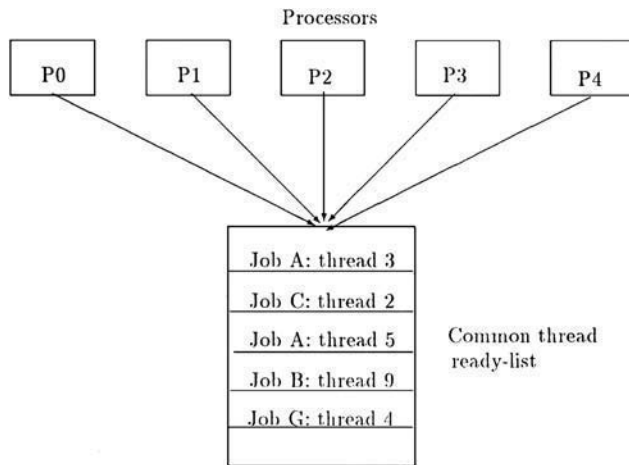

FIGURE 81.2 One-level thread scheduling.

goes from the running state to the not running state as its one thread is preempted. The effect of preemption on the performance of a sequential program is also well defined: if n CPU-intensive jobs are sharing one processor in a preemptive, round-robin fashion, then each job receives $1/n$ th the processor and is slowed down by a factor of n (modulo the preemption and scheduling overhead).

For a parallel program, though, the effects of untimely processor preemption on performance can be more dramatic. In the previous section, we saw how a coarse-grained program can be slowed down by a factor of two when the number of processors is decreased from five to four. That program exemplified a problem that occurs more generally with preemption and barrier-based synchronization. The program had an implicit barrier, which was the final instruction in the phase. Until all threads reached that instruction, the program could not continue. When one processor was removed, it took twice as long to reach the barrier because not all threads within the job could make progress at an equal rate.

Preemptive multiprocessor scheduling also affects program performance when locks are used, but for a different reason than with barriers. Suppose a thread holding a lock while in a critical section is unexpectedly preempted by the operating system. The lock will remain held until the thread is rescheduled. As threads on other processors try to acquire the lock, they will find it held and be forced to block. It is even possible that, as more threads block waiting for the lock to be freed, the number of that job's runnable threads drops to zero and the application can make no progress until the preempted thread is rescheduled. The overhead of this unnecessary blocking and unblocking slows down the program's execution.

In the previous section, we saw how fine-grained parallelism can improve a program's performance by increasing the chance that a processor will find another runnable thread when its current thread blocks. Unfortunately, a fine-grained parallel program that packs the ready-list interacts badly with the behavior of a one-level scheduler. In particular, when a program's thread blocks in the kernel on an I/O request, the parallelism of the program can only be maintained if the kernel can schedule another of the program's threads in place of the one that blocked. This benefit, though, comes at the cost of increased preemption activity and diminished overall performance.

The problems of one-level scheduling are addressed by two-level schedulers. With a two-level scheduler, processors are first assigned to a job, and then threads within that job are executed only on the assigned processors. Each job has its own ready-list, which is used only by the job's processors, as shown in [Figure 81.3](#). Thread preemption may no longer be necessary with a two-level scheduler since a preempted thread will only be replaced by another thread from the same job. Further, for long intervals, a processor runs only threads from the same application, and so the cost of switching between threads is kept low.

In a two-level scheduling system, processors can be allocated to jobs either statically or dynamically. A static two-level scheduler never changes the number of processors given to a job from its initial allocation;

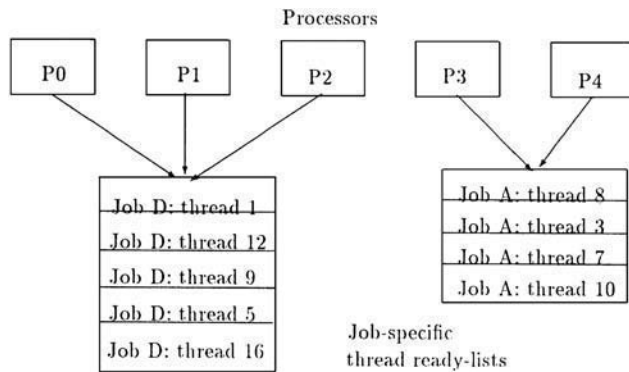

FIGURE 81.3 Two-level thread scheduling.

if some of those processors are needed by another job, the operating system must preempt all of the job's processors. A dynamic scheduler can adapt the number of processors assigned to each job according to changing conditions.

Dynamic two-level scheduling can give better performance, because it overlaps periods of poor parallelism in one job with periods of high parallelism in another. One difficulty with a dynamic scheduler is that it requires more information from an application describing the current processor requirements. As a result, though, dynamic scheduling can also more easily handle changes in the number of running jobs. For example, when a job finishes, its processors can be reallocated to a running job whose parallelism is increasing. To avoid the problems of one-level scheduling, though, it is crucial that the operating system coordinate with each application when it needs to preempt processors (e.g., to avoid preempting a processor when it would seriously affect performance). A dynamic scheduler always has the option, when it needs processors and no application has any available, of reverting to a static policy.

81.3.2.3 Kernel- vs User-Level Thread Management

Processor scheduling controls the allocation of processors to jobs. The operating system must be responsible for processor scheduling because processors are a hardware resource and shifting a processor from one job to another involves updating per-processor address space hardware registers. Spawning a thread so that it runs on an already allocated processor, however, does not require modifying privileged state. Thus, thread management and scheduling within a job can be done entirely by the application instead of by the operating system. In this case, thread management operations can be implemented in an application-level library. The library creates virtual processors using the operating system's processor scheduling interface, and schedules the application's threads on top of these virtual processors.

Unlike processor allocation, where a single systemwide scheduling policy can be used, thread scheduling policies benefit from being application specific. Some applications perform well if their threads are scheduled according to some fixed policy, such as first-in–first-out or last-in–first-out, but others need to schedule threads according to fixed, or even dynamically changing priorities. For example, consider a parallel simulation where each simulation object is represented by its own thread. Different objects become sequential bottlenecks at different times in the simulation; the amount of parallelism can be increased by preferentially scheduling these objects' threads.

It is difficult to provide sufficient thread scheduling flexibility with kernel-level threads. While the kernel could define an interface that allows each application to select its thread scheduling policy, it is unlikely that the system designer could foresee all possible application needs.

Thread management involves more than scheduling. A tradeoff exists between user- and kernel-level thread management. A user-level implementation provides more flexibility and better performance;

implementing threads in the kernel guarantees a uniformity that eases the integration of threads with system tools.

The downside of having many custom-built thread management systems is that there is no standard thread. By implication, a kernel-level thread management system defines a single, systemwide thread model that is used by all applications. Operating systems that support only one thread model, like those that support only one programming language, can more easily provide sophisticated utilities, such as debuggers and performance monitors. These utilities must rely on the abstraction and often the implementation of the thread model, and a single model makes it easier to provide complete versions of these tools since their cost can be amortized over a large number of applications. Peripheral support for multiple models is possible, but expensive.

A standard thread model also makes it possible for applications to use libraries, or canned software utilities. In the same sense that a standard procedure calling sequence sacrifices speed for the ability to call into separately compiled modules, a standard thread model allows one utility to call into another since they both share the same synchronization and concurrency semantics.

It is important to point out that two-level scheduling does not imply that threads are implemented at the application level; the job-specific ready queues shown in [Figure 81.3](#) could be maintained either within the operating system or within the application. Also, a user-level thread implementation does not imply two-level scheduling, even though threads *are* being scheduled by the application. This implication only holds in the absence of multiprogramming, or in cases where processors are explicitly allocated to jobs. For example, a user-level thread implementation built on top of Unix processes that share memory suffers from the same problems relating to preemption and I/O as do one-level kernel threads because both are scheduled in a job-independent fashion.

81.3.3 Performance

The performance of thread operations determines the granularity of parallelism that an application can effectively use. If thread operations are expensive, then applications that have inherently fine-grained parallelism must be restructured (if that is even possible) to reduce the frequency of those operations. As the cost of thread operations begins to approach that of a few procedure calls, several issues become performance critical that, for slower operations, would merely be second-order effects.

Simplicity in the thread system's implementation is crucial to performance [Anderson et al. 1989]. There is a performance advantage to building multiple thread systems, each tuned for a single type of application. Even simple features that are needed by only some applications, such as saving and restoring all floating point registers on a context switch, will markedly affect the performance of applications that do not need the functionality. Each context switch takes only tens of instructions; a feature that adds even a few more instructions must have a large compensating advantage to be worthwhile. For example, the ability to preemptively schedule threads within each job makes the thread management system more sluggish at several levels, because preemption must be disabled (and then re-enabled) whenever scheduling decisions are being made. These scheduling decisions are on the critical path of all thread management operations.

Although kernel-level thread management simplifies the generation and maintenance of system tools, it increases the baseline cost of all thread management operations. Just trapping to the operating system can cost as much as the thread operation itself, making a kernel implementation unattractive for high-performance applications. Further, the generality that must be provided by a kernel-level thread scheduler hurts the performance of those applications needing only basic service. Kernel-level threads are less able to cut corners by exploiting application-specific knowledge. With a user-level thread system, the thread management system can be stripped down to provide exactly the functions needed by an application and no more. User-level thread operations also avoid the cost of trapping to the kernel.

Other performance issues have less to do with what a thread system does, than with how it goes about doing it. For example, using a centralized ready-list can limit performance for applications that have extremely fine-grained parallelism. The ready-list is a shared data structure that must be locked to prevent

it from being modified by multiple processors simultaneously. Even if the ready-list critical sections consist only of simple enqueue and dequeue operations, they can become a sequential bottleneck, since there is little other work involved in spawning/finishing or blocking/unblocking a thread. An application for which thread overhead is 20% of the total execution time, and half of that overhead is spent accessing the ready-list, then its maximum speedup (the time of the parallel program on P processors divided by the time of the program on one processor) is limited to 10.

The bottleneck at the ready-list can be relieved by giving each processor its own ready-list. In this way, enqueueing and dequeueing of work can occur in parallel, with each processor using a different data structure. When a processor becomes idle, it checks its own list for work, and if that list is empty, it scans other processors' lists so that the workload remains balanced.

Per-processor ready-lists have another nice attribute: threads can be preferentially scheduled on the processor on which they last ran, thereby preserving cache state. Computer systems use caches to take advantage of the principle of *locality*, which says that a thread's memory references are directed to or near locations that have been recently referenced. By keeping references close to the processor in fast cache memory, the average time to access a memory location can be kept low. On a multiprocessor, a thread that has been rescheduled on a different processor will initially find fewer of its references in that processor's cache. For some applications, the cost of fetching these references can exceed the processing time of the thread operation that caused the thread to migrate.

The role of spin-waiting as an optimization technique changes in the presence of high-performance thread operations. If a thread needs to wait for an event, it can block, relinquishing its processor, or spin-wait. A thread must spin-wait for low-level scheduler locks, but in application code a thread should block instead of spin if the event is likely to take longer than the cost of the context switch. Even though context switches can be implemented efficiently, reducing the need to spin-wait, a hidden cost is that context switches also reduce cache locality.

81.4 Three Modern Thread Systems

We now outline three modern thread management systems for multiprocessors: Windows NT, Presto, and Multilisp. The choices made in each system illustrate many of the thread management issues raised in the previous section.

The thread management primitives for each of these systems are shown in Table 81.1. The table is organized to indicate how the primitives in one system relate to those in the others, as well as those provided by the basic thread interface outlined in the Basic Thread Functionality section.

Windows NT is an operating system designed to support Microsoft Windows applications on uniprocessors, shared memory multiprocessors, and distributed systems. Windows NT supports multiple threads within an address space. Its thread management functions are implemented in the Windows NT kernel. Since NT's underlying thread implementation is shared by all parallel programs, system services such as debuggers and performance monitors can be economically provided.

Windows NT's scheduler uses a priority-based one-level scheduling discipline. Because Windows NT allocates processors to threads in a job-independent fashion, a parallel program running on top of the Windows NT thread primitives (or even a user-level thread management system based on those primitives) can suffer from anomalous performance profiles due to ill-timed preemptive decisions made by the one-level scheduling system.

TABLE 81.1 The Basic Operations of Thread Management Systems

Basic	Windows NT	Presto	Multilisp
Spawn	thread_create;thread_resume	Thread::new; Thread::start	(future...)
Block	thread_suspend	Thread::sleep	<i>Touch unresolved future.</i>
Unblock	thread_resume	Thread::wakeup	<i>When future is resolved.</i>
Finish	thread_terminate	Thread::terminate	<i>Resolve this future.</i>

Presto is a user-level thread management system originally implemented on top of Sequent's DYNIX operating system, but later ported to DEC workstations. DYNIX provides a Presto program with a fixed number of Unix processes that share memory. The Presto run-time system treats these processes as virtual processors and schedules the user's threads among them. Presto's thread interface is nearly identical to Windows NT's.

Presto is distinguished from most other thread systems in that it is structured for flexibility. Presto is easy to adapt to application-specific needs because it presents a uniform object-oriented interface to threads, synchronization, and scheduling. The object-oriented design of Presto encourages multiple implementations of the thread management functions and so offers the flexibility to efficiently accommodate differing parallel programming needs.

Presto has been tuned to perform well on a multiprocessor; it tries to avoid bottlenecks in the thread management functions through the use of per-processor data structures. Presto does not provide true two-level scheduling, even though the thread management functions (e.g., thread scheduling) are implemented in an application library accessible to the user; DYNIX, the base operating system, schedules the underlying virtual processors (Unix processes) any way that it chooses. Although a Presto program can request that its virtual processors not be preempted, the operating system offers no solid guarantee. As a result, kernel preemption threatens the performance of Presto programs in the same way as it does Windows NT programs.

Although Windows NT and Presto are implemented differently, the interfaces to each represent a similar style of parallel programming in which the programmer is responsible for explicitly spawning new threads of execution *and* for synchronizing their access to shared data. This style is not accidental, but reflects the basic function of the underlying hardware: processors communicating through shared memory. One criticism often made of this style is that it forces the programmer to think about coordinating many concurrent activities, which can be a conceptually difficult task.

Multilisp demonstrates how thread support can be integrated into a programming language in order to simplify writing parallel programs. In Multilisp, a multiprocessor extension to LISP, the basic concurrency mechanism is the **future**, which is a reference to a data value that has not yet been computed. The **future** operator can be included in any Multilisp expression to spawn a new thread which computes the value of the expression in parallel. Once the value has been computed, the future *resolves* to that value. In the meantime, any thread that tries to use the future's value in an expression automatically blocks until the future is resolved. The language support provided by Multilisp can be implemented on top of a system like Windows NT or Presto using locks and condition variables.

With Multilisp, the programmer does not need to include any synchronization code beyond the future operator; the Multilisp interpreter keeps track of which futures remain unresolved. By contrast, using the Windows NT or Presto thread primitives, the programmer must add calls to the appropriate synchronization primitives wherever the data is needed. Multilisp, like Presto, uses per-processor ready-lists to reduce contention in scheduling operations.

81.5 Summary

This chapter has examined some of the key issues in thread management for shared-memory multiprocessors.

Shared-memory multiprocessors are now commonplace in both commercial and research computing. These systems can easily be used to increase throughput for multiprogrammed sequential jobs. However, their greatest potential — as yet not fully realized — is for accelerating the execution of single, parallelized programs.

As programmers make use of finer grained parallelism, the design and implementation of the thread management system becomes increasingly crucial. Modern thread management systems must address the programmer interface, the operating system interface, and performance optimizations; language support and scheduling techniques for multiprogrammed multiprocessors are two areas that require further research.

82.1 Introduction

High-level language programmers and computer users deal with what is really a virtual computer. That virtual computer they see is facilitated by a software bridge that plays the role of interlocutor between the actual computer hardware and the computer user's environment. This software, described in general in [Chapter 80](#), is the operating system. The computer's operating system (OS) is made up of a group of systems programs that serve two basic ends:

- To control the allocation and use of the computing system's resources among the various users and tasks
- To provide an interface between the computer hardware and the programmer or user that simplifies and makes feasible the creation, coding, debugging, maintenance, and use of applications programs

Thus, the OS creates and maintains an environment in which users can have programs executed. That is, it provides a structure in which the user can request and monitor execution of his or her programs and can receive the resulting output. To this end, the OS must make available to the user's program the system resources needed for its execution. These system resources are the processor, primary memory, secondary memory (including the file system), and the various devices. Because most modern computing systems are powerful enough to allow multiple user programs or at least multiple tasks to execute in the same time

frame, the OS must allocate these resources among the potentially competing needs of the multiple tasks in such a way as to ensure that all tasks can execute to completion. Furthermore, these resources must be allocated so that no one task is unnecessarily or unfairly delayed. This requires that the OS *schedule* its resources among the various and competing tasks. The detailed characterization of the problem of scheduling computer system resources in a number of settings; the techniques, algorithms, and policies that have been set forth for its solution; and the criteria and method of assessment of the efficacy of these solutions form the subject of this chapter.

The next section establishes the landscape for the discussion, with a brief review of delivery methods of computing services and a look at the essential concept of a process — a program in execution — the most basic unit of account in an OS. Then, we take a brief look at the components of the OS responsible for the execution of a process. Although this chapter is primarily concerned with the first of the two functions of an OS — that is, control of the allocation and use of computing system resources — it will become clear that the methods brought to bear on the simultaneous achievement of these two functions cannot treat them as wholly independent.

82.2 Background

Computer service delivery systems may be classified into three groups, which are distinguished by the nature of interaction that takes place between the computer user and his or her program during its processing. These classifications are batch, time-shared, and real-time.

In a *batch processing* OS environment, users submit jobs, which are collected into a batch and placed in an input queue at the computer where they will be run. In this case, the user has no interaction with the job during its processing, and the computer's response time is the turnaround time — the time from submission of the job until execution is complete and the results are ready for return to the person who submitted the job.

A second mode for delivering computing services is provided by a *time-sharing* OS. In this environment, a computer provides computing services to several users concurrently online. The various users share the central processor, the memory, and other resources of the computer system in a manner facilitated, controlled, and monitored by the operating system. The user, in this environment, has full interaction with the program during its execution, and the computer's response time may be expected to be no more than a few seconds.

The third class, the *real-time* OS, is designed to service those applications where response time is of the essence in order to prevent error, misrepresentation, or even disaster. Real-time operating systems are subdivided into what are termed *hard* real-time systems and *soft* real-time systems. The former provide for applications that cannot be compromised, such as airline reservations, machine tool control, and monitoring of a nuclear power station. The latter accommodate less critical applications, such as audio and video streaming. In either case, the systems are designed to be interrupted by external signals that require the immediate attention of the computer system.

In fact, many computer operating systems are *hybrids*, providing for more than one of these types of computing service simultaneously. It is especially common to have a background batch system running in conjunction with one of the other two on the same computer system.

Discussion of resource scheduling in this chapter is limited to uniprocessor and multiprocessor systems *sans* network connections. Resource scheduling in networking and distributed computing environments is considered in [Chapter 87](#) and [Chapter 88](#).

Programs proceed through the computer as *processes*. Therefore, the various computer system resources are to be allocated to processes. A thorough understanding of that concept is essential in all that follows here.

82.2.1 Processes

Most operating systems today are **multiprogramming** systems. Systems such as these, where multiple, independent programs are executing, must manage two difficult problems: concurrency and nondeterminacy. The *concurrency* problem arises from the coexistence of several active processes in the system

during any given interval of time. *Nondeterminacy* arises from the fact that each process can be interrupted between any two of its steps. The unpredictability of these interruptions, coupled with the randomness that results from processes entering and leaving the system, makes it impossible to predict the relative speed of execution of interrelated processes in the system. A mechanism is needed to facilitate thinking about, and ultimately dealing with, the problems associated with concurrency and nondeterminacy. An important part of that mechanism is the conceptual and operational isolation of the fundamental unit of computation that the operating system must manage. This unit is called the *task* or **process**. Informally, a process is a program in execution.

This concept of process facilitates an understanding of the twin problems of concurrency and indeterminacy. Concurrency, as we have seen, occurs whenever there are two or more processes active within the system. Concurrency may be *real*, in the case where there is more than one processor and hence more than one process can execute simultaneously, or *apparent*, whenever there are more processes than processors. In the latter case, it is necessary for the OS to provide for the switching of processors from one process to another sufficiently rapidly to present the illusion of concurrency to system users. But this is difficult, for whenever a processor is assigned to a new process (called *context switching*), it is necessary to recall where the first process was stopped in order to allow that process, when it gets the processor back, to continue where it left off.

The idea of context switching implies that a particular process can be interrupted. Indeed, a process may be interrupted, as necessary, between individual steps (machine instructions). Such interruptions occur most often when a particular process has used up its quota of processor time or when it has requested and must wait for completion of an I/O operation. Nondeterminacy arises from the unpredictable order in which such interruptions can occur.

Because active processes in the system can be interrupted, each process can be in one of three states:

- **Running** — The process is currently executing on a processor.
- **Ready** — The process could use a processor if one were available.
- **Blocked** — The process is waiting for some event, such as I/O completion, to occur.

The relationship between these three states for a particular process is portrayed in Figure 82.1.

Here, we see that if a process is currently *running* and requests I/O, for example, it relinquishes its processor and goes to the *blocked* state. In order to maintain the illusion of concurrency, each process is assigned a fixed *quantum* of time, or *time-slice*, which is the maximum time a running process can control the processor. If a process is in the running state and does not complete or block before expiration of its time-slice, that process is placed in the *ready* state, and some other process is granted use of the processor for its quantum of time. A blocked process can move back to the ready state upon completion of the event that blocked it. A process in the ready state becomes running when it is assigned a processor by the system dispatcher.

All of these state changes are interrupt-driven. A request for I/O is effected by issuing a supervisor call via an I/O procedure, which causes a system interrupt. I/O completion is signaled by an I/O interrupt

FIGURE 82.1 Process state transitions.

from a data channel* or device controller. Time-slice exceeded results in an external interrupt from the system's interval timer. And, of course, movement from ready state to running results from the dispatcher giving control of the processor to the most eligible ready process. In each case, when a process gives up the processor, it is necessary to save the particulars of where the process was in its execution when it was interrupted, so that it may properly resume later.

Each process within the system is represented by an associated *process control block* (PCB). The PCB is a data structure containing the essential information about an active process, including the following:

- Process ID
- Current state of the process
- Register save area
- A pointer to the process's allocated memory area
- Pointers to other allocated resources (disk, printer, etc.)

The last three contain the information necessary to restart an interrupted process. There is only one set of registers in the system, shared by all of the active processes. Therefore, the contents of these registers must be saved just before the context switch. Because memory is both space- and time-shared, it is necessary only to save pointers to the locations of the process' memory areas before its interruption. Devices vary. Some are shareable (e.g., disk devices) and so are treated like memory; others (e.g., the printer) are nonshareable and tied up by a process for as long as it is using them. In either case, it is necessary here to keep track only of the device ID and, perhaps, the current position in a file.

Thus, programs solve problems by being executed; they execute as processes. To this end, the OS must allocate, or schedule, to the process sufficient memory to hold its data and at least the part of the program immediately due for execution, the various devices needed, and a processor. Because there certainly will be multiple processes and possibly even multiple jobs, each made up of processes, it is necessary to have the OS schedule these resources in such a way as to enable all the jobs to run to completion. The next section deals with scheduling the processor among the processes competing for it to effect the execution of their parent programs.

82.3 Resources and Scheduling

Programs execute as processes using computer system resources, including a processor, primary memory, and most likely secondary memory, including files, and some devices. Thus, in order for the process to execute, it must enter the system and these resources must be allocated to the process. The OS must schedule the allocation of these resources to a given process so that this process, and any others in the system, may execute in a timely fashion.

The simplest case is a monoprogrammed system, where there is just one program executing in the system at a time. In this case, a process can be scheduled to the system whenever it becomes available following the previous process's execution. Scheduling consists of determining whether sufficient resources are available and, if so, allocating them to the process for the duration of its processing time in the system. The situation is more complex in a multiprogrammed system where there are multiple processes in the system competing for the various resources. In this case, the OS must schedule and allocate, to each active process, sufficient memory to accommodate at least the parts of its data and program instructions needed for execution in the near term. Then, the OS must schedule the processor to execute some instructions. In addition, there must be provision for scheduling access to needed files and required devices, all with some sort of time constraint.

Not all of these resources need to be allocated to a particular process throughout its life in the system, but they must be scheduled in such a manner as to be available when needed and in concert. Otherwise, a

*A data channel may be conceived as a small, special-purpose computer that executes programs to actually do I/O concurrently with the main processor's program execution. In today's desktop computers, this function is largely subsumed in the device controllers.

process may be stalled for lack of one or more resources, tying up other processes waiting for unavailable resources in the interim.

Resource scheduling and allocation is, from the performance point of view, perhaps the most important part of the OS. Good scheduling must consider the following objectives:

- Resource allocation that facilitates minimal average turnaround time
- Resource allocation that facilitates minimal response time
- Mutual exclusion of processes from nonshareable resources
- A high level of resource utilization
- **Deadlock** prevention, avoidance, or detection

It is clear that these objectives cannot necessarily be mutually satisfied. For example, a high level of resource utilization probably will mean a longer average wait for resources, thus lengthening both response and turnaround times. The choice may be, in part, a function of the particular service delivery system that the process has entered. A batch system scheduler would favor resource utilization, whereas a time-sharing system would need to be sensitive to response time, and at the extreme, a real-time system would minimize response time at the expense of resource utilization.

An *allocation mechanism* refers to the implementation of allocations. This includes the data structures used to represent the state of the various resources (shareable or nonshareable, available, busy, or broken), the methods used to assure mutual exclusion in use of nonshareable resources, and the technique for queuing waiting resource requests. The *allocation policy* refers to the rationale and ramifications of applying the mechanisms. Successful scheduling requires consideration of both.

The practices and policies regarding scheduling each resource class, the processor, primary memory, secondary memory and files, and devices, differ significantly and are next considered in turn. Because the processor is arguably the most important resource — certainly a process could not proceed without it — the discussion turns first to processor scheduling.

82.3.1 Processor Scheduling

In this section, it is assumed that adequate memory has been allocated to each process and the needed devices are available, to allow focus on the problems surrounding the allocation of the processor to the various processes. To distinguish scheduling programs from the input queue for entry into the computing system from the problem of allocating the processor among the active processes already in the system, the term *scheduler* is reserved for the former and *dispatcher* for the latter. The term *active process* refers to a process that has been scheduled, in this sense, into the system from the input queue, that is, has been allocated space in memory and has at least some of its needed devices allocated.

Development of methods for processor dispatching is motivated by a number of system performance goals, including the following:

- Reasonable turnaround and/or response time — here, as indicated previously, the tolerance is governed by the service delivery system (e.g., batch processing vs. time-sharing)
- Predictable performance
- Good absolute or relative throughput
- Efficient resource utilization (i.e., low CPU idle time)
- Proportional resource allocation
- Reasonable-length waiting queues
- Insurance that no process must wait forever
- Satisfaction of real-time constraints

Clearly, these goals sometimes conflict. For example, average response time can be improved, but at the expense of the very longest programs, which are likely to have to wait. Or minimization of response time

could result in poor resource utilization if a long program that has many resources allocated to it is forced to wait for a long while, thus idling the resources allocated to it.

A processor scheduler, CPU scheduler, or dispatcher consists of two parts. One is a ready queue, consisting of the active processes that could immediately use a processor were one available. This queue is made up of all of the processes in the ready state of [Figure 82.1](#).^{*} The other part of the dispatcher is the algorithm used to select the process, from those on the ready queue, to get the processor next. A number of dispatching algorithms have been proposed and tried. These algorithms are classified here into three groups: priority algorithms, rotation algorithms, and multilevel algorithms.

82.3.2 Priority Dispatching Algorithms

These dispatching algorithms may be classified by queue organization, whether they are preemptive or nonpreemptive, and the basis for the priority.

The ready queue may be first-in, first-out (FIFO), priority, or unordered. The queue can be maintained in sorted form, which facilitates rapid location of the highest-priority process. However, in this case, inserting a new arrival is expensive because, on average, half of the queue must be searched to find the correct place for the insertion. Alternatively, new entries can simply and quickly be added to an unsorted ready queue. But the entire queue must be searched each time the processor is to be allocated to a new process. In fact, a compromise plan might call for a periodic sort, maintaining a short list of new arrivals on the top of the previously sorted queue. In this case, when a new process is to be selected, the priority of the process at the front of the sorted part of the queue is compared with each of the recently arrived unsorted additions, and the processor is assigned to the process of highest priority.

In a nonpreemptive algorithm, the dispatcher schedules the processor to the process at the front of the ready queue, and that process executes until it blocks or completes. A preemptive algorithm is the same, except that a process, once assigned a processor, will execute until it completes or is blocked, unless a process of higher priority enters the ready queue. In that case, the executing process is interrupted and placed on the ready queue and the now-higher priority process is allocated the processor.

82.3.2.1 First-Come, First-Served (FCFS) Dispatching

When the criterion for priority is arrival time, the dispatching algorithm becomes FCFS. In this case, the ready queue is a FIFO queue. Processor assignment is made to the process with its PCB at the front of the queue, and new arrivals are simply added to the rear of the queue. The algorithm is easy to understand and implement. FCFS is nonpreemptive, so a process, once assigned a processor, keeps it until it blocks (say, for I/O) or completes. Therefore, the performance of the system in this case is left largely in the hands of fate, that is, how jobs happen to arrive.

82.3.2.2 Shortest Job First (SJF) Dispatching

The conventional form of the SJF algorithm is a priority algorithm where the priority is inversely proportional to (user) estimated execution time. The relative accuracy of user estimates is enforced by what is, in effect, a penalty–reward system: too long an estimated execution time puts a job at lower priority than need be, and too short an estimate is controlled by aborting the job when the estimated time is exceeded. This effects a delay with penalty by forcing the user to rerun the job. There are preemptive and nonpreemptive forms of the SJF algorithm. In the nonpreemptive form, once a process is allocated a processor, the process runs until completion or block. The preemptive form of the algorithm allows a new arrival to the ready queue with lower estimated running time to preempt a currently executing process with a longer estimated running time.

^{*}The ready queue contains representations of the ready processes, that is, the corresponding PCBs (or pointers to them).

SJF is clearly advantageous for short jobs. Because a typical execution time distribution is usually weighted toward shorter jobs — especially in an installation providing general computer services — one could argue that a SJF policy would benefit most users. But, as always, there is a trade-off. In this case, it is that long jobs get relatively poor service. This is especially true in the preemptive version, where preemption clearly favors short jobs, with the result that long jobs can be effectively starved out. Although the SJF rule provides the minimum average waiting time, it, like FCFS, appears to apply only to the batch processing system of service delivery.

82.3.2.3 Priority Dispatching

In this algorithm, process priorities are set based on criteria external to the system, reflecting the relative importance of the processes. These include such factors as memory size requirements, estimated job execution time, estimated amount of I/O activity, and/or some measure of the importance of the computation as set by the user or the institutional structure. For example, a class of jobs characterized by low execution time estimates combined with minimal resource requirements may be deemed high priority. Similarly, one might argue that particular systems programs, say device handlers, ought to have high priority. This type of dispatching algorithm can, like the previous ones, be either nonpreemptive or preemptive. In the nonpreemptive form, the highest-priority job is assigned to the CPU and runs until completion or block. In the preemptive form, the arrival of a higher-priority job at the ready queue results in the preemption of the currently running process for the higher-priority process.

It is clear that priority dispatching serves the highest-priority jobs optimally. Thus, to the extent that the externally set priorities reflect actual institutional priorities, priority dispatching is arguably best. However, there are two problems. First, low-priority jobs generally receive poor service. Especially in the preemptive form, low-priority jobs can be blocked indefinitely or starved out from the processor, violating the fairness criterion. Second, to the extent that priorities are set by users, based on the real or perceived importance of their programs without knowledge of the current system workload mix, the system can lose control of its performance parameters. For example, a high-priority process might get good service, but at the cost of other goals, such as maximum system throughput or resource utilization.

82.3.2.4 Dynamic Dispatching Priority Adjustment

Some of the shortcomings of the priority algorithms can be ameliorated by dynamic priority adjustment. In this case, decisions can be based on information about a process that is obtained while the process is in the system. Priorities determined from one of the previously described algorithms can be adjusted dynamically during the process' life in the system, according to a number of criteria, such as the number and type of resources currently allocated, accumulated waiting time since the job entered the system, amount of recent processing time, amount of recent I/O activity, total time in the system, etc.

One such plan advanced by Kleinrock [44] is to allow a process dispatching priority to increase at rate x while the process is in the ready queue, and rate y while it has a processor assigned to it. Priority then depends on the values of x and y . These could be set externally and differ for different jobs. They could also change dynamically over the time a given process is in the system. For example, the starvation problem can be eliminated if x of a high-priority process decreases over time and/or y of a low-priority job increases over time. Use of the SJF rule accompanied by nonlinear functions, where x and y decrease over time for a while and then jump to high values, will ensure that no jobs wait very long for service, yet still favors short jobs.

Another dynamic scheme would increase the priority of a process dynamically during periods of high I/O activity. That is, it would make priority inversely related to the time interval since the last I/O call. This favoring of I/O-bound jobs is desirable because it compensates for the speed disparity between the more mechanical I/O devices and the higher-speed electronic processor. It does this by keeping the devices running, thus minimizing the possibility that the CPU must wait for I/O completion. Moreover, the effect on other, more compute-bound jobs, is minimal because of the limited CPU time required to start I/O operations.

In general, priority algorithms are easy to understand and simple to implement. The main disadvantage is that low-priority jobs tend to get poor service. Moreover, the performance associated with this type of algorithm is not appropriate to some situations. The response times available to processes, especially

lower-priority programs, would not be acceptable in a time-sharing or real-time environment. Apparently, there is a need to consider another approach to dispatching.

82.3.3 Rotation Algorithms

The essence of the rotation algorithms, as the name implies, is that the CPU is scheduled in rotation, so that each job in the ready queue is given some service in order to maintain a reasonable response interval. These algorithms are designed to apply to time-sharing systems.

82.3.3.1 Simple Round Robin (RR)

In the round-robin rotation algorithm, processor time is divided into time-slices, or quanta. The ready queue is treated like a circular queue, and each process in the ready queue is given one time-slice each rotation. If the process does not complete or block during its quantum, at the end of the quantum, the process is preempted and returned to the end of the ready queue. The idea is to provide response that is reasonably independent of job size and/or priority. In simple RR, all time-slices are the same size, say q . A typical q is 50 ms; the range is 10 ms to 100 ms. There is no static or dynamic priority information. Therefore, if there are k processes in the ready queue, each process is scheduled for q out of every kq milliseconds. Thus, users perceive processes running on a processor with $1/k$ of its actual processor speed. Response time is $(k - 1) \times q$ or less.

Clearly, performance is affected by two key parameters: the size of the ready queue, k and the quantum size, q . Response is inversely related to k , so as the system becomes loaded, response time deteriorates. While k is essentially determined externally, quantum size is a system parameter. If q is infinite, then round robin is FCFS. A large q tends to favor some jobs. If a number of processes in the ready queue are in blocked state or will block during their quanta, the remaining processes will cycle frequently, and the corresponding jobs will run to completion quickly and with excellent response times. On the other hand, arrival of new processes, each taking one of the longer quanta, causes the average response to deteriorate substantially. If q is small, these effects are decreased. For example, arrival of a new process to the ready queue will have a much smaller effect on average response time. A small q , in addition to providing a more consistent response, leads to a total waiting time for a job more proportional to the length of the job. At the extreme, a very small q will cause useful execution time of the quantum to be overwhelmed by the context switching delay. This would imply that the size of the quantum ought to be large relative to the time required for a context switch. Turnaround time is also affected by the size of the time-slice. Although one might expect that turnaround time would fall as the quantum size increases, this is not always true. Context switches add to turnaround, and, as a very long quantum moves RR toward FCFS, average turnaround can increase substantially. Silberschatz et al. [77] claim that 80% of the CPU executions should be shorter than q .

82.3.3.2 Round-Robin with Priorities

Simple round robin is designed to provide reasonable and fair response time for all active processes in the system. As such, it has no way of recognizing a “more important” process. Variants of simple round robin have been proposed to address this problem. *Biased round robin* allows for different length time-slices for different processes, based on some external priority. A process with a higher priority is assigned a longer q , allowing processes to proceed through the system in proportion to their priorities. An alternative, *selfish round robin*, is based on Kleinrock’s linearly increasing priority scheme [44], discussed previously. Here, x and y are such that $0 \leq y < x$. The effect is that processes already in execution make entering processes wait in the ready queue until the priority of the new process increases to the value of the older processes’ priority. This will eventually occur because y , the rate of priority increase of an executing process, is less than x , the rate of priority increase of a process in the ready queue.

82.3.3.3 Cycle-Oriented Round Robin

Simple round robin is subject to considerable performance degradation in terms of response time as more processes enter the system and enter the ready queue. This can lead to an increase in response time beyond

that which is reasonable and expected for an interactive time-sharing environment. *Cycle-oriented round robin* was developed to obviate this problem. In this case, the longest tolerable response time, c , is set as the cycle time and becomes the basis for calculation of the quantum length, q . The time-slice, $q = c/k$, will guarantee that response time never exceeds the maximum tolerable, c . There are, however, two problems. Process arrivals during the cycle could cause the response time to exceed the acceptable limit. But this is easily resolved by denying new arrivals entry into the ready queue except at the end of a cycle, when the time-slice size is recalculated. The problem of system overload remains, however. As k becomes large, q becomes small, and k too large implies that q will be too small, leading to unacceptable overhead from context switching. The solution is to enforce a minimum time-slice size.

82.3.4 Multilevel Dispatching

[Section 82.2](#) points out that a single computing system might be designed to provide for two (or more) of the computer service delivery systems, say time-sharing in the foreground and batch in the background. The two delivery systems have different service requirements. Consequently, taken individually, the systems most appropriately would employ different dispatching algorithms. When the two services are available on the same system, it is necessary to account for different scheduling needs and the priority of interactive jobs over background batch jobs.

This is accomplished by a *multilevel dispatching* system, in which the ready queue is partitioned into two (or more) separate queues: one for the interactive jobs, one for batch jobs, etc. Each process entering the system is assigned to one of the queues based on process type. Then, the processes on each of the several queues are scheduled by different algorithms as appropriate (e.g., RR for the interactive job queue and FCFS for the batch job queue). Moreover, a system of preset priorities with preemption is used for scheduling among the multiple queues. For example, there might be three separate queues, one for system processes, one for interactive processes, and one for batch processes. All processes in the system process queue must be completed before any processes from the interactive queue are dispatched to the processor. Similarly, the interactive queue must be empty before any processes from the batch queue are dispatched. A new system process entering the first queue would cause any interactive process or batch process to be preempted, and a new interactive process would preempt a batch process.

Alternately, dispatching could occur among the queues on a time-slice basis (i.e., so much time for the systems queue, then a quantum of time for the interactive process queue, etc.). Of course, the time-slice given to each queue could vary, reflecting the priority of processes assigned to that particular queue. For example, after processes in the system queue complete, 75% of the time could be allocated to interactive jobs and 25% to batch jobs, until another system process comes along.

82.3.4.1 Multilevel Feedback Queue Dispatching

The multilevel queue dispatching described in [Section 82.3.4](#) relies on processes being assigned to one of the queues depending on some external factor, such as process type. Processes, once assigned to a particular queue, remain there for the duration of their time in the system. Multilevel feedback queue dispatching is similar, except that particular processes can move among the separate queues dynamically, based on some aspect or aspects of their progress through the system. For example, three queues could be established as before. Here, the queues are designated queue 0, queue 1, and queue 2, with priority highest for the lowest numbered queue, etc. Accordingly, the quantum q_0 would be shortest for the lowest numbered queue, which would be dispatched according to some form of RR algorithm. Queue 1 would also be RR, but with a longer quantum, q_1 , and queue 2 FCFS with an even longer quantum, q_2 . All new processes enter queue 0. Processes that complete or block within the quantum q_0 remain in this highest-priority queue 0. At q_0 time exceeded, those that do not complete or block are moved to queue 1. Similarly, those in queue 1 that do not complete or block in time q_1 are moved to queue 2. The queues, as before, are scheduled according to a system of preset priorities with preemption. All the processes in queue 0 must be completed or blocked before any processes from queue 1 are dispatched, and so forth. A new process arriving at queue 1 will preempt a currently executing process from queue 2.

FIGURE 82.2 UNIX process priorities (adapted from Bach [1]).

It is evident that the multilevel feedback queue system of dispatching is the most complex. In addition to the three queues and the dispatching algorithms appropriate for each queue, the system requires a description of some algorithm to determine when to move a process to the next lower or next higher priority queue, and a method to determine which queue an entering process should initially join.

82.3.4.2 Process Scheduling in UNIX

The UNIX system uses a system of *decay usage scheduling* that might be characterized in terms of the previous classes as round robin with multilevel feedback [1]. Basically, each user process begins with a base level priority that puts it into a particular ready queue. Periodically, the priority is recalculated on the basis of recent CPU usage, increasing the priorities of processes inversely with recent CPU usage.

In UNIX, the possible priority levels are divided into two classes [1]: kernel priorities and user priorities. Within each class are a number of priority levels, as shown in Figure 82.2. Note that higher priorities are associated with lower priority values.

The basic operation is for the dispatcher to execute a context switch whenever the currently executing process blocks or exits, or when returning to user mode from kernel mode if a process with a priority higher than the process currently allocated the CPU is ready to run.

A process entering the system is assigned the highest user-level priority, called the *base-level priority*. If there are several processes in the highest user process level, the dispatcher selects the one that has been there longest. The CPU is dispatched to that process. The clock interrupts the executing process perhaps several times during its quantum. At each clock interrupt, the clock interrupt handler increases an execution time field in the PCB. Approximately once a second (in UNIX system V), the clock interrupt handler applies a decay function to the execution time field in the PCB of each active process in the system. Thus

$$C(\text{execution time field}) = \text{decay}(C(\text{execution time field})) = C(\text{execution time field})/2$$

At this same time, the process priority is recalculated based on recent CPU usage [1]:

$$\text{priority} = C(\text{execution time field})/2 + \text{base level priority}$$

A process that does not block or exit, and therefore uses its entire quantum, would be assigned a higher number, corresponding to a lower priority. If the process blocks, it is assigned a priority by the system call routine. The priority is not dependent on whether the process is I/O-bound or processor-bound, as in the multilevel feedback queue dispatching described previously. Rather, it is a function of the particular reason the process blocked. The kernel adjusts the priority of processes returning from kernel mode back to a user-level mode, reflecting the fact that it has just had access to kernel resources. Kernel-level priorities can only be obtained via a system call. When the event that caused the block has been completed, the process can resume execution, unless preempted by the dispatcher due to the arrival of a process with a higher priority in the ready queue. This could occur upon completion of some event that previously led to block state for some higher-priority process or if the periodic priority changes by the clock interrupt handler have made one of the other process's priority higher. In either case, the dispatcher initiates a context switch.

The periodic priority recalculation effectively redistributes the processes among the user-level priority levels. This, along with the policy of dispatching first the process longest in the highest-priority queue, assures round-robin scheduling for processes in user mode. It should be clear that this scheduler will provide preferential service to highly interactive tasks, such as editing, because their typically low ratio of CPU time to idle time causes their priority level to increase quickly, on account of their low recent CPU usage.

The UNIX process scheduler includes a feature allowing users to exercise some control over process priority. There is a system call

```
nice (priority_level)
```

that permits an additional element in the formula for recalculating priority [1]:

```
priority = C(execution time field)/2 + base level priority + nice  
priority_level
```

This allows the user with a nonurgent process to increment the priority calculation “nicely,” resulting in the process’ moving to a lower level in the user process priority queue. A user cannot use `nice` to raise the priority level of a process or to lower the priority of any other process. Only the superuser can use `nice` to increase a process priority level, and even the superuser cannot use `nice` to give another process a lower priority level. But superuser can, of course, kill any process.

82.3.5 Dispatching Algorithms for Real-Time Systems

Priority dispatching algorithms are well suited for the batch method of service delivery, and rotation algorithms provide for the performance requirements imposed by multiprogramming time-sharing systems. But what about real-time systems, where the constraints on response time are very strict?

Real-time systems for critical systems appear as stand-alone, dedicated systems. In this case, when a requesting process arrives, the system must consider the parameters of the request in conjunction with its then current resource availabilities and accept the request only if it can service the request within the strict time constraint. However, other real-time processes, such as those associated with multimedia, interactive graphics, etc., can be handled by a real-time component of a system also providing time-sharing or batch services. However, combining real-time applications with others will lead inevitably to a degradation in response and/or turnaround time for the others. For the combination to be workable, real-time applications must have the highest priority, that priority must not be allowed to deteriorate over time (no aging), and the time required for the dispatcher to interrupt a process and start (or restart) the real-time application must be acceptably small.

The dispatch time problem is complicated by the fact that an effectively higher priority process, such as a system call, may be running when the real-time application arrives. One solution to this problem is to interrupt the system call process as soon as possible, that is, when it is not modifying some kernel data structure. This means that even systems applications would contain at least some “interrupt points,” where they can be swapped out to make way for a real-time process. Another approach is to use IPC primitives (see [Chapter 84](#)) to guarantee mutual exclusion for critical kernel data structures, thus allowing systems programs to be interruptible. This latter is the technique used in Solaris 2. According to Silberschatz et al. [77], the Solaris 2 dispatch time with no preemption is around 100 ms, but with preemption and mutual exclusion protection, the dispatch time is closer to 2 ms.

82.4 Memory Scheduling

Memory allocation and scheduling are the functions of the OS’s memory management subsystem. The options include real and virtual memory systems. The mechanisms for scheduling memory include the following:

- Data structures used to implement free block lists and page and/or segment tables, depending on the memory management system structure

- Cooperation with the processor scheduler to place a process waiting for a memory block, page, or segment in blocked state
- Cooperation with the I/O subsystem to queue processes waiting for page or segment transfers to wait for the concomitant I/O service from a disk drive

The details for the memory management subsystem are in [Chapter 85](#) for standalone and networked systems and [Chapter 87](#) for distributed systems.

82.5 Device Scheduling

The devices — sometimes called *peripheral* devices — that can be attached to a computer system are many and varied. They range from terminals, to tape drives and printers, plotters, etc., to disk drives. These devices differ significantly in terms of both type of operations and speed of operation. In particular, the various devices use different media, encodings, and formats for the data read, written, and stored. On this count, devices can be divided into two groups:

- **Block devices** — Devices that store and transfer information in fixed-sized blocks
- **Character devices** — Devices that transfer sequences of characters

Disks are block devices: they read, write, and store blocks ranging in size from 128 to 1024 bytes, depending on the system [80]. In a block device, each block can be read or written independently of the others. Terminals, tape drives, printers, and network interfaces are character devices. In these cases, data is transferred as a string of characters; there are no block addresses, and it is not possible to find a specific character by address on the device.

Devices also differ with respect to the speed of data transmission. A terminal may be able to send perhaps 1000 characters per second, as compared to a disk, which has a transfer rate of closer to a million characters per second. Finally, devices differ with respect to the operations they support. A disk drive facilitates arm movement of a head for a seek operation, and a tape drive allows rewind; neither operation is appropriate for the other device.

Devices in general consist of two parts: the physical device itself and a controller. The actual device is the mechanical part: the turntables and heads for a tape, the disk spindle, platters, heads, and arms for a disk. The controller is the electronic part — a small computer of sorts that contains the circuitry necessary to effect the operation of the one or more similar devices connected to it. Thus, it is the controller that initiates the operation of a device and translates a stream of bits to (input) or from (output) a block of information in the controller's local buffer. In addition, the controller has registers that are used to receive device operation commands and parameters from the operating system and hold status information regarding the device's most recent operation.

Although the buffer in the device's controller effectively separates the slower, mechanical operations of a device from the much faster, electronic CPU, data transfer can still exact a delay on system performance. For input, eventually the block of data must be transferred from the controller's buffer to main memory for use by the program requesting it. The transfer requires a loop involving the CPU in a character-by-character transfer. For this reason, many block device controllers contain a direct memory access (DMA) capability. In this instance, the CPU need only send to the controller the main memory start address for the block and the number of characters to send. The controller will effect the transfer asynchronously of CPU operation, until the transfer of the entire block is complete, at which time the controller sends an interrupt to the CPU.

This overview of device operation makes it clear that I/O is one of the more detailed and difficult parts of the programming process. This, plus the obvious need for control over device allocation and utilization, led to the early incorporation of low-level I/O programs as one of the principal functions of the operating system. Thus, it is the responsibility of the I/O subsystem to provide a straightforward interface to user programs, to translate user I/O requests into instructions to the device controller, to handle errors, and indicate completion to the user program.

In this context, several goals apply to the design of the I/O subsystem. Of course, the I/O subsystem should be efficient because all programs perform at least some I/O, and I/O, with the inherently slower devices, can often become a bottleneck to system performance. I/O software should provide for device independence in two ways. First, it should be possible for user programs to be written and translated so as to be independent of a particular device of a given type. That is, it should not be necessary to rewrite or retranslate a program to direct output to a printer used instead of another, available one. Moreover, it should be possible to have a user program independent even from device type. The program should not have to be rewritten or retranslated to obtain input from a file rather than the keyboard.

In the UNIX system, this is effected by treating devices as special files, allowing a uniform naming scheme, a *directory path*, which allows device independence to include files as well as devices. Similarly, user programs should be free from character code dependence. The user should not need to know or care about the particular codes associated with any one device. These requirements are equivalent to the goal of uniform treatment of devices. A good user interface should provide for simplicity and therefore minimization of error. The most obvious implication of these goals, especially the last, is that all device-specific information — that is, instructions for operation of the device, device character encodings, error handling, etc. — should be as closely associated with the specific device or device class as possible. This suggests a layered structure for design of the I/O subsystem.

The structure of the I/O subsystem can be seen as four layers [50] [80], proceeding from I/O functions employed in user programs to the device drivers and interrupt handlers that provide low-level program control of the various devices:

- User program calls to library I/O functions
- System I/O call interface (device-independent)
- Device drivers (device-dependent)
- Interrupt routines

User programs invoke I/O by means of calls to library functions. These functions, which reside in system libraries, are linked to user programs at execution time, and run outside the kernel, provide for two basic services: formatting I/O and setting parameters for the system I/O call interface. An example of a library function that facilitates this is `printf` in UNIX, which processes an input format string to format an ASCII string and then invokes the library function `write` to assemble the parameters for the system I/O call interface [80]. These parameters include the name of the logical device or file where I/O is to be done, the type of operation (e.g., read, write, seek, backspace), the amount of data to be transferred (number of characters or blocks), and the source or destination storage location into which (input) or from which (output) a data transfer is to occur.

The system I/O call interface, which is an integral part of the operating system, has three basic functions:

- Link the logical device or file specified in the user-level I/O function to an appropriate physical device
- Perform error checks on the parameters supplied by the user in the I/O function
- Set up and initiate the request for the physical I/O

Thus, after ensuring that the I/O parameters in the user request are consistent with the operation requested (e.g., the amount of data in the transfer request is equal to 1 for a character device, or some multiple of the block size for a block device), the I/O call interface assembles the needed parameters into what Lister [50] terms an *I/O request block* (IORB). In addition to the previous parameters, the IORB will contain pointers to the PCB of the requesting process and an error location for any error codes, should the requested operation turn out to be unsuccessful.

In order to maintain device independence and to accommodate the unique features and operations associated with the various types of devices, the I/O requests, I/O in progress, and the device characteristics are manifest in a number of data structures. The exact nature of these is, of course, dependent on the system and the computer. These data structures are associated with each device type in so far as is possible. A device control block, I/O block, I/O control block (IOCB), unit control block, or channel control block

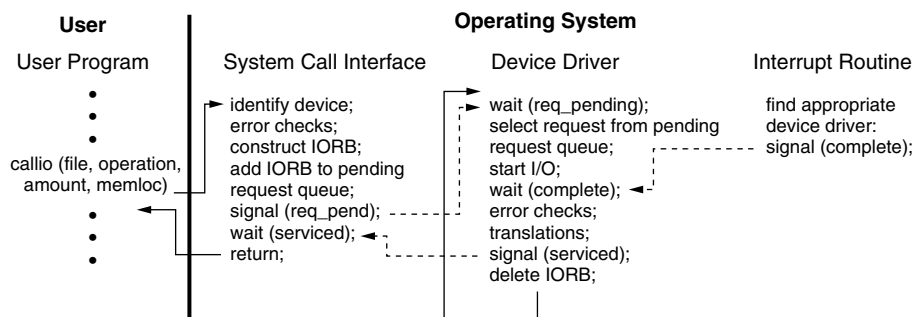

FIGURE 82.3 A sketch of the I/O subsystem (adapted from Lister [50]).

is used to parameterize the characteristics for each device (and/or control unit). In addition to the device identification, such characteristics include specific instructions to operate the device, the device status (available, busy, offline), pointers to character translation tables, and a pointer to the PCB of the process that has the device allocated to it. The IOCB also has a pointer to a queue of requests. This request-pending queue is a linked list of the IORBs prepared and linked by the system I/O call interface in response to user program I/O requests. There are two possibilities for the structure of the queue of pending requests. It could be organized as a single queue, holding IORBs for all devices, or as multiple queues: one for each specific device and/or controller type in the system.

The device drivers contain the code for operating the various controllers and devices, utilizing the parameters found in the IOCB. There is a separate device driver for each device type. The device drivers operate in a continuous loop, servicing requests from the pending-request queue and, in turn, notifying the user process that requested the I/O when the operation is complete. After selecting a request from the pending-request queue, the driver initiates the I/O operation. For some computers, this is done by issuing a particular machine instruction, such as start I/O (SIO) or, for computers that use memory mapped I/O, writing to registers in the device controller. The device driver then waits for I/O completion.

Upon completion of the physical I/O operation, the device controller generates an interrupt. The corresponding interrupt routine signals the device driver, using semaphores or some other IPC construct. The device driver translates and transmits the data to the destination indicated in the IORB and then signals the requesting user process of I/O completion. The whole process is summarized in Figure 82.3.

For purposes of scheduling, the various devices can be divided into two groups: shareable and nonshareable. Devices are *shareable* in the sense that primary memory is shared — more than one process can share space on the device and the several process' data transmissions to and from the device may be interleaved. In this sense, the disk, like primary memory, is a shareable device. Most other devices are *nonshareable*. A device is nonshareable because its physical characteristics make it impossible to share. Tape devices are nonshareable because it is impractical to switch tapes between characters. Similarly, line-printers are nonshareable because it is not practical to switch the paper between lines. In both cases, attempts to share the devices for output would result in a random intermixing of outputs from the processes writing the output.

Accordingly, techniques for scheduling the two classes of devices differ. By their nature, nonshareable devices cannot be dynamically allocated, that is, allocated by requested operation. These devices must be scheduled at a higher level (i.e., when processes enter the system, or at least on a longer term “capture and release” basis). Hence, scheduling in this case is analogous to the high-level scheduling that admits processes to the system from the input queue. Shareable devices, on the other hand, can be scheduled on an operation-by-operation basis. Since requests for these operations appear on an unpredictable and random basis, in exactly the same sense that I/O operations block and unblock process execution, the scheduling of shareable devices is a low-level function, analogous to processor scheduling as described previously.

Device scheduling is largely a question of queue organization and management. The problem varies in complexity. The simplest case is a monoprogrammed system: a job is admitted to the system, and needed resources, if available (connected and working), are scheduled to the process until its completion. Of course, even in this case, it should be possible to overlap I/O operations and execution of the main program — requiring interprocess communication so that the I/O subsystem can notify the main program of completion (or error). Multiprogramming requires that pending request queues be supported both for nonshareable devices that may be otherwise allocated or not ready (e.g., printer out of paper or tape not mounted on tape device) and shareable devices that may be busy serving another process's request. Thus, device scheduling, like process scheduling is essentially the question of selecting a request from the queue to be serviced next. The policy decision, as before, becomes choosing the logical and simple FCFS or some system based on a priority given to the requesting processes. But there are some additional considerations in the case of shareable devices, such as the disk, to which we now turn.

A shareable device not only has operations from various processes interleaved with one another, but as a consequence of this interleaving, must have subareas of the medium allocated to these various processes. Therefore, a file name alone, unlike a logical device name in the case of a nonshareable device, is insufficient to specify the particular location of the information on a shareable device. Such data areas are commonly called files. An I/O operation to a device that can accommodate files must first be able to find the specific location of the file on the medium. The file maintenance subsystem of the OS (see [Chapter 86](#)) keeps a directory of file names and their corresponding locations for this purpose. Therefore, on the occurrence of the first reference to a file operation, the system must reference the directory to obtain the device and the location of the needed file on that device before the actual I/O can be accomplished. This is termed *opening* the file. Because this requires a look-up and usually an additional disk read (to get the directory), it is a time-consuming operation. Doing this multiple referencing for every file operation (read or write) would be inefficient. Therefore, when a file is opened, a file descriptor is created. The file descriptor contains information to facilitate future references to the same file, including the device identification, the location of the file on that device, a description of the file organization, whether the file is open for read or write, and the position of the last operation. This file descriptor is referenced from the file or device descriptor created by the I/O subsystem when a device or file is allocated to a process, obviating the need to re-reference the directory to find the location of the file.

82.5.1 Scheduling Shareable Devices

The most important shareable device in the modern computer system is the disk. Disks provide the majority of the secondary storage used in support of virtual memory and the file system. It is appropriate, therefore, to single out the disk and consider disk scheduling as an example of shareable device scheduling.

A disk is organized as a set of concentric circles, called tracks, on a magnetic surface. Each track is divided into *sectors*, the physical unit in which data is transferred to or from the disk. A track normally has from 8 to 32 sectors per track [80]. The tracks are read from, or written to, by means of a head attached to a moveable arm allowing placement of the head over any track on the disk. A floppy disk, or diskette, consists of one such platter, which is removable from the drive unit itself. A so-called hard disk consists of a set of such platters stacked vertically around a common spindle. In this case, there are a number of surfaces on both sides of all but the top and bottom platters (which only record information on the inner surfaces). Corresponding to each usable surface, there is a read/write head. These read/write heads are fixed to a comblike set of arms that move the heads together, to position all of the heads over corresponding tracks on all of the disk surfaces. Taken together, these corresponding tracks are called a *cylinder*. Thus, all of the data stored on a particular cylinder can be referenced without moving the head assembly.

In this environment, information on a disk is referenced by an address consisting of several parts: disk drive number, disk surface, track, and sector. A sector is the smallest physical amount of information that can be read or written in a single disk operation. Sector size is a function of the particular disk drive; sizes vary from 32 to 4096 bytes, but the most common size is 512 bytes [77].

To read or write from or to the disk, the heads must be moved to the proper cylinder (track), then wait until the needed sector appears under the head. Then, the information can be transferred to the control unit buffer. The time for a disk transfer is made up of three components:

- **Seek time** — The time it takes to move the head assembly from its current location to the required cylinder
- **Latency** — The rotational delay needed for the selected sector to come under the read/write heads
- **Transfer time** — The time for the actual transfer of the data in the sector

In order to improve efficiency, data is usually read or written in blocks of one or more sectors. Still, for most disks, the seek time dominates, so one aim of disk scheduling algorithms is to reduce or minimize average disk seek time for each disk operation.

As with other system resource requests, if the needed disk and its controller are available, the disk request is attended to immediately. However, if the disk drive or its controller is busy servicing another request, new requests will be queued. Especially in a modern multiprogramming system, because most jobs depend on the disk for program loading and data files, it is likely that the disk request queue will be populated with new requests arriving regularly. When the current request is serviced, the system must choose the next to service from among those in the queue. Selection of the next disk request to service is controlled by a disk scheduling algorithm. Several possibilities exist:

First come, first served (FCFS) — The most obvious approach is to take disk requests from the disk request queue in the order of their arrival, that is, first come, first served. This algorithm is the easiest to understand and implement. Moreover, as in the case of any waiting line, FCFS appears to be naturally fair. Its performance, however, is a function of the likely random cylinder locations of the various requests on the queue. Particularly when successive requests are for disk blocks whose locations are on cylinders far removed from one another, seek time, which is roughly proportional to the distance that the read/write heads must move, will be significant. This leads to a high average seek time and consequently poor performance. Thus, performance depends more on the nature and requirements of currently active processes than on OS design. It is possible to improve upon the FCFS algorithm.

Shortest seek time first (SSTF) — The quest for shortest seek time would appear to favor selecting the request requiring the minimum head movement, the request at the closest cylinder (i.e., the request requiring the minimum seek time). SSTF will always provide better performance than FCFS. However, like its analog in processor scheduling SJF, SSTF takes requests found on nearby tracks, including newly arriving requests. This tends to provide poor service to requests for disk blocks that happen to start far away from the current read/write head position. Assuming that disk block allocation is evenly distributed across the disk, this is particularly true for requests at the extreme outside and inside cylinders, once the heads get positioned near the middle cylinders. Again, following the analogy to SJF, arrival of a string of requests for blocks in nearby cylinders may cause some requests to be starved under the SSTF algorithm. SSTF gains response time at the expense of fairness — the other extreme from FCFS.

Bidirectional scan scheduling (SCAN) — The search for requests at relatively nearby tracks without completely abandoning fairness can be accommodated by the bidirectional scan algorithm. SCAN works analogously to the scan/seek button on a modern digital audio tuner. That is, the read/write head mechanism begins a scan at one end of the disk (outside or inside) and scans, servicing requests from the queue as the heads come to the corresponding cylinder. The scan continues to the other end of the disk, assuring that no requesting process must wait too long for service. At the other end of the disk, the head assembly reverses and continues its scan in the opposite direction. This algorithm is sometimes called the *elevator algorithm* because its operation is nearly analogous to the operation of a building elevator. The analogy is complete, except for the fact that for elevator passengers, the elevator's direction at pickup makes a difference, depending on whether they wish to go up or down; disk requests are serviced equally well regardless of the direction from which

TABLE 82.1 Total Head Movements for Various Scheduling Algorithms

	FCFS	SSTF	SCAN	CSS	BBDS	BCSS
Pattern 1	540	195	186	223	186	208
Pattern 2	101	91	175	218	91	92
Pattern 3	381	162	186	242	180	216

Pattern 1 73, 125, 32, 127, 10, 120, 62

Pattern 2 81, 82, 83, 84, 85, 21, 22

Pattern 3 10, 46, 91, 124, 32, 85, 11

FIGURE 82.4 Sample patterns of disk requests.

the disk heads arrived. This latter point, however, is significant and a disadvantage of the SCAN scheme. If the requests are to disk blocks uniformly placed throughout the disk cylinders, the heads, once they reach one end, are unlikely to find many requests because the first cylinders scanned on the reverse trip are the ones just scanned. The requests now most in need of service, according to the fairness criteria, are at the other end of the disk head travel. This problem is addressed in a variant of SCAN.

Circular-scan scheduling (CSS) — This algorithm is similar to SCAN, except that when the scanning heads reach the end of their travel, rather than simply reversing direction, they return to the beginning end of the disk. The effect is a circular scan, where the first disk cylinder, in effect, immediately follows the last, and disk requests are provided with a more uniform wait time.

Bounded-scan scheduling (BSS) — Both SCAN and CSS were characterized as scanning from one end of the disk to the other, that is, from the lowest numbered cylinder to the highest. In fact, both SCAN and CSS do too much. They need only scan to the most extreme cylinder represented by the requests in the queue, that is, scan in one direction as long as there are requests beyond the current location, a bound represented by the block location of the highest or lowest numbered cylinder of a request in the queue. In actuality, both SCAN and CSS are implemented in these bounded (in this sense) versions.

Optimal scheduling — Optimal scheduling requires selecting the next request so that the total seek time is minimal. The problem with optimal scheduling is that the continuing arrival of new disk requests to the queue requires reordering the queue as each request arrives. To the extent that the disk is a heavily used resource with requests arriving continually and often, the computation needed to obtain optimal scheduling is not likely to be worth it. The concept, however, is useful as a reference for comparing the performance of the other algorithms.

82.5.2 Evaluation and Selection of a Disk Scheduling Algorithm

As with the processor scheduling algorithms, performance is related to the request pattern. It is possible to evaluate this performance by estimating or tracing a disk request sequence. Consider, as an example, a disk with 128 cylinders. For the three patterns of disk requests shown in Figure 82.4, the total head movements for each of the scheduling algorithms described above are shown in Table 82.1. In each case, assume that the disk head is initially at cylinder 58 and scanning in the direction of increasing cylinder numbers.

Though the FCFS scheme is easy to implement and conveys a sense of fairness, it leads to the poorest performance in each of the three example cases. SSTF seems, on cursory examination, to yield the best performance, but as the examples show, this is not always the case. Bounded bidirectional scheduling (BBDS) is as good or better in two of the three examples. From the table, it is clear that performance is a function of the intensity and order of the disk requests, as well as the disk scheduling algorithm. If disk usage is light and the request queue nearly always empty, then choice of a scheduling algorithm is insignificant,

because they are all effectively the same. Heavy disk usage and short interarrival times of entries on the disk request queue effectively rule out FCFS and make the choice more critical. Because one of the primary uses of the disk is for the file system, disk performance is also influenced by the file space allocation technique. The examples of [Table 82.1](#) suggest that contiguous allocation would result in less head movement and, consequently, in significantly better performance. Pattern 2, with its requests to sequentially numbered cylinders, is associated with better performance with all of the scheduling algorithms considered here. Directories and index blocks, if used, will cause extra disk traffic and, depending on their locations, could affect performance. Because references to files must pass through the directories and index blocks, placement of these near the center tracks of the disk would limit head movement to at most one-half of the total number of cylinders to find the file contents and, consequently, would lead to better performance, regardless of the scheduling algorithm.

Although seek times have been improved in modern disk drives, the combination of seek and latency times still dominates transfer time. This suggests an augmented SSTF to consider the sum of seek and latency times, called shortest access time first (SATF) or shortest positioning time first (SPTF).

82.5.3 Scheduling Nonshareable Devices

Because they cannot be scheduled dynamically on an operation-by-operation basis, nonshareable devices require a different approach to scheduling than shareable devices. This level of scheduling is particularly important for two reasons: most device types are nonshareable and scheduling of nonshareable resources can lead to deadlock — a situation in which the system is effectively locked up because none of the active processes can continue for want of some resource held exclusively by some other process.

By their very nature, nonshareable devices must be allocated to a single process for the duration of a use session. That is, a tape drive must be allocated to a particular process for the duration of a sequence of input and/or output operations, a printer for the duration of the print output of the process, etc. The duration can be explicitly indicated under program control by open and close operations or by default at the entry and exit of a process from the system. Regardless of the origin of the use session, the mechanism is described above. The particular device is described by an IOCB, and processes with requests for allocation of the device are queued in the pending requests queue attached to the IOCB. Nonshareability is enforced by an initial value of 1 for the queuing semaphore. Scheduling, then, amounts to waiting for the resource to be freed, then selecting a device request from the pending request queue FCFS, or by some measure of priority. In the latter case, the rationale or criteria for assignment of priorities clearly parallels that for processes in process scheduling. But the mutual exclusion requirement of nonshareability raises the possibility of deadlock. Therefore, dealing explicitly with this potential must be an integral part of the policy consideration in scheduling of nonshareable devices.

82.5.3.1 Files

The taxonomy used in this chapter for the classification of the computing system resources, processor: primary memory, and devices, with the subclassification of shareable and nonshareable devices, is not perfect. A single file may be shared among a number of processes and, in this sense, it also becomes a resource. The problem here is that though a particular file opened in read mode is a shareable resource, that same file, when opened by one process for writing, becomes a nonshareable resource. Thus, allocation of a file to a process's request may proceed only after appropriate read/write mode checks. A file in read mode may be scheduled (i.e., queued) as any other shareable resource — forcing the process to wait (in order) only for availability of the corresponding control unit and device. On the other hand, a process requesting a file already in use in write mode must wait until the process currently writing the file closes the file or exits the system — as in the case of any other nonshareable resource.

82.5.3.2 Virtual Devices

Process requests for nonshareable devices can often lead to unavoidable delays, the extent of which is a function of the activity of the process currently holding the needed nonshareable device. In the aggregate,

such delays can have a significant adverse effect on overall system performance. There are two possible ways out of this difficulty: increase the number of the offending nonshareable devices (e.g., add more printers) or introduce virtual devices. In this latter case, a process's request for data transfer to a nonshareable device, such as a printer which is allocated elsewhere, is directed instead to some anonymous file on the disk, thus freeing the requesting process from the wait for the otherwise allocated nonshareable device. In this case, the file acts as a virtual printer. Then, a special process called a *spooling daemon*, or *spooler*, becomes responsible for scheduling and moving the data from the intermediate file to the printer when it becomes available. Of course, operation of the spooler admits yet another opportunity for scheduling — again, usually FCFS or priority, depending on the policy adopted.

82.6 Scheduling Policies

In the preceding sections, the various resources of the system were classified (i.e., processors, primary memory, devices, files, and virtual devices) and subclassified into shareable and nonshareable resources. Moreover, the subsystem in which allocation is performed was identified (i.e., process manager, memory manager, I/O subsystem, and file system). In each instance, resource allocation was characterized in terms of some form of a queue and an algorithm for managing the queue.

However, algorithm and mechanisms are not enough to make optimal scheduling unambiguous. What remains is to establish a policy framework that governs selection of the particular algorithms from the choices, setting and adjusting the priorities where appropriate, and other considerations necessary to keep the overall system running smoothly and serving its customers fairly and in a timely manner. Thus, it is not unlikely that use of the queuing algorithms described previously, to allocate resources as they and/or their associated software (e.g., process or memory manager) or hardware (memory, I/O device, or file) become available, can lead to a situation where the system is overcommitted to a particular resource (e.g., printer) or resource area (e.g., printers or network connections). This leads to diminished throughput for the system or to deadlock, where the entire system is halted due to a resource allocation state, where each of the processes has allocated to it some resource critically needed by another. Perhaps these policy decisions are most difficult, for they are not considered at the algorithmic/queuing level and are less amenable to quantification and algorithmic solution. In this regard, the problem of deadlock appears to be potentially the most debilitating.

82.6.1 Deadlock

Deadlock may occur when system resources are allocated solely on the basis of availability. The simplest example is when process 1 has been allocated nonshareable resource A, say a tape drive, and process 2 has been allocated nonshareable resource B, say a printer. Now, if it turns out that process 1 needs resource B (the printer) to proceed and process 2 needs resource A (the tape drive) to proceed and these are the only two processes in the system, each is blocking the other and all useful work in the system stops. This situation is termed deadlock. To be sure, a modern system is likely to have more than two active processes, and therefore the circumstances leading to deadlock are generally more complex; nonetheless, the possibility exists.

Deadlock is a possibility that must be considered in resource scheduling and allocation. For this chapter, the concern is with hardware resources, such as CPU cycles, primary memory space, printers, tape drives, and communications ports, but deadlock can also occur in the allocation of logical resources, such as files, semaphores, and monitors. Coffman et al. [14] identified four conditions necessary and sufficient for the occurrence of system deadlock:

- The resources involved are nonshareable.
- Requesting processes hold already allocated resources while waiting for requested resources.
- Resources already allocated to a process cannot be preempted.
- The processes in the system form a circular list when each process in the list is waiting for a resource held by the next process in the list.

There are basically four ways of dealing with the deadlock problem:

- Ignore deadlock
- Detect deadlock and, when it occurs, take steps to recover
- Avoid deadlock by cautious resource scheduling
- Prevent deadlock by resource scheduling so as to obviate at least one of the four necessary conditions

Each approach is considered, in order of decreasing severity, in terms of adverse effects on system performance.

82.6.1.1 Deadlock Prevention

Because all four conditions are necessary for deadlock to occur, it follows that deadlock may be prevented by obviating any one of the conditions. The first condition, that all resources involved be nonshareable, is difficult to eliminate because some resources, such as the tape drive and printer, are inherently nonshareable. However, in some cases this situation can be alleviated by spooling requests to a nonshareable device, such as the printer, to a temporary file on the disk for later transfer to the nonshareable device, as described previously.

There are two possibilities for elimination of the second condition. One is to require that a process request be granted all the resources it needs at once, before execution. An alternative is to disallow a process from requesting resources whenever it has previously allocated resources. That is, it must finish with those resources previously allocated and relinquish all of them before an additional resource request. Both methods assure that a process cannot be in possession of some resources while waiting for others. The first has the disadvantage of causing poor resource utilization by forcing allocation for a period likely to exceed, perhaps considerably, that needed for actual use of the resource. Moreover, depending upon the scheduling algorithm, some processes could face starvation from having to wait, perhaps indefinitely, for some resource or resources.

The third condition, nonpreemption, can be alleviated by forcing a process waiting for a resource that cannot immediately be allocated to relinquish all of its currently held resources, so other processes may use them to finish. Alternatively, the requesting process' request can be satisfied by preempting the requested resource from some currently blocked process, thus effectively eliminating the nonpreemption condition. The problem with these approaches is that some devices are simply not amenable to preemption — for instance, a printer, if preempted, will generate useless pages of output interleaved from several processes.

The fourth condition, the circular list, can be obviated by imposing an ordering on all of the resource types (presumably reflecting the order in which the resource types are likely to be used), and then forcing all processes to request the resources in order. Thus, if a process has resources of type m , it can only request resources of type $n > m$. If it needs more than one unit of a particular resource type, it must request all of them together. Although this will ensure that the circular list condition is denied, it can hurt resource utilization by requiring that a particular resource be allocated in advance of its logical need.

Deadlock prevention works by forcing rather severe constraints on resource allocation, leading to poor resource utilization and throughput. A less severe approach is to consider, individually, the implications of each resource request with respect to deadlock.

82.6.1.2 Deadlock Avoidance

This approach to the deadlock problem employs an algorithm to assess the possibility that deadlock could occur as a result of granting a particular resource request and acting accordingly. This method differs from deadlock prevention, which guarantees that deadlock cannot occur by obviating one of the necessary conditions, and from deadlock detection, in that it anticipates deadlock before it actually occurs.

The basic idea is to maintain a status indicator reflecting whether the current situation, with respect to resource availability and allocation, is safe from deadlock. When a resource request occurs, the system invokes the avoidance algorithm to determine whether granting the request for a set of resources would lead to an unsafe state and, if so, denies the request. The most common algorithm, due to Dijkstra [23], is called the *banker's algorithm*, because the process is analogous to that used by a banker in deciding whether

a loan can be safely made. The algorithm is sketched in [Figure 82.5](#). Here, i and j are the process and resource indices, and N and R are the number of processes and resources, respectively. Other variables and what they represent include the following:

- maxneed**[i , j]— The maximum number of resources of type j needed by process i
- totalunits**[j]— The total number of units of resource j available in the system
- allocated**[i , j]— The number of units of resource j currently allocated to process i
- availableunits**[i , j]— The number of units of resource j available after **allocated**[i , j] units are assigned to process i
- needed**[i , j]— The remaining need for resource j by process i
- finish**[i]— Represents the status of process i
 - 0 if it is not clear that process i can finish
 - 1 if process i can finish

What makes the deadlock avoidance strategy difficult is that granting a resource request that will lead to deadlock may not result in deadlock immediately. Thus, a successful strategy requires some knowledge about possible patterns of future resource needs. In the case of the banker's algorithm, that knowledge is the maximum quantity of each resource type that a particular process will need during its execution. As shown in [Figure 82.5](#), the algorithm permits requests only when the current request added to the number of units already allocated is less than that maximum — and then only if granting the request still leaves some path for all the process in the system to complete, even if every one needs its maximum request.

But this last requirement — that each process know its maximum resource needs in advance, an unlikely supposition particularly for interactive jobs — severely limits the applicability of the banker's algorithm. Also, the interactive environment is characterized by a changing number of processes (i.e., N is not set) and a varying set of resources, R , as units occasionally malfunction and must be taken off-line. Further, even if the algorithm were to be applicable, Haberman [29] has shown that its execution has complexity proportional to N^2 . Because the algorithm is executed each time a resource request occurs, the overhead is significant.

82.6.1.3 Deadlock Detection

An alternative to the costly prevention and avoidance strategies outlined previously is deadlock detection. This approach has two parts:

- An algorithm that tests the system status for deadlock
- A technique to recover from the deadlock

The detection algorithm, which could be invoked in response to each resource request (or if that is too expensive, at periodic time intervals), is similar in many ways to that used in avoidance. The basic idea is to check allocations against resource availability for all possible allocation sequences to determine whether the system is in a deadlocked state. There is no requirement that the maximum requests that a process will need must be stated here. The details of the algorithm are shown in [Figure 82.6](#).

Of course, the deadlock detection algorithm is only half of this strategy. Once a deadlock is detected, there must be a way to recover. Several alternatives exist:

- Temporarily preempt resources from deadlocked processes. In this case, there must be some criteria for selecting the process and the resource affected. The criteria may include minimization of some cost function, based on parameters such as the number of resources a particular process holds and resource preemptability (e.g., a printer is difficult to preempt temporarily).
- Back off a process to some checkpoint, allowing preemption of a needed resource, and restart the process at the checkpoint later. In this case, the simplest way to find a safe checkpoint is to stop the process, return all of its allocated resources, and restart the process from the beginning at a later time.
- Successively kill processes until the system is deadlock-free.

```

const int safe = 1;
for (j = 1; j <= R; j++)          /* R resource types */
    available_units[j] = total_units[j];

for (j = 1; j <= R; j++)
{
    for (i = 1; i <= N; i++)      /* N processes */
    {
        available_units[j] = available_units[j] - allocated[i, j];
        /*allocated [i, j] = number of units of resource j currently
           allocated to process i */
        finish[i] = 0;
        /* initialize - process i may not be able to finish */
        needed[i, j] = max_need[i, j] - allocated[i, j];
        /* needed is remaining need of process i for resource j;
        }
    not_done = 1;
    while (not_done)
    {
        not_done = 0;
        for (i = 1; i <= N; i++)
            if (! finish[i] && needed [i, j] <= available_units[j])
            {
                /* process i can finish */
                finish[i] = 1;
                available_units[j] = available_units[j] + allocated[i, j];
                /* give back process i's resources as done */
                not_done = 1;
            }
        }
    /* Continue loop until a process needed request cannot be met */
    /* Determine if all N processes could be completed. */
    if (allocated_units[j] = total_units[j])
        status = safe;
    else
        status = !safe;
    }
    if (status == safe)
        /* allocate the requested resource */

```

FIGURE 82.5 The banker's algorithm for deadlock avoidance.*

These methods are expensive in the sense that the detection algorithm is rerun with each iteration until the system proves to be deadlock-free. The detection algorithm, like the avoidance algorithm of Figure 82.5, has time complexity N^2 . Another potential problem is starvation — care must be taken to ensure that resources are not continually preempted from the same process or that the same process is not repeatedly backed off or killed.

*Based on statements of the algorithm in Dijkstra [23] and Tsichritzis and Bernstein [84].

```

for (j = 1; j <= R; j++)          /* R resource types */
    available_units[j] = total_units[j];

for (j = 1; j <= R; j++)
{
    for (i = 1; i <= N; i++)      /* N processes */
    {
        available_units[j] = available_units[j] - allocated[i, j];
        /*allocated[i, j] = number of units of resource j currently
        allocated to process i */
        finish[i] = 0;
        /* initialize - process i may not be able to finish */
    }
    not_done = 1;
    while (not_done)
    {
        not_done = 0;
        for (i = 1; i <= N; i++)
            if (! finish[i] && request[i, j] <= available_units[j])
            {
                /* process i can finish */
                finish[i] = 1;
                available_units[j] = available_units[j] + allocated[i, j];
                /* give back process i's resources */
                not_done = 1;
            }
    }
    deadlock = 0;
    for (i = 1; i <= N && deadlock == 0; i++)
        if (finish[i] != 1)
            deadlock = 1;
    if (deadlock == 1)
        /* system deadlocked */

```

FIGURE 82.6 Deadlock detection algorithm.*

82.6.1.4 Ignore Deadlock

The fourth approach — do nothing and hope — reflects the observation that deadlocks and their concomitant effects including possible system crashes, do not occur with sufficient frequency to justify the expense in terms of system overhead required to handle deadlock by any of the other three approaches. This is the approach taken in the UNIX operating system.

82.6.1.5 The Eclectic Approach

It is clear that none of the conventional choices for dealing with the potential for deadlock is entirely satisfactory. An alternative strategy is to divide the system resources into classes and apply the most

*Based on statements of the algorithm in Dijkstra [23] and Tsichritzis and Bernstein [84].

appropriate technique for dealing with potential deadlocks in each class. Silberschatz et al. [77] suggest four classes:

1. In the case of resources, such as the process control blocks used by the system itself, deadlock prevention can be used by forcing resource ordering because there is no contention among pending requests.
2. Primary memory can be shared in the sense that an active process (or part of it) can be swapped out without destroying the process. Therefore, deadlock can be prevented by preemption.
3. For nonshareable resources, including devices such as the printer and writeable files, deadlock avoidance can be used as resource requirements become known.
4. Virtual memory space on the disk can be protected from deadlock by avoidance because maximum virtual storage requirements are generally known before execution.

In spite of this, most systems today take the optimistic approach and do nothing to prevent, avoid, or even detect deadlock.

82.7 High-Level Scheduling

Process and device scheduling operate in the context of a higher-level system scheduling. This higher-level scheduling deals with admitting new processes to the system, setting and changing priorities on the basis of system operation, and generally implementing the policy controls of system operation. In fact, because scheduling system resources is prerequisite to resource allocation, criteria and policy regarding scheduling are intimately related to system resource allocation. To this end, criteria for scheduling decisions match the objectives for the operating system as a whole, that is, to provide good service to processes within a context of operation at a high level of resource utilization. Other factors that cannot be overlooked are the need to assure mutual exclusion for nonshareable resources and prevention or mitigation of starvation and deadlock. A portion of the responsibility for this lies in a system scheduler process. Lister [50] suggests that the tasks of the scheduler include admission of processes into the system, determination of process priorities, and enforcement of system policies for resource allocation. In the first instance, the scheduler selects batch jobs from an input queue, using criteria such as resources required and priority. In a time-sharing environment, this task is more difficult because processes enter the system at user login. However, the scheduler can monitor resource utilization and deny access in order to maintain performance criteria for the currently active processes. Secondly, the scheduler determines the process priorities that govern placement in system queues. Because a primary system scheduling mechanism is manifest in these queues, the scheduler plays a key role here. Finally, the scheduler is responsible for system policies that deal with balance (ensuring that no resource class is either over- or underutilized) and deadlock.

The importance of these activities in determining overall system performance suggests that the scheduler itself should be a high-priority process. In particular, the scheduler executes whenever a resource request or release occurs or a process arrives at the system or terminates [50]. The lower-level schedulers discussed previously are analogously activated by interrupts — both are unpredictable, though interrupts may be expected more frequently than process entry and exit or resource request and release.

The criteria for high-level scheduling decisions are many and varied. System response time is enhanced by minimizing context switches and the associated overhead. Scheduling fewer new processes into the system is an obvious way to achieve this. But such a scheduling policy is likely to result in less-than-optimal resource utilization because fewer processes (a lower degree of multiprogramming) are together unlikely to use all the resources declared needed throughout these processes' time in the system. As more processes enter the system, the scheduler has more policy decisions to make when resources are requested and released. The criteria are numerous, and their effectiveness is generally affirmed or denied by empirical observation. Several possibilities are summarized in [50]:

1. Give priority in resource requests to processes already in possession of a significant quantity of resources, to advance their progress through the system in the hope of reclaiming the resources allocated at the earliest possible time.

2. Give resource-rich processes high dispatching priority, for the same reason as in 1.
3. Use the working set principle [22] as a criterion for memory allocation.
4. Priorities should reflect process importance. Most system processes have higher priorities than user processes. Among system processes, the scheduler itself is high priority.
5. Device drivers should have high priority, and drivers for higher-speed devices should have relatively higher priority. This is designed to keep the devices running, mitigating the possibility of I/O delays.

In summary, process and device scheduling is a tricky business with goals that are not always mutually consistent. Different possibilities serve different needs. Experimentation and empirical observation are necessary to judge effectiveness in a particular situation.

82.8 Recent Work and Current Research

Although much of the work on process and device scheduling took place during the late 1960s and the 1970s, with the advent of multiprogramming and time-sharing systems and as the subject of operating systems came into its own, technical advances continue to spur new developments. In this section, some of the more significant recent discoveries are summarized, and pointers are given for further study.

82.8.1 Processor Scheduling

The goals listed previously, which underlie the development of techniques for processor scheduling, are often mutually conflicting. This inevitability has led to the priority and dynamic dispatching priority adjustment algorithms described earlier. Recent work in processor scheduling has continued to focus on refinement of dynamic scheduling schemes.

The problem with priority methods that set priority once at the process's entry into the system is inflexibility. Resource needs do not always match the priorities, and separate resources may require resource allocation mechanisms isolated from one another. The dynamic priority adjustment mechanisms described previously begin to address these problems. Recent alternatives include fair-share schedulers [33] [41], microeconomic schedulers [86], lottery schedulers [87], time-function scheduling [25], and observation-based improvements [39] [79].

A *fair-share scheduler* is designed to allocate resources to provide each user or group of users with an equitable share of the CPU over some period of time. This is accomplished by adding facilities to track the actual amount of processor usage allocated to each process and to adjust priorities dynamically to assure allocation of processor time to each process remains close to established shares.

Henry [33] describes a fair-share scheduler utilized at AT&T Bell Laboratories. This scheme divides users into groups and schedules, so that each group is allocated a fair share of CPU time for execution. Within a particular group, processes are scheduled according to the regular dispatcher relative to other processes in the group.

The implementation is a straightforward modification of the standard decay usage scheduling algorithm. In addition to the process's "execution time field," which is incremented at each clock interrupt, there is another "fair share group execution field" that is updated at clock interrupt when any process from the group is executing. The fair-share group execution field is decayed exactly as the individual process' execution time fields, once a second. Then, process priorities are recalculated using the modified formula:

$$\text{priority} = C(\text{execution time field})/2 + \text{base priority} + C(\text{fair share group execution field})/2$$

The result is that the more CPU time the processes from a particular group have used recently, the higher the priority number and the lower the priority for processes in that group. Overall, however, each group ultimately gets an equitable share of the CPU time.

Kay and Lauder [41] describe Share, a fair-share scheduler that is designed to work at both the individual user level and the group level. Unlike the AT&T fair-share scheduler, the Share scheduler explicitly considers use of resources other than the CPU. The goal is to have a scheduler that is fair to users, rather than just

to processes. Therefore, the approach is designed to schedule resources so that users get a fair share of the machine over time, balancing an entitlement expressed as a number of shares and recent resource use history. Allocation of shares is, of course, an administrative matter and depends on the organization's entitlement and the user's entitlement within the organization.

The implementation is considerably more complex than that of the AT&T algorithm. There are basically three levels of operation. At the first (user) level, a figure representing usage is adjusted by both a decay factor and a measure of total resource consumption. Thus, every t_1 seconds (several seconds, Kay and Lauder used 4)

$$\text{usage} = \text{usage} \times K_1 + \text{charges}$$

where K_1 is a suitable decay factor, and charges represents the sum of price times quantity for resources used since the last calculation.

Subsequently, every t_2 seconds (e.g., $t_2 = 1$ second), process priorities are decayed according to

$$\text{priority} = \text{priority} \times K_2 \times (\text{nice} + K_2')$$

where K_2 and K_2' are factors reflecting priority decay rate and the effect of the UNIX `nice` command parameter (0 is default).

Finally, every t_3 seconds (1/60 to 1/100 of a second), a priority recalculation occurs, taking into account recent usage and remaining shares:

$$\text{priority} = \text{priority} + (\text{usage} \times \#\text{active processes}) / (\#\text{shares})^2$$

A user's process priority is not only a function of recent usage and entitlement, but also of the number of active processes. Thus, a single user's share is effectively spread among the number of currently active processes.

The Share system is also applicable to scheduling in a context where a computer is shared among a number of groups. In this case, shares are allocated to each group in proportion to the division of the machine. This requires more calculations to allocate and reallocate shares within a particular group when a new user logs on, subject to keeping the total number of shares allocated to the group constant. The system allows for different decay rates for usage in the various groups. The Share system does provide users with a sense of fairness, but at a cost of additional overhead.

The *lottery scheduling* scheme of Waldspurger and Weihl [87] is similar to the Kay and Lauder [41] Share scheduler in the sense that it provides for proportional share resource allocation. In this case, lottery "tickets," rather than shares, represent the resource entitlements. The scheme is designed to provide active and flexible control of resource allocation in proportion to share allocations.

The scheduler works in the context of a scheduling quantum of 10 ms. Resources are allocated by lottery in the sense that a resource is allocated to the process that holds the "winning ticket." The system is fair in that the probability that a particular process will be allocated a particular resource is proportional to the number of tickets held by that process. It follows that allocation of resources in general will be proportional to the number of tickets held, that is, to entitlement. This is so because the tickets are fungible in that they represent resource rights independent of the type or mix of resources needed.

Lottery scheduling has the advantage of being relatively straightforward to implement and efficient, in that its overhead is comparable to that of a standard time-sharing policy. By definition, the scheduling algorithm is randomized. Hence, actual allocation at any given moment may not match entitlement shares exactly. But allocations occur every 10 ms and fairness, in the sense of matching entitlements, increases quickly over time as the number of allocations grows. Moreover, the problem of starvation is obviated, because any client with tickets will eventually win a lottery and thus be allocated resources.

A more general approach to resource scheduling, called *time-function scheduling*, has been proposed by Fong and Squillante [25]. The method uses dynamically changing priorities based on general functions of such factors as the time a given process has waited for a particular resource. The idea is to support a wide and varying range of scheduling objectives by implementing time-functions reflecting these objectives.

Further, these time-functions are effectively variable in response to changes in the system in order to preserve the desired scheduling objectives. Fong and Squillante have found time-function scheduling to provide the same fair-share objectives as lottery scheduling, with less waiting time variance (resulting from the probabilistic nature of the lottery scheduling).

A number of empirical studies [69] [74] [78] have concluded that maximum CPU utilization and system throughput results from a CPU scheduling policy that gives preemptive priority to I/O bound jobs over compute bound jobs. Kamada [39] has used a Markovian model of job processing (identical to the finite source queuing model) to verify that scheduling policies which assure that I/O bound jobs are given preemptive priority over processor bound jobs provide maximum processor utilization and optimal throughput. Within the confines of the theoretical model and its concomitant assumptions, it is not possible to show that any additional sophistication of the sort described previously can improve upon this result. Kamada concludes that general applicability of the theoretical results is limited by the model and its underlying assumptions.

Suranauwarat and Taniguchi [79] describe an augmented process scheduler that facilitates both reduced execution time and wall clock time for programs that are run multiple times. The idea is to observe the context-switch behavior of a program and use this information to identify normal end of time-slice context switches that are closely followed by a process block (e.g., to wait for I/O completion). In these cases, they conjecture that it makes sense to extend the time-slice until the process blocks, thus improving run time for programs that are run repeatedly.

The method is to have the process scheduler log context switches for all the processes in the system and, at the end of a particular program's execution, create an experiential knowledge record called a program flow sequence (PFS) from the context switch log for the given program's processes. During subsequent executions of the program, when a process from the program is running and at the end of its current time-slice, the scheduler consults the PFS to determine whether a small (less than a proscribed factor) extension of the time-slice will, by allowing the process to proceed until it blocks, obviate a context switch. With each run of the program, its PFS is modified to develop an accurate portrayal of its context-switching behavior.

Experimentation with a parameterized test program and three existing programs showed that the knowledge-based scheduler provided for reduced run times for the test program and two out of three of the existing programs (from .05% to 13%). Moreover, the performance enhancement was a direct function of the maximum dispatch delay time permitted, and the information in the PFS for the program improved with the number of times the programs were run. However, it remains to assess more fully the impact of reducing the execution time of repeatedly run programs on the fairness of the overall system.

Other work in processor scheduling includes predictive deadline scheduling and dynamic mixed priority schemes for real-time systems. See Miller [59] [60].

82.8.2 Disk Scheduling

Recent work in disk scheduling continues the search for an optimal algorithm through experimental studies and refinement of the well known algorithms described previously, anticipatory algorithms causing movement of the disk heads in advance of the next disk I/O request, and use of application-specific requirements. Approaches to the former included extensive simulation studies [34] [82] [81] and analytical modeling [15]; anticipation algorithms have been suggested by King [43] and by Iyer and Druschel [37]; and algorithms based on use of application-specific requirements were presented by Cao et al. [11] and Shenoy and Vin [73].

Geist and Daniel [26] have proposed a disk scheduling scheme that is a varying mixture of SSTF and SCAN, designed to obviate both the considerable seek time variances and potential for starvation of SSTF and the potential delays for opposite end requests of SCAN. The continuum algorithm, $V(R)$, $R \in [0, 1]$, takes as its next request the one closest, in a recast sense of closest, to the current position of the head. As with SCAN, $V(R)$ keeps track of the current direction of head movement — but, in this case, the direction of the just-previous seek. The distance to the nearest request in that same direction is the number of cylinders away as before. But the distance to the nearest request in the direction opposite to that of the last seek is R times the total number of cylinders plus the number of cylinders to the request. Note that R is

any real number in the interval 0 to 1. If $R = 0$, $V(R)$ is SSTF, and if $R = 1$, $V(R)$ is SCAN. For values of $0 < R < 1$, $V(R)$ is somewhere between the two.

The implementation requires maintaining two request queues: one each for requests in either direction from the current head position. The requests in both queues are kept in order of increasing distance from the current head position. Selection of the next request to process is made by calculating the distance to the first request on each queue, adjusting the distance requiring a change in direction. The request associated with the least adjusted distance is selected, and the current head position and direction are updated. A simulation was used to test different values for R . With respect to improvements in mean waiting time and throughput, the simulation showed $V(0.2)$ to be superior to FCFS and to either pure SSTF or SCAN.

In an effort to enhance the effectiveness of SSTF, Seltzer et al. [72] and Jacobson and Wilkes [38] have refined the idea to include rotation time. Thus, shortest access time first (SATF) serves first the request that has the least access time, compiled as the sum of seek and rotation times, from the current head position.

The efficacy of prerequest disk arm movement has been explored by King [43]. Anticipatory disk arm scheduling policies have been largely overlooked due to the supposition of a continuous substantial request queue length [21] [82]. This constant backlog would mean there was insufficient time to position the disk heads optimally for successive requests. However, Geist and Daniel [26] and Lynch [51] reported disk drive utilization rates on the order of 20% to 35%, suggesting that there is time, after all, that might profitably be used for positioning the disk heads in anticipation of the next request. This possibility was investigated by Coffman and Hofri [15], Hofri [34], and more recently by King [43]. King shows that the potential for performance improvements due to anticipatory scheduling is a function not only of disk idle time, but also of the pattern of the request locations over the physical disk space. If the data requests are spaced uniformly over the disk and a FCFS scheduling algorithm is used, prepositioning the disk heads at the middle cylinder results in 25% less head movement on average, which translates to a 13% reduction in mean seek time. In the case of a nonuniform distribution of request data locations on the disk, the optimal anticipatory location is between the most frequently accessed locations, so-called *hot spots*, and the midway point, the particular location a function of the probability of requests at the hot spots. Inasmuch as the locations and probabilities of these hot spots are known (perhaps from system performance data) and the request rate is sufficiently low as rarely to interfere with an anticipatory move, the anticipatory algorithm saves time.

As the frequency of request arrivals increases, so does the possibility that the arriving request will have to wait for completion of an anticipatory seek operation. Ultimately, the demand for disk service could become so high that, in the worst case, disk requests must wait the entire time needed for anticipatory repositioning. Possible ways out of this dilemma are suggested in King [43]. The first is to move the heads in short spurts toward the optimal anticipatory location, thus allowing for timely attention to currently arriving disk data requests. The second is to develop technology to facilitate an interruptible disk head seek. The former leads to seek time improvements of 8% to 10% for an anticipatory version of FCFS.

Simulation was used to assess the effect of anticipatory head motion in the case of a workload representing more realistic data from McNutt [58] — a workload that reflects the high probability that a given job will generate repeated requests to the same disk location. In this case, especially if the disk request rate is low, few requests will benefit from an anticipatory seek until that particular job completes. This suggests modifying the anticipatory algorithm by including a delay, representing job completion time, between a request and an anticipatory move. This modification also yielded a small performance improvement.

Other, more complex disk systems with two arms and duplexed disks with separate control and data lines to two disk arms were also considered. Modifications to the anticipatory algorithm yielded reductions of mean seek distances of 10% to 29% over more conventional disk scheduling algorithms.

Another approach to anticipatory scheduling, by Iyer and Druschel [37], is based on the observation that processes frequently issue multiple requests for disk service, separated by short spurts of computation time, and that a given process' disk requests exhibit spatial locality. They argue that, in an environment of queued disk service requests, a disk scheduler that immediately selects from its queue a request that arose from a process different from the one issuing the last request may incur an expensive disk seek and lose out on the opportunity to service a forthcoming request from the former process to a nearby location on the disk. In fact, they argue that waiting a short period to determine whether the original process

will, in fact, issue another request is “deceptive idleness,” that is, it may well pay off in overall throughput to do so. In particular, a seek reducing scheduler, such as SSTF, CSS, or the variant SPTF, is frustrated in its attempts to minimize the cost of head movement by immediately servicing a disk request from a new process. Similarly, a proportional-share scheduler, such as lottery scheduling [87] or Yet Another Fair Queuing [6], may find it impossible to provide disk service to multiple processes (applications) according to the preassigned ratios when it must select requests immediately from the disk request queue.

The solution proposed by Iyer and Druschel [37] is to wrap any given disk scheduling strategy in an anticipatory scheduling framework. This framework consists of an anticipatory scheduling core that envelopes an adaptive scheduler type-specific anticipation heuristic processor coupled with the original disk scheduler. The anticipatory core provides the generic waiting apparatus to be informed by the heuristic. A separate heuristic processor is implemented for each of the two classes of scheduler. For the seek-reducing schedulers, it determines the wait or no-wait decision based on the benefit of waiting (expected reduction in seek time) vs. the cost (potential waste of time). For the proportional schedulers, a decision is made to wait for the last process if it has received the smallest amount of disk service so far, perhaps with a relaxed time scale to enable some beneficial seek reduction. The waiting period is that where there is a 95% probability that a disk request will arrive from the last process. Experimental evaluation using FreeBSD confirms the effectiveness of this anticipatory scheduling framework. Throughput increases ranged from 8% for the Andrew file system benchmark, to up to 60% for variants of the TPC-B database benchmark, to between 29% and 71% for the Apache Web server. Moreover, proportional-share schedulers augmented by the anticipatory scheduling scheme were able to meet their objectives with reasonable overhead.

An alternative to anticipatory scheduling is to look explicitly ahead at two or three requests and service the most desirable set of requests by modifying existing disk scheduling algorithms. Thomasian and Liu [83] have done this for the CSS and the SATF algorithms to address the difficult case of random requests for small blocks of data, as in transaction systems, such as an airline reservation system. This lookahead scheme for CSS algorithms considers the next several pending requests and orders them so as to minimize the total of their service times. Subsequently, scanning continues in the original direction, possibly picking up newly arrived requests between those just processed. The SATF algorithm is augmented to look at several requests and process at least two at a time. Again, the two are chosen to minimize access time. SATF with lookahead is designed to consider several requests — those beyond the first two are evaluated with a discount factor. The third algorithm is an SATF algorithm with higher priority given to read requests. A higher-priority write request is processed first only if the ratio of its service time to that of the highest priority read is less than a certain experimentally determined factor. Performance of these disk scheduling algorithms was compared to each other and to their established (non-augmented) counterparts, using experiments based on a random number driven simulation model. This was done to assess performance, especially in cases of random requests. Response times for the modified CSS algorithm were better than the unmodified version, although service times were nearly equal. Response times for the modified SATF algorithm were at most 10% improved. Finally, the SATF algorithm modified to give read requests higher priority showed minimal improvement over a more conventional, nonpreemptive read priority system, in which write requests are serviced only when there are no read requests waiting.

Cao et al. [11] suggest a technique that combines application-controlled file caching, prefetching, and disk scheduling. Modern operating systems typically deal with the wide and increasing disparity in performance between disks and processors by establishing a file cache in memory to hold demand and prefetched file information. Cao et al. showed that a system which utilizes application-based caching and prefetching policies can outperform a more typical system utilizing predefined cache replacement (usually LRU) and prefetching (sequential or one-block lookahead) policies. Previous work [10], however, indicated that performance improvements can be obtained by utilizing application-specific replacement policies. They propose integration of a controlled-aggressive policy that they showed theoretically closely approximates optimal cache block replacement [10]. In this case, even with imperfect and limited lookahead knowledge and in spite of the complicating interplay between applications and between applications and the kernel in the multiprocess case, substantial improvements result when disk prefetches are batched and the disk scheduler assembles the requests according to increasing logical block numbers.

This is accomplished by using a two-level cache management strategy: a kernel-implemented global policy, which allocates cache blocks among the various processes, and a local policy, which allows each user process to control use of its own cache blocks. The kernel's global policy is critical in ensuring that no individual process's policy can negatively affect another. To this end, the kernel utilizes an LRU policy with swapping and place holders that allows the process with the least recently used block, using its application-specific knowledge, to replace a block other than that least recently used with a block less likely to be used by swapping the two and marking the position of the removed block with a place holder. This protects the process from continually having the least recently used block (if it were not swapped) and provides a place for cache replacement in case the displaced block is recalled. This provides for a more optimal choice while preserving fairness. Further, each process contributes to more efficient disk utilization by grouping prefetches into batches. Experimentation with an implemented prototype system showed an average 26% reduction in running times when just a single process is using the file system at any given time and an average 32% reduction when multiple processes are concurrently accessing the file system.

In a similar vein, Shenoy and Vin [73] have proposed a disk scheduling framework, Cello, designed to accommodate the varying service requirements of today's diverse set of applications while preserving efficient disk utilization. The Cello framework consists of a two-level disk scheduling framework: a low-level, class-independent scheduler, which maintains the queue of disk service requests processed by the disk device driver, and a higher-level set of application class specific schedulers, that maintain individual queues of disk requests organized according to needs specific to applications in that class. This two-level organization recognizes the disparate needs of categories of applications, such as hard real-time applications (e.g., machine tool control) and soft real-time applications (e.g., audio or video playback), typically utilizing algorithms such as earliest deadline first (EDF), priority SCAN (PSCAN), or feasible deadline SCAN (FD-SCAN), for interactive best-effort applications (e.g., word processors), and high throughput best-effort applications (e.g., file servers), which utilize FCFS, SSTE, SCAN, LOOK, $V(R)$, SATF, or aged SAFT (ASATF).

In the Cello framework, the class-independent scheduler sets the portion of the available disk bandwidth for each of the class-specific schedulers. It does this either by proportionate time allocation or by proportionate space allocation. It tracks the various requests in a series of time intervals, ensuring that no class-specific scheduler uses more than its share. The class-independent scheduler interfaces with the class-specific scheduler by providing the current state of the disk device request queue it maintains, along with a measure of the constraints of those requests already queued — a factor it terms *slack*.

The application-specific schedulers maintain an ordering of disk requests according to the needs of applications in that particular class, while minimizing seek and rotational delay. For example, the best-effort class schedulers might use FCFS, SCAN, or SATF; the real-time schedulers might use EDF or SCAN-EDF. When requested by the class-independent scheduler, the application-specific scheduler calculates a position, perhaps using a first-fit, best-fit or other policy, for inserting the request at the head of its queue into the disk request queue of the class-independent scheduler. The latter checks that the insertion will not cause delays that would cause deadlines to be missed or the proportionate share of bandwidth to be exceeded (including changes in seek and rotational delay resulting from the proposed insertion).

Experiments with a trace-driven simulator and a prototype file system running on an Intel 233 MHz, Pentium machine running Solaris 2.5 allowed analysis of various parameters (e.g., time vs. space proportions, different weights and workloads), and established feasibility by showing a minimal increase in overhead running Cello.

The search for improvements in disk and file system performance has been marked by the development of redundant arrays of inexpensive disks (RAIDs) [63] [64]. The idea, as the name implies, is to connect a number of small disks to improve both reliability and performance. Initially, a RAID system was made up of a central controller connected to a host computer on one side and, on the other, to a number of disk controllers, each connected to a series of small disks. Performance is improved by distributing data across a number of disk drives, affording the possibility of parallel operation. Reliability is enhanced by *striping*, that is, storing a "stripe" of data blocks across a number of drives, thus minimizing the possibility of data loss from drive failure; *mirroring*, where a complete copy of the data is kept on separate drives; or *parity*

techniques, with parity blocks on a dedicated drive or distributed throughout the disk array. Cao et al. [9] have proposed an architecture in which the central controller is replaced by a number of “array controller nodes,” some of which are dubbed “worker” nodes and connect to local disks, and others “origination” nodes that provide for communication with the host computer. This latter arrangement enhances reliability by obviating the central controller — and thus the potential that its failure could disable the entire array. The “TickerTAIP” architecture also has the potential for improved performance by allowing for greater parallelism (e.g., for parity calculation).

The design of the RAID system preserves reliability and minimizes disruption from a failure of any single component: a disk failure, a worker failure, or an originator failure. The latter is assured by an *atomic write* policy: not allowing a write operation to make any changes until there is sufficient redundancy to guarantee successful completion of the write. Ensuring reliability becomes more difficult in the event of simultaneous failure of more than one component, a disaster according to Lampson and Sturgis [46]. However, following UNIX 4.2 BSD-type file systems [57], Cao et al. [9] propose controlling the effects of simultaneous component failure by using request sequencing, in essence assuming that no request can begin until all requests on which it depends (e.g., directory or inode requests) are complete.

Atomic requests and sequencing enable the TickerTAIP RAID to handle multiple requests requiring queues of requests at worker nodes. This leads to consideration again of request scheduling algorithms — this time, inside the disk array system. Thus, the worker system could use the previously described algorithms, such as FCFS, SSTF, or SATF. An additional algorithm [9], batched nearest neighbor (BNN), is a variant of SATF in that when a worker is available, it takes the entire batch of requests in its queue as a group and applies SATF until the entire batch is served, before picking up a new request. BBN provides much of the performance of SATF without the concomitant starvation problem.

Simulations showed that the distributed controller system of Cao et al. [9] provided greater throughput and lower response times with less CPU power. In addition, the tests showed that when the SATF and BNN algorithms were used, throughput improved substantially over FCFS (more so with SATF), especially when run with real world type workloads. Mean response time for the same workload tests were minimal with BNN, probably because of its built-in tendency to mitigate starvation.

Disk scheduling and allocation problems are, of course, closely related to both disk architecture and to the design and implementation of virtual memory and file systems. In particular, see the work of Patterson et al. [63] [64], Rosenblum and Ousterhout [67], and Hartman and Ousterhout [31]. See also [Chapter 85](#) and [Chapter 100](#) of this Handbook.

82.8.3 Deadlock

In [Section 82.6.1.2](#) and [Section 82.6.1.3](#), classical monoproccessor algorithms were shown to have time complexity $O(N^2)$, where N is the number of processes which, given that the algorithm must be executed for each resource request, presents unacceptable overhead. In fact, the best software algorithms, even for multiprocessor systems, have run-time complexities of $O(n \times r)$, where n is the number of processors and r is the number of resources [7] [42] [76]. Significant improvement apparently requires hardware implementation. Shiu et al. have developed a hardware implementation of a parallel deadlock detection algorithm [75]. Their simulated implementation experiments showed that this hardware detection algorithm could lower detection time by more than 99% and overall execution time by up to 68%. The algorithm uses a resource allocation graph [70], represented as an augmented adjacency matrix, to locate deadlocks by identifying cycles of resource requests and grants. The existence of such a cycle indicates a deadlock and vice versa. This enhanced adjacency matrix of elements representing requests and grants is further characterized as having [75]

Dead rows or columns — Those with no request or grant entries

Source rows or columns — Rows with at least one request, but no grants or columns with at least one grant but no requests

Sink rows or columns — Rows with at least one grant, but no requests or columns with at least one request but no grants

The implementation is a hardware parallel algorithm that identifies dead, source, and sink rows and columns and reduces the augmented adjacency matrix by iteratively eliminating these rows and columns as far as possible. Any remaining entries indicate existence of a deadlock; an empty matrix indicates freedom from deadlock. The algorithm has a run-time complexity of $O(\min(n, r))$.

Other recent work on deadlock is primarily focused on related areas:

Threads — [5] and [Chapter 84](#) and [Chapter 96](#) of this Handbook

Acknowledgments

Parts of [Section 82.1](#) and [Section 82.2](#) of this chapter are reprinted, with permission, from this author's contribution to [85].

Defining Terms

Deadlock: “A set of processes is deadlocked if each process in the set is waiting for an event [release] that only another process in the set can cause” [80, p 242].

Distributed system: “A *distributed computing system* consists of a number of computers that are connected and managed so that they *automatically* share the job processing load among the constituent computers or separate the job load as appropriate among particularly configured processors. Such a system requires an operating system which, in addition to the typical stand-alone functionality, provides coordination of the operations and information flow among the component computers” [85, p 403].

Multiprocessing: “A *multiprocessing system* is a computer hardware configuration that includes more than one independent processing unit” [85, p 403].

Multiprogramming: “A *multiprogramming operating system* is an OS which allows more than one active user program (or part of user program) to be stored in main memory simultaneously” [85, p 403].

Network: “A *networked computing system* is a collection of physically interconnected computers. The operating system of each of the interconnected computers must contain, in addition to its own stand-alone functionality, provisions for handling communication and transfer of programs and data among the other computers with which it is connected” [85, p 403].

Process: “A *process* is a series of operations associated with the execution of a sequence of instructions which effect a particular system or user action” [85, p 425].

Further Information

A good introduction to the practical problems in processor and device scheduling is presented in Tanenbaum [80], Silberschatz et al. [77], and Lister [50].

Current work is presented at the annual ACM Symposium on Operating System Principles, the USENIX Symposium on Operating System Design and Implementation, and the International Conference on Architectural Support for Programming Languages and Operating Systems. Copies of the proceedings are available from the ACM Special Interest Group on Operating Systems, ACM Headquarters, 1515 Broadway, New York, NY 10036.

The ACM quarterly *Transactions on Computer Systems* reports new developments in computer system scheduling. Also, the *Operating Systems Review*, a publication of the ACM Special Interest Group on Operating Systems, and ACM SIGMETRICS *Performance Evaluation Review* document current research in the area.

John A. Stankovic
University of Virginia

83.1 Introduction

Real-time systems are defined as those systems in which the correctness of the system depends not only on the logical result of computation, but also on the time in which the results are produced [Stankovic 1988]. Real-time systems span a broad spectrum of complexity from very simple microcontrollers in **embedded systems** (such as a microprocessor controlling an automobile engine) to highly sophisticated, complex, and distributed systems (such as air traffic control for the continental U.S.). Other examples of real-time systems include command and control systems, process control systems, flight control systems, the Space Shuttle avionics system, flexible manufacturing applications, the space station, space-based defense systems, intensive care monitoring, collections of humans/robots coordinating to achieve common objectives (usually in hazardous environments such as undersea exploration or chemical plants), intelligent highway systems, mobile and wireless computing, and multimedia and high-speed communication systems. We are also beginning to see some of these real-time systems adding expert systems [Wright et al. 1986] and other artificial intelligence (AI) technology creating additional requirements and complexities. From this extensive list of applications we can see that real-time and embedded systems technology is a key *enabling* technology for the future in an ever growing domain of important applications.

At least three major trends in the real-time and embedded systems field have had major impacts on its technology. The first is the increased growth and sophistication of embedded systems; the second is the development of more scientific and technological results for **hard real-time systems**; and the third is the advent of distributed multimedia, a **soft real-time system**. In a hard real-time system there is no value to executing tasks after their deadlines have passed. A soft real-time system has tasks that retain some diminished value after their deadlines so these tasks should still be executed, even if they miss their deadlines.

Most embedded systems consist of a small microcontroller and limited software situated within some *product* such as a microwave oven or automobile. Often, the design of embedded systems is severely

constrained by power, size, and cost constraints. However, to support increasing sophistication of embedded systems, we now see the common use of powerful microcontrollers and digital signal processor (DSP) chips, as well as the use of off-the-shelf real-time operating systems and design and debugging tools. Many people involved with embedded systems deal on a daily basis with sensors and data acquisition technology and systems; others construct architectures based on single board computers [many are still 68000 based, but reduced instruction set computer (RISC) processors are beginning to be used more and more] and busses such as the VME bus. Many people are involved with the programming and debugging of embedded systems, largely using the C programming language and cross development and debugging platforms. Embedded systems may or may not have real-time constraints.

In the hard real-time area, many fundamental results have been developed in real-time scheduling, operating systems, architecture and fault tolerance, communication protocols, specification and design tools, formal verification, databases and object-oriented systems. Increased emphasis on all of these areas is expected to continue for the foreseeable future. Many hard real-time systems are embedded systems.

Distributed multimedia has produced a new set of soft real-time requirements and when its potential is fully realized, it will fundamentally change how the world operates. Real-time principles lie at the heart of distributed multimedia, but without the concomitant high-reliability requirements found in safety-critical, hard real-time systems.

83.2 Underlying Principles

Typically, a real-time system consists of a *controlling system* and a *controlled system*. For example, in an automated factory, the controlled system is the factory floor with its robots, assembling stations, and the assembled parts; whereas the controlling system is the computer and human interfaces that manage and coordinate the activities on the factory floor. Thus, the controlled system can be viewed as the *environment* with which the computer interacts.

The controlling system interacts with its environment based on the information available about the environment from various **sensors**. It is imperative that the state of the environment, as perceived by the controlling system, be consistent with the actual state of the environment. Otherwise, the effects of the controlling systems' activities may be disastrous. Hence, periodic monitoring of the environment as well as timely processing of the sensed information is necessary.

Timing correctness requirements in a real-time system arise because of the *physical impact* of the controlling systems' activities upon its environment. For example, if the computer controlling a robot does not command it to stop or turn on time, the robot might collide with another object on the factory floor possibly causing serious damage. In many real-time systems even more severe consequences will result if timing as well as logical correctness properties of the system are not satisfied. For example, consider the effects of nuclear power plants or air traffic control systems failing.

Timing constraints for tasks can be arbitrarily complicated but the most common timing constraints for tasks are either *periodic*, *aperiodic*, or *sporadic*. A periodic task is one that is activated once every T units of time. The deadline for each activated instance may be less than, equal to, or greater than the period T . An aperiodic task is activated at unpredictable times. A sporadic task is an aperiodic task with an additional constraint that there is a minimum interarrival time between task activations.

Low-level application tasks such as those that process information obtained from sensors, or those that activate elements in the environment (through actuators), typically have stringent timing constraints dictated by the physical characteristics of the environment. A majority of sensory processing is periodic in nature. For example, a radar that tracks flights produces data at a fixed rate. A temperature monitor of a nuclear reactor core should be read periodically to detect any changes promptly. Some of these periodic tasks may exist from the point of system initialization whereas others may come into existence dynamically. The temperature monitor is an instance of a permanent task. An example of a dynamically created task is a (periodic) task that monitors a particular flight; this comes into existence when the aircraft enters an air traffic control region and will cease to exist when the aircraft leaves the region.

More complex types of timing constraints also occur. For example, spray painting a car on a moving conveyor must be started after time t_1 and completed before time t_2 . Aperiodic requirements can arise from dynamic events, such as an object falling in front of a moving robot or a human operator pushing a button on a console.

Time related requirements may also be specified in indirect terms. For example, a value may be attached to the completion of each task where the value may increase or decrease with time; or a value may be placed on the *quality* of an answer whereby an inexact but fast answer might be considered more valuable than a slow but accurate answer. In other situations, missing X deadlines might be tolerated, but missing $X + 1$ deadlines cannot be tolerated.

What happens when timing constraints are not met? The answer depends, for the most part, on the type of application. A real-time system that controls a nuclear power plant or one that controls a missile, cannot afford to miss timing constraints of the **critical tasks**. Resources needed for critical tasks in such systems have to be preallocated so that the tasks can execute without delay. In many situations, however, some leeway does exist. For example, even on an automated factory floor, if it is estimated that the correct command to a robot cannot be generated on time, it may be appropriate to command the robot to stop (provided it will not cause other moving objects to collide with it and result in a different type of disaster), or to slow down (thereby dynamically generating more time to produce a correct command). Another example is a periodic task monitoring the position of an aircraft; depending on the aircraft's location and trajectory, missing the processing of one or two radar readings may not cause any problems.

In a real-time system, the characteristics of the various application tasks are usually known a priori and might be scheduled statically or dynamically. Whereas static specification of schedules is typically the case for periodic tasks, the opposite is true for aperiodic tasks. When the periodic temperature monitor of a nuclear reactor senses a problem in the core, it can invoke another (aperiodic) task to activate the appropriate elements of the reactor to correct the problem, for example, to force more coolant into the reactor core. In this case, the deadline for the aperiodic task can be statically determined as a function of the physical characteristics of the reactions within the core. On the other hand, the deadline of a task that controls a robot on a factory floor can be determined dynamically depending on the speed, direction, and weight of the robot. The command to the robot forcing it to turn right, left, or stop should be generated before this deadline.

In a real-time system that is designed in a static manner, the characteristics of the controlled system are assumed to be known a priori and, hence, the nature of activities and the sequence in which these activities take place can be determined off line before the system begins operation. Such systems are quite inflexible even though they may incur lower run-time overheads. In practice, most applications involve a number of components that can be statically specified along with many dynamic components. If handled appropriately, a system with high-resource utilization and low overheads can be produced for such applications.

Although a large proportion of currently implemented real-time systems are static in nature, many next generation systems will have to adopt solutions that are more dynamic and flexible. This is because such systems will be large and complex and they will function in environments that are both uncertain and physically distributed. More importantly, they will have to be maintainable and extensible due to their evolving nature and projected long lifetimes. Because of these characteristics, real-time systems, in general, and systems with the previously described characteristics, in particular, need to be *fast, predictable, reliable, and adaptive*.

One long-held misconception about real-time systems is that they only need to be fast to be effective. Basically, being fast is usually a necessary condition, but it is not sufficient. A real-time system has to meet explicit deadlines and being fast on average does not guarantee that a deadline will be met. If a real-time system can be shown to meet its deadlines (using a worst-case rather than an average-case behavior analysis), then we say that it is predictable. Predictability, itself, has many meanings and an entire journal article has been devoted to its meaning [Stankovic and Ramamritham 1990]. For purposes of this chapter it is sufficient to take a simplistic view of predictability. Consider that predictability means that when a task or set of tasks is activated it should be possible to determine their completion time subject to failure assumptions.

This must be done taking into account the state of the system (including the state of the operating system and the state of the resources controlled by the operating system) and the tasks' resource needs.

The task of building a real-time system can be very simple or it can be extremely complex. The difficulty depends on the characteristics of the real-time system along five dimensions, which we now discuss.

1. *Granularity of the deadline and laxity of the tasks:* In a real-time system some of the tasks have deadlines and/or periodic timing constraints. If the time between when a task is activated (required to be executed) and when it must complete execution is short, then the deadline is tight (i.e., the granularity of the deadline is small or the deadline is close). This implies that the operating system reaction time has to be short, and the scheduling algorithm to be executed must be fast and very simple. Tight time constraints may also arise when the deadline granularity is large (i.e., from the time of activation), but the amount of computation required is also great. In other words even large granularity deadlines can be tight when the laxity (deadline minus computation time) is small. In many real-time systems tight timing constraints predominate. Consequently, designers focus on developing very fast and simple techniques to react to this type of task activation. In general, the tighter the deadline the more difficult the design task.
2. *Strictness of deadline:* The strictness of the deadline refers to the value of executing a task after its deadline. For a hard real-time task there is no value to executing the task after the deadline has passed. A soft real-time task retains some diminished value after its deadline and so it should still be executed. Very different techniques are usually used for hard and soft real-time tasks. In many cases hard real-time tasks are preallocated and prescheduled resulting in 100% of them making their deadlines. Soft real-time tasks are often scheduled either with nonreal-time scheduling algorithms, with algorithms that explicitly address the timing constraints but aim only at good average-case performance, or with algorithms that combine importance and timing requirements. Hard real-time tasks are more difficult to deal with than soft real-time tasks, and systems which must deal with both types simultaneously are yet even more difficult. Multimedia in a timesharing environment is a soft real-time application, but multimedia in a real-time control environment such as an automated factory must deal with both hard and soft real-time constraints.
3. *Reliability:* Many real-time systems operate under severe reliability requirements. That is, if certain tasks, called critical tasks, miss their deadline then a catastrophe may occur. These tasks are usually guaranteed to make their deadlines by an off-line analysis and by schemes that reserve resources for these tasks even if it means that those resources are idle most of the time. In other words, the requirement for critical tasks should be that all of them always make their deadline (a 100% guarantee), subject to certain failure and workload assumptions. However, too many systems treat all of the tasks that have hard timing constraints as critical tasks (when, in fact, only some of those tasks are truly critical). This can result in erroneous requirements and an overdesigned and inflexible system. It is also common to see hard real-time tasks defined as those with both strict deadlines and critical importance. We prefer to keep a clear separation between these notions because they are not always related. Of course, many other reliability issues must also be resolved, but here we only mention the key issue that deals with timing constraints and reliability.
4. *Size of system and degree of coordination:* Real-time systems vary considerably in size and complexity. In most current real-time systems the entire system is loaded into memory; if there are well-defined phases, each phase is loaded just prior to the beginning of the phase. In many applications, subsystems are highly independent of each other and there is limited cooperation among tasks. The ability to load entire systems into memory and to limit task interactions simplifies many aspects of building and analyzing real-time systems. However, for future large, complex, real-time systems, having completely resident code and highly independent tasks will not always be practical. Moreover, solutions based on virtual memory are not acceptable because of the large degree of unpredictability associated with this technique. Consequently, increased size and coordination raise many new problems that must be addressed and further complicate the notion of predictability. Embedded systems may also have power, physical size, memory, and severe cost constraints adding to the difficulty of their design.

5. *Environment*: The environment in which a real-time system is to operate plays an important role in the design of the system. Many environments are very well defined (a laboratory experiment, an automobile engine, or an assembly line). Designers think of these as deterministic environments (even though they may not be intrinsically deterministic, they are well controlled and assumed to be deterministic). These environments give rise to small, static real-time systems where all deadlines are guaranteed a priori. Even in these simple environments we need to place restrictions on the inputs. For example, a particular assembly line may only be able to cope with five items per minute; given more than that, the system fails. Taking this approach enables an off-line quantitative analysis of the timing properties to be made. Since we know exactly what to expect given the assumptions about the well-defined environment we can usually design and build these systems to be predictable. However, the approaches taken in relatively small, static systems do not scale to other environments which are larger, much more complicated, and less controllable. Consider a next generation real-time system such as a team of cooperating mobile robots on the planet Mars. This system will be large, complex, distributed, adaptive, contain many types of timing constraints, need to operate in a highly nondeterministic environment, and evolve over a long system lifetime. It is not possible to assume that this environment is deterministic or to control it sufficiently well to make it look deterministic. If that were done, the system would be too inflexible and would not be able to react to unexpected events or combinations of events.

83.3 Best Practices

Now that we have presented some of the basic principles of real-time and embedded systems, we can discuss some of the applications in various areas of **real-time computing**, including: real-time scheduling, real-time kernels, real-time architectures and fault tolerance, real-time communications, distributed multimedia, **real-time databases**, real-time formal verification, design and languages, and real-time AI.

83.3.1 Real-Time Scheduling

Real-time scheduling results in recent years have been extensive. Theoretical results have identified worst-case bounds for dynamic on-line algorithms, and complexity results have been produced for various types of assumed task set characteristics. Queueing theoretic analysis has been applied to soft real-time systems covering algorithms based on real-time variations of **first-come-first-serve (FCFS)**, earliest deadline, and least laxity. We have seen the development of scheduling results for imprecise computation (a situation where tasks obtain a greater value the longer they execute, up to some maximum value) [Liu et al. 1991].

More applied scheduling results have also been produced with an extensive set of improvements to the rate monotonic algorithm (this includes the deferrable server and sporadic server algorithms [Sprunt et al. 1989], techniques to address the problem of priority inversion [Sha et al. 1990], and a set of algorithms that perform dynamic on-line planning [Ramamritham et al. 1990]). We have also seen practical application of a priori calculation of static schedules to provide what is called 100% guarantees for critical tasks. Although these a priori analyses are very valuable, system designers should not be lulled into thinking that 100% guarantees mean that no scheduling error can occur. It is important to know that these 100% guarantees are based on many (often unrealistic) assumptions. If the assumptions are a poor match for what can be expected from the environment (more and more likely in a distributed environment), then even with 100% guarantees the system can indeed miss deadlines. Hence, a key issue is to choose an algorithm whose assumptions provide the greatest coverage over what *really* happens in the environment. For all of these scheduling results outlined, the trend has been to deal with increasingly more complicated task set and environment characteristics (e.g., multiprocessing and distributed computing and tasks with precedence constraints).

An exciting trend is the extensive use of schedulability analysis for both static and dynamic real-time systems. For example, the Software Engineering Institute has developed a handbook [Klein et al. 1993] on rate monotonic analysis and gives seminars and tutorials regarding its use in real-time systems.

83.3.2 Real-Time Kernels

One focal point for next generation complex real-time systems is the operating system. The operating system must provide basic support for predictably satisfying real-time constraints, for fault tolerance and distribution, and for integrating time-constrained resource allocations and scheduling across a spectrum of resource types including sensor processing, communications, CPU, memory, and other forms of I/O. Toward this end, at least three major scientific issues need to be addressed:

- The *time dimension* must be elevated to a central principle of the system and should not be simply an afterthought. An especially perplexing aspect of this problem is that most system specification, design, and verification techniques are based on abstraction, which ignores implementation details. This is obviously a good idea; however, in real-time systems, timing constraints are derived from the environment and the implementation. This dilemma is a key scientific issue.
- The basic paradigms found in today's general purpose distributed operating systems must change. Currently, they are based on the notion that application tasks request resources as if they were random processes; operating systems are designed to expect random inputs and to display good average-case behavior. The new paradigm must be based on the delicate balance of *flexibility* and *predictability*: the system must remain flexible enough to allow a highly dynamic and adaptive environment, but at the same time be able to predict and possibly avoid resource conflicts so that timing constraints can be met. This is especially difficult in distributed environments where layers of operating system code and communication protocols interfere with predictability.
- A highly *integrated and time-constrained resource allocation approach* is necessary to adequately address timing constraints, predictability, adaptability, correctness, safety, and fault tolerance. For a task to meet its deadline, resources must be available *in time*, and events must be ordered to meet precedence constraints. Many coordinated actions are necessary for this type of processing to be accomplished on time. The state of the art lacks completely effective solutions to this problem.

For relatively small, less complex, real-time systems, it is often the case that real-time systems are supported by stripped down and optimized versions of timesharing operating systems. To reduce the run-time overheads incurred by the kernel and to make the system *fast*, the kernel underlying the real-time system:

- Has a fast context switch
- Has a small size (with its associated minimal functionality)
- Responds to external interrupts quickly
- Minimizes intervals during which interrupts are disabled
- Provides fixed or variable sized partitions for memory management (i.e., no virtual memory) as well as the ability to lock code and data in memory
- Provides special sequential files that can accumulate data at a fast rate

To deal with timing requirements, the kernel:

- Maintains a real-time clock
- Provides a priority scheduling mechanism
- Provides for special alarms and timeouts
- Permits tasks to invoke primitives to delay by a fixed amount of time and to pause/resume execution

In general, the kernels perform multitasking; intertask communication and synchronization are achieved via standard, well-known primitives such as mailboxes, events, signals, and semaphores. Examples of existing real-time kernels include: QNX, LynxOS, OS-9, VxWorks, and VRTXsa (over 70 commercial real-time kernels exist). Specialized kernels for DSP chips and homegrown kernels for microcontrollers are also still widely found.

Real-time kernels are also being extended to operate in highly cooperative multiprocessor and distributed system environments [Tokuda et al. 1990]. This means that there is an **end-to-end timing requirement** (in the sense that a set of communication tasks must complete before a deadline), i.e., a collection of activities must occur (possibly with complicated precedence constraints) before some deadline. Much research is being done on developing time constrained communication protocols to serve as a platform for supporting this user-level end-to-end timing requirement. However, while the communication protocols are being developed to support host-to-host bounded delivery time, using the current operating system (OS) paradigm of allowing arbitrary waits for resources or events, or treating the operation of a task as a *random process* causes great uncertainty in accomplishing the application level end-to-end requirements. As an example, the Mars project [Kopetz et al. 1989], the Spring project [Stankovic and Ramamritham 1991], and a project at the University of Michigan [Shin 1991] are all attempting to solve this problem. The Mars project uses an a priori analysis and then statically schedules and reserves resources so that distributed execution can be guaranteed to make its deadline. The Spring approach supports dynamic requests for real-time virtual circuits (guaranteed delivery time) and real-time datagrams (best effort delivery) integrated with CPU scheduling so as to guarantee the application level end-to-end timing requirements. The Spring project uses a distributed reflective memory based on a fiber optic ring to achieve lower level predictable communication properties. The Michigan work also supports dynamic real-time virtual circuits and datagrams, but it is based on a general multihop communication subnet.

Research is also being done on developing real-time object-oriented kernels to support the structuring of distributed real-time applications. As far as we know, no commercial products of this type are available. However, due to the major advantages of object orientation, it is likely that many such products will become available in the near future.

The diversity of the applications requiring predictable distributed systems technology will be significant. To handle this diversity, we expect the distributed real-time operating systems must use an *open system* approach, and the applications need to be portable. Regarding the open systems approach, it is important to avoid having to rewrite the operating system for each application area which may have differing timing and fault tolerance requirements. A library of real-time operating system objects might provide the level of functionality, performance, predictability, and portability required. We envision a Smalltalk-like system for hard real time, so that a designer can tailor the OS to the application without having to write everything from scratch. In particular, a library of real-time scheduling algorithms should be available that can be plugged in depending on the run-time task model being used and the load, timing, and fault tolerance requirements of the system.

Regarding the portability of applications, many real-time Unix operating systems are appearing [Furht et al. 1991], and a standard for real-time operating systems, called RT POSIX, is being developed [Gallmeister 1995]. Although such a standard facilitates porting the code, it is still an open issue on how to assess the timing properties of the ported application.

83.3.3 Real-Time Architecture and Fault Tolerance

Real-time systems are usually special purpose. In the past, architectures to support such applications tended to be special purpose too. The current trend is one in which more off-the-shelf components are being used to produce more generic architectures. Although considerable discussion could be given to real-time architectures, we shall consider only briefly how architecture impacts the computation of worst-case execution time and how it supports fault tolerance.

One aspect of architecture for real-time computing is the facility with which the worst-case execution time can be calculated. Worst-case execution times of programs are dependent on the system hardware, the operating system, the compiler used, and the programming language used. Many hardware features that have been introduced to speed up the average-case behavior of programs pose problems when information about worst-case behavior is sought (especially true on many state-of-the-art RISC CPUs). For instance, the ubiquitous caches, pipelining, dynamic random access memories (RAMs), and virtual (secondary) memory, lead to highly nondeterministic hardware behavior. Similarly, compiler optimizations tailored to make better use of these architectural enhancements, as well as more standard techniques such as

constant folding, which is the replacement of run-time computation by compile-time computation, contribute to poor predictability of code execution times. System interferences due to interrupt handling, shared memory references, and preemptions are additional complications. In summary, any approach to the determination of execution times of real-time programs has many complexities which must be solved.

Many real-time system architectures consist of multiprocessors, networks of uniprocessors, or networks of uni- and multiprocessors. Such architectures have potential for high fault tolerance, but they are also much more difficult to manage in a way such that deadlines are predictably met. Fault tolerance must be designed in at the start, must encompass both hardware and software, and must be integrated with timing constraints. In many situations, the fault tolerant design must be static due to extremely high data rates and severe timing constraints. Ultrareliable systems need to employ proof of correctness techniques to ensure fault tolerance properties [Vytopil 1993]. Primary and backup schedules computed off line are often found in hard real-time systems. We also see new approaches where on-line schedulers predict that timing constraints will be missed, enabling early action on such faults. Dynamic reconfigurability is needed but little progress has been reported in this area. Also, whereas considerable advance has been made in the area of software fault-tolerance, techniques that explicitly take timing into account are lacking.

Since fault tolerance is difficult, the trend is to let experts build the proper underlying support for it. For example, implementing checkpointing, reliable atomic broadcasts, logging, lightweight network protocols, synchronization support for replicas, and recovery techniques, and having these primitives available to applications, then simplifies creating fault tolerant applications. However, many of these techniques have not carefully addressed timing considerations nor the need to be predictable in the presence of failures. Many real-time systems, which require a high degree of fault tolerance, have been designed with significant architectural support, but the design and scheduling to meet deadlines is done statically, with all replicas in lock step. This may be too restrictive for many future applications. What is required is the integration of fault tolerance and real-time scheduling to produce a much more flexible system. For example, the use of the **imprecise computation** model [Liu et al. 1991], or a planning scheduler [Ramamritham et al. 1990] gives rise to a more flexible approach to fault tolerance than static schedules and fixed backup schemes. Adaptive fault tolerance with an explicit interaction with real-time constraints can be found in Bondavali et al. [1993].

83.3.4 Real-Time Communications

Distributed real-time systems require time-constrained message delivery. In many applications the communication protocols and network provide deterministic behavior. An alternative, applicable in other situations, is a best effort approach. Hybrid approaches also exist [Arvind et al. 1991]. Those systems requiring hard guarantees often use time-domain multiple access (TDMA), fiber distributed data interface (FDDI), Institute of Electrical and Electronics Engineers (IEEE) 802.4 token bus or 802.5 token ring [Strosnider and Marchok 1989]. Careful assumptions and analysis accompany the use of these networks to produce a deterministic guarantee. For best effort approaches, variations of carrier sense multiple access/collision detection (CSMA/CD) or window-based schemes can be used [Malcolm and Zhao 1995]. For distributed multimedia [Govindan and Anderson 1991, Clark et al. 1992], timing constraints on the network include end-to-end delays, minimum jitter, and interpacket maximum delays. Other requirements for transmitting audio, video, text, and data traffic include extremely high volume and high speeds. To support these requirements, asynchronous transfer mode (ATM) switches [Newman 1994] have been developed. With the advent of ATM technology we are seeing the projected use of ATMs as the local area network of real-time systems.

Specialized busses are still widely utilized today. The controller area network (CAN) bus for automobiles and the SAFEbus for commercial aircraft [Hoyme et al. 1991] are examples.

83.3.5 Distributed Multimedia

Many real-time control applications such as agile manufacturing and process control operate in highly nondeterministic environments under timing constraints of many types. Significant improvements in

these applications can be created by embedding continuous and multimedia support in these applications. For example, in agile manufacturing, remote factories, each consisting of many automated workcells, must coordinate to handle new strategies for incoming product orders, to develop the design of new products, to schedule just-in-time deliveries of manufactured components, to monitor the plant operations, and to collaboratively solve difficult manufacturing floor problems.

To implement solutions cost effectively and to allow multimedia applications direct access to plant operational data, it is envisioned that the same computers would control the time-constrained operations in and across the workcells and support multimedia [Guha et al. 1995]. The backbone network would likely be ATM. Distributed multimedia over ATM networks has enormous potential to provide these applications with teleconferencing for real-time coordination, collaborative design, and a wealth of real-time information such as visual access to remote and local plant operations via cameras, as well as supporting real-time control. These applications would also benefit from an integrated design of a distributed database that contains such information as sensor information and control variables constrained by temporal validity intervals, plant operational data, information on availability of raw materials, inventory of products, customer orders, etc. The confluence of an integrated database, multimedia, and real-time control has great potential for moving application areas such as manufacturing and process control into the next generation.

It is important to point out that although the commercial world is developing multimedia support, most of this work is done in the context of general purpose timesharing systems and **not** integrated with real-time control applications. This difference is significant and will likely require solutions not likely to be developed for commercial multimedia. One reason for this is that the nonreal-time control applications can accept a probability that other applications that are executing can fail (or be late), and so it is likely that simpler solutions and less expensive systems can be built for these applications. This assumption is reasonable for many commercial multimedia-based systems, but not for real-time control applications. On the other hand, real-time control applications have focused on solutions for hard deadline systems, which would be too inefficient if they were used for multimedia. This new, distributed, multimedia, information technology environment will require greater support for soft real-time systems, especially in their continuous and multimedia aspects. Here, new models of guarantees and resource reservations are required.

Distributed multimedia applications require both high-performance operating system features (in order to respond to the high data and processing rates) as well as a **quality-of-service (QOS)** guarantee. A quality-of-service guarantee is a promise to provide a certain level of performance to a multimedia application. Quality of service may be defined in a number of ways even within the same system. Hence, it is important that the OS be flexible enough to accept different types of quality of service requests. Because QOS guarantees are end-to-end, this necessitates an integrated and synergistic approach to the problem, encompassing the scheduling algorithm, the underlying I/O system (e.g., mass storage), the database system, associated operating system components, and the network. The scheduling algorithms must be able to *cosupport* the hard deadline control tasks and the distributed multimedia aspects of the system. Solving the main issues for the I/O system includes interfacing to real-time databases, achieving adequate sustained transfer rates, I/O scheduling, data layout on the disk array, and I/O buffer management. Whereas some aspects of the operating system infrastructure required to meet these needs can be found in today's real-time kernels or as specially developed parts of commercial kernels, OS features typically available today are not sufficient especially in the context of real-time control applications with hard deadlines. Further, much of the current work has concentrated on either single site [Anderson et al. 1992], or network level end-to-end delays; what is required is support for distributed application level to application level processing.

Another issue is call admission in which the system dynamically decides whether to admit a new multimedia session or not. Note that this concept was previously used in hard real-time systems since 1984 [Ramamritham and Stankovic 1984]. In the context of multimedia, call admission requires that we determine that either the session being requested is possible (so we can admit it), or it is not possible even to an acceptable degraded level (so we reject the request, or identify what the degraded service will be). In control applications we may need to override previously admitted sessions or compute tradeoffs to maximize the likelihood of success of the overall mission.

83.3.6 Real-Time Databases

A real-time database is a database system where (at least some) transactions have explicit timing constraints such as deadlines and where data may become invalid with the passage of time. In such a system, transaction processing must satisfy not only the database consistency constraints, but also the timing constraints. Real-time database systems can be found, for instance, in program trading in the stock market, radar tracking systems, battle management systems, and computer integrated manufacturing systems. Some of these systems (such as program trading in the stock market) are soft real-time systems, because missing a deadline is not catastrophic. Usually, research into algorithms and protocols for such systems explicitly addresses deadlines and makes a best effort at meeting deadlines. In soft real-time systems there are no guarantees that specific tasks will make their deadlines.

In real-time databases there is a need for an integrated approach that includes time constrained protocols for concurrency control, conflict resolution, CPU and I/O scheduling, transaction restart and wakeup, deadlock resolution, buffer management, and commit processing. Many protocols based on locking, optimistic, and time-stamped concurrency control have been developed and evaluated in testbed or simulation environments [Abbott and Garcia-Molina 1988]. In most cases the optimistic approaches seem to work best [Huang et al. 1991].

In a typical database system a transaction is a sequence of operations performed on a database. Normally, consistency (serializability), atomicity, and permanence are properties supported by the transaction mechanism. Transaction throughput and response time are the usual metrics. In a soft real-time database, transactions have similar properties, but, in addition, have soft real-time constraints. Metrics include response time and throughput, but also include the percentage of transactions which meet their deadlines, or a weighted value function which reflects the value imparted by a transaction completing on time. On the other hand, in a hard real-time database, not all transactions have serializability, atomicity, and permanence properties. These requirements need to be supported only in certain situations. For example, hard real-time systems are characterized by their close interactions with the environment that they control. This is especially true for subsystems that receive sensory information or that control actuators. Processing involved in these subsystems is such that it is typically not possible to *rollback* a previous interaction with the environment.

Whereas the notion of consistency is relevant here (for example, the interactions of a real-time task with the environment should be consistent with each other), traditional approaches to achieving consistency, involving waits, rollbacks, and aborts are not directly applicable. Instead, compensating transactions may have to be invoked to nullify the effects of previously committed transactions. Also, another transaction property, namely, *permanence*, is of limited applicability in this context. This is because real-time data, such as those arriving from sensors, have limited *lifetimes*: they become obsolete after a certain point in time. Data received from the environment by the lower levels of a real-time system undergo a series of processing steps (e.g., filtering, integration, and correlation). Traditional transaction properties are less relevant at the lowest levels and become more relevant at higher levels in the system. Most hard real-time database systems are main memory databases of small size, with predefined transactions, and handcrafted for efficient performance.

A new trend is the use of active database technology for real-time databases. A **real-time active database (RTADB)** is a system where transactions have timing constraints such as deadlines, where data may become invalid with the passage of time, and where transactions may trigger other transactions. This type of database follows an event–condition–action paradigm subject to timing constraints. RTADBs are in their infancy and no commercial products yet exist, although many products contain *triggers*.

83.3.7 Real-Time Formal Verification, Design, and Languages

Today, when constructing a complex real-time system it is becoming more common to use a formal verification technique [Vytopil 1993, Jahanian and Mok 1986] for certain aspects of the design and to use a commercially available design tool [Kavi 1992]. Many formal verification approaches are available, e.g., those based on Petri nets, temporal logic, timed communicating sequential processes (CSP), probabilistic

durational calculus, real-time logic (RTL), or prototype verification system (PVS). Although limitations still exist on the use of these techniques, the value of formal techniques early in the design process has been amply demonstrated. The trend is to develop formalisms that can directly address timing constraints.

Regarding design methods, commercial tools such as STATEMATE [Harel et al. 1990], CARDtools, or Control Shell provide graphical interfaces and many nice database features. Many design methodologies have been extended to deal with real-time systems and recently have included an object-oriented approach [Ellis 1994]. Since tools such as these are so important, continual improvements occur. The future should bring more understandable tools that better and better reflect and support the reliability and timing constraints of real-time systems.

A discussion on real-time languages (those specifically designed for real-time programming and specification) and languages used for real-time systems (assembler, C, ADA, etc.) can be found in Burns and Wellings [1989]. ADA and C are now commonly used for programming many complex real-time systems. Synchronous languages [Halbwachs 1993] are also widely used, mostly in Europe.

83.3.8 Real-Time Artificial Intelligence

Many complex real-time applications now require or will require knowledge-based on-line assistance operating in real time [Paul et al. 1991]. This necessitates a major change to some of the paradigms and implementations previously used by AI researchers. For example, AI systems must be made to run much faster (a necessary but not sufficient condition), allow preemption to reduce latency for responding to new stimuli, attain predictable memory management via incremental garbage collection or by explicit management of memory, include deadlines and other timing constraints in search techniques, develop anytime algorithms (algorithms where a nonoptimal solution is available at any point in time), develop time-driven inferencing, and develop time-driven planning and scheduling. Rules and constraints may also have to be imposed on the design, models, and languages used in order to facilitate predictability, e.g., limit recursion and backtracking to some fixed bound. Coming to grips with what predictability means in such applications is also very important.

In addition to these changes within AI, real-time AI (RTAI) techniques must be interfaced with lower level real-time systems technology to produce a functioning, reliable, and carefully analyzable system. Should the higher level RTAI techniques ignore the system level, treat it as a black box with *general* characteristics, or be developed in an integrated fashion with it so as to best build complex systems? What is the correct interface between these two traditionally separate systems? Integrating RTAI and low-level real-time systems software is quite a challenge because RTAI applications are operating in nondeterministic environments, there is missing or noisy information, some of the control laws are heuristic at best, objectives may change dynamically, partial solutions are sometimes acceptable (so that a tradeoff between the quality of the solution and the time needed to derive it can be made), the amount of processing is significant and highly data dependent, and the execution time of tasks may be difficult to determine. These demanding requirements will drive real-time research for many years to come.

Competing software architectures for real-time AI include production rule architectures, blackboard architectures, and a process trellis architecture. Some real-time AI systems have been built by carefully and severely restricting how production rules and blackboard systems are built and used. Research is ongoing to relax the restrictions so that the power of these architectures can be utilized, but at the same time providing a high degree of predictability. The process trellis architecture, used in the medical domain, is a highly static approach whereas the other two are much more dynamic. The trellis architecture (because it is static) has potential to provide static real-time guarantees for those applications characterized by enough time to completely compute results from a set of inputs before the next set of inputs arrive. This approach is suitable for certain types of real-time AI monitoring systems, but its generality for complex real-time AI systems has not been demonstrated.

In a distributed setting, high-level decision support requires organizing computations with networks of cooperative, semiautonomous agents, each capable of sophisticated problem solving. Theories of communication and organizational structure for groups of cooperative problem solving agents must be developed. These theories must include problem solving under uncertainty and under timing constraints.

83.4 Research Issues and Summary

Many research issues exist in all areas of real-time computing. Many of the problems are of a fundamental nature and others are more applied. It is impossible to list all of the key research issues; instead we identify representative examples of open research problems.

Although many interesting scheduling results have been produced, the state of the art still provides piecemeal solutions. Many realistic issues have not yet been addressed in an integrated and comprehensive manner. The real-time scheduling area still requires analyzable scheduling approaches (it may be a collection of algorithms) that are comprehensive and integrated. For example, the overall approach must be comprehensive enough to handle:

- Preemptable and nonpreemptable tasks
- Periodic and nonperiodic tasks
- Tasks with multiple levels of importance (or a value function)
- Groups of tasks with a single deadline
- End-to-end timing constraints
- Precedence constraints
- Communication requirements
- Resource requirements
- Placement constraints
- Fault tolerance needs
- Tight and loose deadlines
- Normal and overload conditions

The solution must be integrated enough to handle the interfaces between:

- CPU scheduling and resource allocation
- I/O scheduling and CPU scheduling
- CPU scheduling and real-time communication scheduling
- Local and distributed scheduling
- Static scheduling of critical tasks and dynamic scheduling of essential and nonessential tasks

One key issue is the need to provide predictability. Predictability requires bounded operating system primitives, some knowledge of the application, proper scheduling algorithms, and a viewpoint based on a *team* attitude between the operating system and the application. For example, simply having a very primitive kernel that is itself predictable is only the first step. More direct support is needed for developing predictable and fault tolerant real-time applications. One aspect of this support comes in the form of scheduling algorithms. For example, if the operating system is able to perform integrated CPU scheduling and resource allocation in a planning mode so that collections of cooperating tasks can obtain the resources they need at the right time, in order to meet timing constraints, this facilitates the design and analysis of real-time applications. Further, if the operating systems retains information about the importance of a task and what actions to take if the task is assessed as not being able to make its deadline, then a more intelligent decision can be made as to alternative actions, and graceful degradation of the performance of the system can be better supported (rather than a possible catastrophic collapse of the system if no such information is available). Kernels which support retaining and using semantic information about the application are sometimes referred to as *reflective* kernels [Stankovic and Ramamritham 1995].

Basic research is also required in many areas of distributed multimedia, including:

- Specification of quality of service
- Algorithmic and kernel support to actually achieve this guaranteed service and to dynamically negotiate other levels of service, if necessary

- How to perform reservations of sets of resources
- Integrated scheduling across a set of resources (e.g., so that CPU, I/O buffer, disk controller, network bandwidth, and resources at the receiver are reserved together)
- End-to-end scheduling
- Atomic guarantees for sets of tasks (This supports the call admission policies needed in multimedia.)

Obviously, achieving complex, real-time systems is nontrivial and will require research breakthroughs in many aspects of system design and implementation. For example, good design methodologies and tools which include programming rules and constraints must be used to guide real-time system developers so that subsequent implementation and *analysis* can be facilitated. This includes proper application decomposition into subsystems and allocation of those subsystems onto distributed architectures. The programming language must provide features tailored to these rules and constraints, must limit its features to enhance predictability, and must provide the ability to specify timing, fault tolerance, and other information for subsequent use at run time. Many language features are continuously being proposed, although few of them are currently used in practice. Execution time of each primitive of the kernel must be bounded and predictable, and the operating system should provide explicit support for all of the requirements including the real-time requirements. New trends in the OS area include the use of microkernels, support for multiprocessors and distributed systems, and real-time thread packages. The architecture and hardware must also be designed to support predictability and facilitate analysis. For example, hardware should be simple enough so that predictable timing information can be obtained. This has implications for how to deal with caching, memory refresh and wait states, pipelining, and some complex instructions, which all contribute to timing analysis difficulties. The resulting system must be scalable to account for the significant computing needs that occur both initially and as the system evolves. An insidious aspect of critical real-time systems, especially with respect to their real-time requirements, is that the weakest link in the entire system can undermine careful design and analysis at other levels. Research is required to address all of these issues in an integrated fashion.

Finally, a number of new trends involve the use of formal verification for real-time systems and the development of real-time databases, real-time object-oriented systems, and real-time artificial intelligence. Since these areas are very new, many open problems exist.

Defining Terms

Constant folding: A compiler optimization technique where run-time computations are replaced by compile-time computations.

Critical real-time task: One in which missing its deadline may cause a catastrophe or total failure of the system.

Embedded system: A system that is a component of a larger system, e.g., an automobile cruise control system or the navigation system of the space shuttle.

End-to-end timing requirement: A single overall timing requirement for a set of tasks that operate with some precedence constraints. This is typical of a distributed set of tasks communicating over a network.

First-come–first-served (FCFS): Scheduling policy that chooses which task to execute based on the earliest time of arrival.

Hard real-time task: One in which there is no value in continuing to execute the task after the deadline has passed.

Imprecise computation: One where if the computation terminates before completion, the intermediate result produced is usable.

Quality-of-service (QOS): Guarantee that is a promise to provide a certain level of performance to a multimedia application.

Real-time active database: One where transactions have timing constraints such as deadlines, where data may become invalid with the passage of time, and where transactions or events may trigger other transactions.

- Real-time computing:** That computing where the results must be logically correct and produced on time.
- Real-time database:** One where transactions have timing constraints such as deadlines and where data may become invalid with the passage of time.
- Sensor:** A device that outputs a signal for the purpose of detecting or measuring a physical property.
- Soft real-time task:** One that retains some diminished value after its deadline so it should still be executed even if its deadline has passed.

Further Information

Tutorial Texts

A good introduction to real-time systems can be found in *Hard Real-Time Systems* by John A. Stankovic and Krithi Ramamritham. More recent research results in the field can be found in a follow-on text entitled *Advances in Real-Time Systems* by the same authors. Yann Hang Lee and C. M. Krishna have edited a tutorial text entitled *Readings in Real-Time Systems* where papers on key real-time concepts are presented. Krishna Kavi has also produced a tutorial text on real-time systems entitled *Real-Time Systems, Abstractions, Languages, and Design Methodologies*. This latter book approaches real-time systems from the design point of view, whereas the others mentioned take a systems implementation perspective. All of these texts are published by the IEEE Computer Society Press.

Other Information

Proceedings of the Real-Time Systems Symposium are published annually by the IEEE Computer Society. The conference is held each December and research papers are presented.

A new annual IEEE Computer Society Symposium was started in 1995 titled the Real-Time Technology and Applications Symposium. This symposium focuses on the interaction between industry and academia; a proceedings is published.

An archival journal entitled *Real-Time Systems* is published six times a year by Kluwer Academic Publishers. Kluwer also publishes an international book series on real-time computing. There are approximately 20 volumes in this series. For subscription information for the journal or for information on the book series contact: Kluwer Academic Publishers, 101 Philip Drive, Assinippi Park, Norwell, MA 02061.

Embedded Systems Programming is published monthly by Miller Freeman Inc., 600 Harrison St., San Francisco, CA 94107.

Embedded Systems Conference East and Embedded Systems Conference West are each held once per year. These conferences include product exhibitions and technical instruction.

84.1 Introduction

Process **synchronization** (also referred to as process coordination) is a fundamental problem in operating system design and implementation. It is a situation that occurs when two or more processes coordinate their activities based on a condition. An example is when one process must wait for another process to place a value in a buffer before the first process can proceed. A specific problem of synchronization is **mutual exclusion**, which requires that two or more concurrent activities do not simultaneously access a shared resource. This resource may be shared data among a set of processes where the instructions that access these shared data form a **critical region** (also referred to as a critical section). A solution to the mutual exclusion problem guarantees that among the set of processes, only one process is executing in the critical region at a time.

Processes involved in synchronization are indirectly aware of each other by waiting on a condition that is set by another process. Processes can also communicate directly with each other through **interprocess communication (IPC)**. IPC causes communication to be sent between two (or more) processes. A common form of IPC is message passing.

The origins of process synchronization and IPC are work in concurrent program control by people such as Dijkstra, Hoare, and Brinch Hansen. Dijkstra described and presented a solution to the mutual exclusion problem [Dijkstra 1965] and proposed other fundamental synchronization problems and solutions such as the dining philosophers problem [Dijkstra 1971] and semaphores [Dijkstra 1968]. Brinch Hansen [1972] and Hoare [1972] suggested the concept of a critical region. Brinch Hansen published a classic text with

many examples of concurrency in operating systems [Brinch Hansen 1973]. Hoare [1974] provided a complete description of monitors following work by Brinch Hansen [1973].

Modern work in the area includes development of multithreaded, message-based operating systems executing on multiprocessors. Many of the primitives used for synchronizing processes also work for synchronizing threads, which are discussed in [Chapter 76](#). Investigation is being done on mechanisms that work in a multiprocessor environment and extend to a distributed one. Concurrent programming using synchronization and IPC in a distributed environment, discussed in [Chapters 85](#) and [98](#), is more complex than the mechanisms described in this chapter because of additional complications. In a distributed environment, there may be a failure by some processes participating in synchronization while others continue, or it is possible for messages to be lost or delayed in an IPC mechanism.

The remainder of this chapter discusses the underlying principles and practices commonly used for synchronization and IPC. [Section 84.2](#) identifies fundamental problems needing solutions and issues that arise in considering various solutions. [Section 84.3](#) discusses specific solutions to synchronization and IPC problems and discusses their relative merits in terms of these issues. The chapter concludes with a summary, a glossary of terms that have been defined, references, and sources of further information.

84.2 Underlying Principles

Process synchronization and IPC arose from the need to coordinating concurrent activities in a multiprogrammed operating system. This section defines and illustrates the fundamental synchronization and IPC problems and characterizes the issues on which to compare the solutions.

84.2.1 Synchronization Problems

A fundamental synchronization problem is mutual exclusion, as described by Dijkstra [1965]. Lamport [1986] provides a formal treatment of the problem, with Anderson [2001] surveying Lamport's contributions on this topic. In this problem, multiple processes wish to coordinate so that only one process is in its critical region of code at any one time. During this critical region, each process accesses a shared resource such as a variable or table in memory. The use of a mutual exclusion primitive for access to a shared resource is illustrated in [Figure 84.1](#), where two processes have been created that each access a shared global variable through the routine **Deposit()**.

The routines **BeginRegion()** and **EndRegion()** define a critical region ensuring that **Deposit()** is not executed simultaneously by both processes. With these routines, the final value of **balance** is always 20, although the execution order of the two processes is not defined.

To illustrate the need for mutual exclusion, consider the same example without the **BeginRegion()** and **EndRegion()** routines. In this case, the execution order of the statements for each process is time dependent. The final value of **balance** may be 20 if **Deposit()** is executed to completion for each process, or the value of **balance** may be 10 if the execution of **Deposit()** is interleaved for the two processes. This example illustrates a **race condition**, where multiple processes access and manipulate the same data with the outcome dependent on the relative timing of these processes. The use of a critical region avoids a race condition.

Many solutions have been proposed for the implementation of these two primitives; the most well known of which are given in the following section. Solutions to the mutual exclusion synchronization problem must meet a number of requirements, which were first set forth in Dijkstra [1965] and are summarized in Stallings [2000]. These requirements are as follows:

- Mutual exclusion must be enforced so that at most one process is in its critical region at any point in time.
- A process must spend a finite amount of time in its critical region.

```

int balance = 0; /* global shared variable */

ProcessA()
{
    Deposit(10);
    cout << "Balance is " << balance << '\n';
}

ProcessB()
{
    Deposit(10);
    cout << "Balance is " << balance << '\n';
}

Deposit(int deposit)
{
    int newbalance; /* local variable */

    BeginRegion(); /* enter critical region */
    newbalance = balance + deposit;
    balance = newbalance;
    EndRegion(); /* exit critical region */
}

```

FIGURE 84.1 Shared variable access handled as a critical region.

- The solution must make no assumptions about the relative speeds of the processes or the number of processes.
- A process stopped outside of its critical region must not lead to blocking of other processes.
- A process requesting to enter a critical region held by no other process must be permitted to enter without delay.
- A process requesting to enter a critical region must be granted access within a finite amount of time.

Another fundamental synchronization problem is the producer/consumer problem. In this problem, one process produces data to be consumed by another process. [Figure 84.2](#) shows one form of this problem where a *producer* process continually increments a shared global variable and a *consumer* process continually prints out the shared variable. This variable is a fixed-size buffer between the two processes, and hence this specific problem is called the bounded-buffer producer/consumer problem.

The ideal of this example is for the consumer to print each value produced. However, the processes are not synchronized and the output generated is timing dependent. The number 0 is printed 2000 times if the consumer process executes before the producer begins. At the other extreme, the number 2000 is printed 2000 times if the producer process executes before the consumer begins. In general, increasing values of **n** are printed with some values printed many times and others not at all. This example illustrates the need for the producer and consumer to synchronize with each other.

The producer/consumer problem is a specific type of synchronization that is needed between two processes. In general, many types of synchronization between processes can be expressed with a *synchronization graph*, such as shown in [Figure 84.3](#). A synchronization graph is a directed graph showing the relative execution order for a set of actions (code segments). In the example, actions B and C execute after action

```

int n = 0; /* shared by all processes */

main()
{
    int producer(), consumer();
    CreateProcess(producer);
    CreateProcess(consumer);
    /* wait until done */
}
producer() // produce values of n
{
    int i;
    for (i=0; i<2000; i++)
        n++; // increment n
}
consumer() // consume and print values of n
{
    int i;
    for (i=0; i<2000; i++)
        printf("n is %d\n", n); /* print value of n */
}

```

FIGURE 84.2 Example of producer/consumer synchronization problem.

FIGURE 84.3 Synchronization graph for four actions.

A completes, with action D executing after both B and C are complete. Solutions to the synchronization problem need to allow for implementation of this type of problem.

84.2.2 Synchronization Issues

There are many approaches available for solving mutual exclusion and synchronization problems. There are a number of issues concerning the implementation of solutions to these problems, with the primary ones described in the following:

- *Processor and store synchronicity.* Solutions to synchronization problems that are processor synchronous require that processors can be made uninterruptable. These solutions work for uniprocessor

machines but not for multiprocessors where disabling the interrupts on one processor does not affect another. Solutions to synchronization problems that are store synchronous, which assumes individual references to main memory are atomic, are applicable to both uni- and multiprocessor machines.

- *Busy waiting.* Another issue in synchronization solutions is the consumption of CPU resources while a process is waiting for a condition to occur. Some solutions require **busy waiting**, the continued polling of a condition variable. These solutions are less efficient, particularly on a uniprocessor where busy waiting continues until the time slice of the waiting process is complete.
- *Programmer errors.* Another issue is the potential programming errors inherent in using a particular synchronization approach. Ordering of synchronization primitives is necessary for correct solutions with some primitives. Other primitives for synchronization have been specifically designed to minimize the possibility of such a programmer error.
- *Starvation.* It is possible for synchronization solutions to lead to the condition of **starvation**. Starvation occurs when a process is indefinitely denied access to a resource while other processes are granted access to the resource. Starvation is an issue in mutual exclusion if it is possible for one process to be indefinitely denied access to its critical region while access is granted to other processes.
- *Deadlock.* Another fundamental problem confronted by solutions is **deadlock**. Deadlock is the condition when a set of processes using shared resources or communicating with each other are permanently blocked. Coffman et al. [1971] describe three necessary, but not sufficient, conditions that must exist for deadlock to occur among a set of processes sharing resources:
 1. *Mutual exclusion.* A resource may be used by only one process at a time.
 2. *Hold and wait.* Processes holding resources can request new resources.
 3. *No preemption.* A resource given to a process cannot be taken back. For deadlock to actually take place, a fourth condition must also exist:
 4. *Circular wait.* A set of processes are in a circular wait; that is, there is a set of processes $\{p_0, p_1, \dots, p_n\}$ where p_i is waiting for a resource held by p_{i+1} , and p_n is waiting for a resource held by p_0 .

When combined with the three necessary conditions, the presence of the circular wait condition indicates that a deadlock has occurred and that no means exists for breaking the deadlock. When designing solutions to synchronization problems such as mutual exclusion, preventing deadlock involves disallowing one or more of the preceding conditions. Specific solutions to the deadlock problem are given in [Section 84.3](#).

84.2.3 Interprocess Communication Problems

Interprocess communication problems generally involve direct communication between two or more processes, in contrast to synchronization where processes communicate indirectly by waiting on or setting a condition. Thus, communication is indirect between the processes when using synchronization, whereas IPC mechanisms generally communicate by passing messages directly between processes. The primitives for handling messages are

- **send(pid, &message)**
- **pid = receive(&message)**

where **send()** sends the given message to a specific destination process and **receive()** receives the last message sent to it returning the process identifier (pid) of the sender.

Message passing is commonly used in operating systems and user applications for communicating between processes. In a message-based operating system where server processes perform many of the

```

int serverpid;          /* well-known pid of the server */
Server()                /* server process code */
{
    int pid;            /* process id of the requesting process */
    Message request_msg, reply_msg;

    while (TRUE) {
        pid = receive(&request_msg);          /* receive message */
        /* handle request and build reply message */
        send(pid, &reply_msg);                /* send the reply */
    }
}

int ServiceRequest(args) /* service request function with arguments */
{
    Message request_msg, reply_msg;

    /* load args into request_msg */
    send(serverpid, &request_msg);
    (void)receive(&reply_msg);
    return(reply_msg.status);
}

```

FIGURE 84.4 Service request for a message-based operating system.

functions associated with an operating system, message passing is used to pass requests to the appropriate server and to receive replies, as is shown in the example of Figure 84.4.

84.2.4 Interprocess Communication Issues

As described in the previous example, IPC mechanisms typically involve the exchange of messages from one process to another. There are a number of issues concerning the implementation of a message passing mechanism, with the primary ones described in the following. Implementations of IPC mechanisms that address these issues are described in [Section 84.3](#).

- *Direct vs. indirect communication.* A key issue in a message passing system is how messages are addressed to their recipient. In a direct message passing scheme, the delivery address is a process id. This approach was illustrated in [Figure 84.4](#). In an indirect scheme, the address is an intermediate repository, such as a mailbox or port, that is a drop-off point for the message for later pick-up by the recipient.
- *Buffering of data.* Another issue is whether the message passing mechanism allows messages to be buffered if the receiving process is currently not ready to receive a message. If buffering is allowed, then another issue is the size of this buffer.
- *Blocking vs. nonblocking operations.* Related to the issue of buffering is the semantics of the **send()** operation when the message cannot be delivered. The operation can either block until the message can be delivered or the operation can immediately return with an error if blocking would occur. Similarly, the **receive()** operation can be defined to either block and wait for message delivery if no message is available or not block and return an error.
- *Fixed- or variable-size messages.* Fixed-size messages allow for easier implementation but may require more work for the programmer. In contrast, variable-size messages are easier to program but require more work to implement.

- *Synchronous vs. asynchronous reception.* Message passing mechanisms allow more process control if messages are received only when the **receive()** operation is invoked. However, some mechanisms allow for communication to be received when it arrives through an asynchronous approach using message handlers.

84.3 Best Practices

This section discusses specific solutions for synchronization and IPC. Each solution contains an example of its use, its relative merits, and problems for which it is useful. More examples of synchronization mechanisms can be found in operating system texts [Silberschatz et al. 2002, Tanenbaum 2001, Stallings 2000, Flynn and McHoes 1997, Finkel 1988]. Comer [1984] and Tanenbaum [1987] present code for actual operating systems to show how synchronization and IPC mechanisms can be implemented. More concurrent programming examples can be found in Ben-Ari [1982, 1990], Raynal [1986], and Brinch Hansen [1973]. Andrews and Schneider [1983] provide a survey of synchronization and IPC techniques. The chapter concludes with more classic synchronization problems and specific solutions to the deadlock problem.

84.3.1 Synchronization Mechanisms

The mechanisms for synchronization are divided into four types based on their level of implementation and support: software only, hardware support, operating system support, and language support. In addition, hybrid solutions exist that combine more than one of these approaches. Each approach shows a solution to the mutual exclusion problem along with other applicable synchronization problems and discusses the relevant synchronization issues.

84.3.1.1 Software Solutions

Software-based synchronization solutions require only that multiple processes can access shared global variables. The solutions use these variables to control access to the critical region. Dekker was the first to devise a software solution that correctly handles the mutual exclusion problem among a set of processes. A discussion of this solution is given in Dijkstra [1965]. Peterson [1981] provided a simpler solution of the same problem, which is given in [Figure 84.5](#) for two processes in terms of the **BeginRegion()** and **EndRegion()** routines.

This solution works correctly on any hardware (uni- or multiprocessor) in which references to main memory are atomic. The main disadvantage is that it requires busy waiting, continued polling of a status variable, before gaining access to the critical region if another process is already in the critical region. The solution can generalize to more processes, but better solutions are available.

84.3.1.2 Solutions Using Hardware Support

Not all problems of synchronization, particularly ones in the operating system itself, can be handled solely with software-based solutions. As in other aspects of computing, hardware support can not only make the task easier but is also necessary for some levels of synchronization within the operating system.

One of the simplest ways to enforce mutual exclusion is to disable hardware interrupts at the start of the critical region, thus ensuring that the process does not give up the CPU (through a context switch) before completing the critical region. When the critical region is done, the process re-enables interrupts. The **BeginRegion()** and **EndRegion()** routines with this approach are shown in [Figure 84.6](#).

This approach is fast and is used for manipulation of shared operating system data structures on a uniprocessor but in general has many disadvantages for general-purpose use:

- Programmers must be careful not to disable interrupts for too long; devices that raise interrupts need to be serviced.
- The programmer must be careful about nesting. Activities that disable interrupts must restore them to their previous settings. In particular, if interrupts are already disabled before entering a critical

```

int turn;                                /* whose turn is it? */
int flag[2];                             /* want the mutex? Initially FALSE */

BeginRegion(int pid)                     /* pid is 0 or 1 */
{
    int other;                            /* pid of other process */

    other = 1 - pid;                      /* the opposite of pid */
    flag[pid] = TRUE;                     /* express interest in mutex */
    turn = pid;                            /* set flag */
    while ((turn == pid) && (flag[other] == TRUE))
        ;                                 /* busy wait */
}

EndRegion(int pid)
{
    flag[pid] = FALSE;                    /* drop interest in mutex */
}

```

FIGURE 84.5 Peterson's solution of mutual exclusion for two processes. Based on statements of the algorithm in Tanenbaum [2001].

```

BeginRegion()
{
    DisableInterrupts();
}

EndRegion()
{
    EnableInterrupts();
}

```

FIGURE 84.6 Mutual exclusion by disabling/enabling hardware interrupts.

region, they must remain disabled after leaving the critical region. Code in one critical region may call a routine that executes a different critical region.

- Disabling interrupts prevents all other activities, even though many may never execute the same critical region. Disabling interrupts is like using a sledge hammer; it is a powerful tool but bigger than is needed for most jobs.
- The technique is ineffective on multiprocessor architectures, where disabling interrupts on one processor still allows other processes to run on other processors.

Rather than perform mutual exclusion by controlling interrupts, a common approach is to use special instructions provided by the hardware to implement mutual exclusion. One such instruction is **Test.and.Set**, which is functionally defined by the procedure of [Figure 84.7](#). It returns the previous value of a target variable and sets the target to the given value. Most importantly, this instruction is performed in an atomic manner so a context switch cannot occur in the middle of it. In addition, operations performed on two separate processors of a multiprocessor are guaranteed to occur in sequential order because of store synchronicity. [Figure 84.7](#) shows how the **BeginRegion()** and **EndRegion()** primitives are implemented using this instruction. The variable **mutex** is also referred to as a lock variable, and this approach to mutual exclusion is called a **spin lock** because a process spins in an infinite loop waiting for the lock. When the **mutex** variable is set to **FALSE** by a process exiting from its critical region, another process is allowed to gain access to its critical region.

```

int mutex = FALSE;                               /* global variable for mutex */
int Test_and_Set(int *pVar, int value) /* atomic machine instruction */
{
    int temp;
    temp = *pVar;
    *pVar = value;
    return(temp);
}
BeginRegion()      /* Loop until safe to enter */
{
    while (Test_and_Set(&mutex, TRUE)) ;
        ; /* Loop until return value is FALSE */
}
EndRegion()
{
    mutex = FALSE;
}

```

FIGURE 84.7 Mutual exclusion using the test-and-set machine instruction.

Solutions using other machine instructions are also available. Another common instruction is **EXCH**, which swaps the contents of two memory locations in an atomic fashion. This instruction also can be used to implement mutual exclusion. The advantages of these machine-instruction approaches are their simplicity and the fact they work for any number of processes in either a uni- or a multiprocessor environment. Through the use of more than one mutex variable, multiple critical regions can be easily created.

The primary disadvantage of this approach is its use of busy waiting, thus wasting CPU resources. The use of busy waiting also allows for process starvation if multiple processes are contending for a critical region. Finally, deadlock is possible on a uniprocessor machine if a lower priority process gets interrupted in the middle of its critical region and then a higher priority process tries to gain access to the same critical region. The higher priority process busy waits forever because the lower priority process never runs.

84.3.1.3 Operating System Support

All of the synchronization approaches shown thus far can be implemented with the bare features of the hardware. The approaches also cause busy waiting if another process already is in its critical region. **Semaphores**, an important synchronization primitive, can be constructed by adding process coordination support to the operating system. Semaphores are data structures consisting of an identifier, a counter, and a queue; where processes waiting on a semaphore are blocked and placed on the queue, processes signaling a semaphore may unblock and remove a process from the queue, and the counter maintains a count of waiting processes.

The concept of a semaphore was first introduced by Dijkstra [1968]. Dijkstra defined two atomic semaphore operations: wait and signal, which he termed the P-operation (for wait; from the Dutch word *proberen*, to test) and the V-operation (for signal; from the Dutch word *verhogen*, to increment).

A restricted version of a semaphore, called a *binary semaphore*, limits the value of the counter to 0 and 1. However, the more general case is to use a *counting semaphore*, which has the following properties concerning the counter:

- A nonnegative count always means that the queue is empty.
- A count of negative **n** indicates that the queue contains **n** waiting processes.
- A count of positive **n** indicates that **n** resources are available and **n** requests can be granted without delay.

```

int semid;

Initialization()
{
semid = semcreate(1);    /* initialize the semaphore count to 1 */
}

BeginRegion()
{
    semwait(semid);
}

EndRegion()
{
    semsignal(semid);
}

```

FIGURE 84.8 Mutual exclusion using semaphores.

There are four basic operations defined for creating, deleting, waiting on, and signaling a semaphore:

1. **semid = semcreate(val)**: create a semaphore with the given initial value for the counter.
2. **semdelete(semid)**: Delete a semaphore.
3. **semwait(semid)**: wait on a semaphore. Decrement the semaphore counter. If the counter is negative, then suspend execution of the process and place it in the semaphore queue.
4. **semsignal(semid)**: signal a semaphore. Increment the semaphore counter. Make the first process in the semaphore queue ready for execution.

Given these operations, a simple solution to the mutual exclusion problem is shown in Figure 84.8. Unlike previous solutions, a process waiting for its critical region does not busy wait. While it is waiting, it is in a suspended state, allowing the CPU to perform other activities. Because semaphores are provided by the operating system, they work correctly on either uni- or multiprocessor machines.

Semaphores also provide a mechanism to solve the bounded-buffer producer/consumer problem, which was introduced in the example of Figure 84.2. A solution for this problem using semaphores is shown in Figure 84.9. This solution ensures that the consumer process prints all integer values from 1 to 2000 by alternating between the producer and consumer.

Although semaphores provide straightforward solutions to both of these problems, semaphores themselves must be implemented in the operating system with lower level primitives such as the **Test.and.Set** machine instruction. Semaphores work well for processes, that are allowed to block, but must not be used in code that cannot block, such as interrupt service routines.

84.3.1.4 Language Constructs

The solutions presented thus far to the mutual exclusion problem each require the programmer to take explicit action to ensure mutual exclusion. To guarantee mutual exclusion, some programming languages provide constructs to implicitly guarantee mutual exclusion. One such construct is a **monitor** [Hoare 1974], which permits only one process to be executing in a monitor at a time.

Monitors are a programming language construct, similar to abstract data types in that the programmer defines a set of data types and procedures that can manipulate the data, procedures can be exported to other modules, and the system invokes an initialization routine before execution begins. Monitors differ in that they support guard procedures. When a process invokes a guard procedure, its execution is delayed until no other processes are executing a guard procedure within the monitor. The Java programming language

```

int psem, csem; /* semaphores */
int n = 0;      /* shared by all processes */
main()
{
    int producer(), consumer();
    csem = semcreate(0); /* consumer initially blocks */
    psem = semcreate(1); /* producer initially allowed to run */
    CreateProcess(producer);
    CreateProcess(consumer);
    /* wait until done */
}
producer()
{
    int i;
    for (i=0; i<2000; i++) {
        wait(psem);
        n++; /* increment n by 1 */
        signal(csem);
    }
}
consumer()
{
    int i;
    for (i=0; i<2000; i++) {
        wait(csem);
        printf("n is %d\n", n); /* print value of n */
        signal(psem);
    }
}

```

FIGURE 84.9 Bounded-buffer producer/consumer problem with semaphores.

supports monitors using the **synchronized** primitive on methods within a class to prevent threads from simultaneously access of these methods [Arnold and Gosling 1998]. [Figure 84.10](#) revisits the mutual exclusion problem of [Figure 84.1](#) using a solution written in Java. The definition of a monitor guarantees that the variable **balance** is not updated and read simultaneously.

Monitors are a programming language construct that must be implemented using a lower level facility provided by the hardware or operating system, such as semaphores. Although monitors provide mutual exclusion, they need additional primitives to provide synchronization. To do so, monitors are defined to have condition variables, which are waited on and signaled similar to semaphores. Java provides a single, unnamed condition for a class with the **wait()** method used by a thread to wait on the condition and the **notify()** or **notifyAll()** methods to wake up one or all waiting threads. These primitives allow other synchronization problems such as the producer/consumer problem to be implemented with monitors.

84.3.1.5 Hybrid Solutions

Modern operating systems have migrated from monolithic systems written for a uniprocessor in which critical regions were used to access shared data structures. These critical regions were guarded by setting the interrupt level appropriately. Current operating systems must not only support multiprocessors but also provide real-time capabilities, thus leading to multithreaded designs. In these designs, the use of interrupts to control access to shared data does not work. Rather, these systems have moved to solutions using complex locks, which combine the use of spin locks with the semantics of semaphores.

```

public class Account {
    private int balance;

    public Account() {
        balance = 0;           // initialize balance to zero
    }

    // use synchronized to prohibit concurrent access of balance
    public synchronized void Deposit(int deposit) {
        int newbalance; // local variable

        newbalance = balance + deposit;
        balance = newbalance;
    }

    public synchronized int GetBalance() {
        return balance;       // return current balance
    }
}

```

FIGURE 84.10 Mutual exclusion using monitors.

As one example, the Solaris 2 operating system [Eykholt et al. 1992] uses adaptive mutex locks, a type of complex lock, to protect access to shared data among a set of threads. The adaptive lock starts out executing like a standard spin lock. If the lock is currently free, then the issuing thread immediately obtains the lock. However, if the lock is in use, then the operating system checks the status of the thread holding the lock. If this thread is currently in the run state (as could be the case on a multiprocessor), then the issuing thread continues in a spin lock waiting for what is expected to be a short time for the lock to be released. If the holding thread is not in the run state (as would always be the case on a uniprocessor), then the issuing thread is suspended until the lock is released. The rationale is to use a spin lock if the wait for the lock is expected to be short and to actually suspend the thread if the wait is expected to be longer.

This hybrid approach tries to minimize overhead and maximize performance. If the size of a critical region is large (hundreds of instructions), then the adaptive mutex lock is less desirable compared to a lock that simply causes a thread to suspend when the lock is not available.

Another type of complex lock used in multithreaded operating systems is a read/write lock. These locks allow either a single writer or multiple readers to simultaneously hold the lock, thus increasing the parallelism when reading of a shared data structure predominates. Writers must wait until all readers have released the lock before obtaining the lock, whereas readers are granted immediate access to the lock in the absence of a writer. To prevent starvation of a writer, all read requests after a write request has been issued are queued until the write request has been satisfied. Starvation of readers in the face of multiple writers is similarly avoided.

84.3.1.6 Other Solutions

Many other synchronization primitives have been proposed but, in general, can be expressed in terms of the solutions already given. A sampling of these primitives are critical regions [Hoare 1972, Brinch Hansen 1972], serializers [Atkinson and Hewitt 1979], path expressions [Campbell and Habermann 1974], and event counts and sequencers [Reed and Kanodia 1979].

84.3.2 Interprocess Communication (IPC) Mechanisms

As with synchronization, a variety of IPC mechanisms are available. The following discusses a number of these mechanisms and how they handle the IPC issues raised in [Section 84.2](#).

84.3.2.1 Direct Message Passing

The simplest form of message passing is to send messages directly from one process to another. An example of this approach is the low-level message passing facility used in the Xinu operating system [Comer 1984]. The primitive operations used are:

- **send(pid, msg)**
- **msg = receive()**

where **send()** sends a fixed, integer-size message to a specific process and **receive()** returns the last message sent to it. A process can buffer only one message. If **send()** detects a message already buffered at the process, then it returns immediately with an error, not delivering the message. If no message is buffered, then **send()** buffers the message and readies the receiving process if it is waiting for a message. The **receive()** operation blocks if a message is not available.

Another direct message passing mechanism is implemented in Minix [Tanenbaum 1987]. The primitives for handling messages are:

- **send(destpid, &message)**
- **receive(srcpid, &message)**

where **send()** sends the given message to a specific destination process and **receive()** receives a message from a particular process. The source process for **receive()** can contain a wildcard value of **ANY**, indicating that messages from any process are accepted. Messages are a fixed size, but there is no buffering. Rather, the **send()** and **receive()** operations *rendezvous* so that both operations block until the receiving process has actually copied the message from the sender. The use of rendezvous explicitly synchronizes the execution of the sending and receiving process.

84.3.2.2 Mailboxes/Ports

Rather than send directly to process, a more common approach is to define another operating system abstraction called a **mailbox** (also referred to as a port). Mailboxes are buffers that hold messages sent by one process to be received by another process. Thus, there is indirect communication between the two processes. The primitives for handling messages are:

- **send(mailbox, &message)**
- **receive(mailbox, &message)**

where **send()** buffers the message in the given mailbox and **receive()** removes a message from the mailbox.

As an example, the Unix operating system provides ports to allow for intra- and inter-machine communication between processes. Ports often represent well-known services where a server process binds to a port and client processes of the service send requests to the port. The port buffers communication sent to the buffer until it is read by the receiving process. The messages sent to the port can be of variable size.

Message passing can also be implemented using shared memory and semaphores, illustrating the equivalence of synchronization and IPC primitives. [Figure 84.11](#) shows message passing with shared memory and semaphores to implement a set of mailboxes. The mechanism uses fixed-size messages with each of four mailboxes containing eight message buffers. The **send()** operation blocks if there is no buffer space in the mailbox; similarly, the **receive()** operation blocks if there is no message available in the mailbox. The mutex semaphore is needed to guarantee that no more than one process tries to send to or receive from a mailbox at the same time. This semaphore would not be needed if only one process could send to and receive from a mailbox. The mutex semaphore would also not be needed if a mailbox contained only one buffer

```

#define N 8                /* number of msgs buffered in a mailbox */
#define M 4                /* number of mailboxes */

Message mailboxes[M][N]; /* shared memory for mailboxes of
                           messages */

int semidMsg[M];          /* message available */
int semidSlot[M];        /* slot available */
int semidMutex[M];       /* controls access to critical region */

Initialization()
{
    int i;

    for (i = 0; i < M; i++) {
        semidMsg[i] = semcreate(0); /* no messages are available */
        semidSlot[i] = semcreate(N); /* N slots are available
                                       for messages */
        semidMutex[i] = semcreate(1); /* one process can enter
                                       region */
        /* initialize indices for inserting/deleting in
        mailboxes[i] */
    }
}

send(int m, Message *pmsg) /* send message to mailbox m */
{
    semwait(semidSlot[m]); /* is a slot available */
    semwait(semidMutex[m]); /* enter critical region */
    addmessage(m, pmsg); /* add msg to circular
                          queue for mailbox m */
    semsignal(semidMutex[m]); /* exit critical region */
    semsignal(semidMsg[m]); /* signal message available */
}

receive(int m, Message *pmsg) /* retrieve message from
                               mailbox m */
{
    semwait(semidMsg[m]); /* is a message available */
    semwait(semidMutex[m]); /* enter critical region */
    removemessage(m, pmsg); /* remove next msg from queue for
                              mailbox m */
    semsignal(semidMutex[m]); /* exit critical region */
    semsignal(semidSlot[m]); /* signal slot available */
}

```

FIGURE 84.11 Message passing with semaphores and shared memory.

```

#define DATA "hello world"
#define BUFFSIZE 1024

int rgfd[2];          /* file descriptors of pipe ends */

main()
{
    char sbBuf[BUFFSIZE];

    pipe(rgfd);       /* create a pipe returning two file descriptors */
    if (fork()) {     /* parent, read data from pipe */
        close(rgfd[1]); /* close write end */
        read(rgfd[0], sbBuf, BUFFSIZE);
        printf("Pipe contents: %s\n", sbBuf);
        close(rgfd[0]);
    }
    else {            /* child, write data to pipe */
        close(rgfd[0]); /* close read end */
        write(rgfd[1], DATA, sizeof(DATA)); /* write data to pipe */
        close(rgfd[1]);
        exit(0);
    }
}

```

FIGURE 84.12 Pipe example in the Unix operating system.

slot. This is also an example of a bounded-buffer producer/consumer problem where sending processes produce messages and receiving processes consume them.

84.3.2.3 Pipes

A special case of IPC is the pipe abstraction available in the Unix operating system. A *pipe* is a unidirectional, stream communication abstraction. One process writes data to the write end of the pipe, and a second process reads data from the read end of the pipe. The pipe itself is a buffer between the two processes that causes the reader to block if no data is available and the writer to block if the buffer is full. As it implements a stream abstraction, there is no notion of fixed-size messages. A pipe is another example of a solution to the bounded-buffer producer/consumer problem where the writing process is a producer and the reading process is a consumer.

Figure 84.12 shows a simple example of the use of pipes in the UNIX operating system. Pipes are typically requested and set up by a UNIX command interpreter, but the example shows one process creating another process with **fork()** with a pipe between them. A string of characters is then written to and read from the pipe.

84.3.2.4 Software Interrupts

Software interrupts are a primitive form of IPC. They are similar to hardware interrupts in that when an interrupt of a process occurs, an interrupt handler routine corresponding to the type of interrupt is invoked. Interrupts are asynchronous; so when an interrupt is received, execution of the process stops and is restarted after the interrupt handling routine has been executed. Software interrupts are sent to a process using the process id of the process. Many interrupts are used for well-known functions, such as when the user types the interrupt key, a child process completes, or an alarm scheduled by the process has expired.

```

#include <signal.h>

int n;

main(int argc, char **argv)
{
    void InterruptHandler(), InitHandler();

    n = 0;

    signal(SIGINT, InterruptHandler); /* signal 2 */
    signal(SIGHUP, InitHandler);     /* signal 1 */
    while (1) {
        n++;
        sleep(1);                     /* sleep for one second */
    }
}

void InterruptHandler()
{
    printf("The current value of n is %d\n", n);
    exit(0);
}

void InitHandler()
{
    printf("Resetting the value of n to zero\n");
    n = 0;
}

% cc -o signalex signalex.c
% signalex
^C          (interrupt character)
The current value of n is 3
% signalex &
[1] 20822
% kill -1 20822
Resetting the value of n to zero
% kill -2 20822
The current value of n is 19
[1] Done          signalex

```

FIGURE 84.13 Software interrupt program and script in the Unix operating system.

Two routines are used to send and handle software interrupts:

1. **SendInterrupt(pid, num)**: an interrupt of type **num** is sent to process **pid**. In the Unix operating system this routine is **kill()**.
2. **HandleInterrupt(num, handler)**: this specifies that user supplied **handler** routine should be invoked when interrupt of type **num** occurs. Typical handlers are to ignore the interrupt, terminate the process, or execute a user-supplied interrupt handler. In the Unix operating system, this routine is **signal()**.

Figure 84.13 shows a sample program for the UNIX operating system with software interrupts. It sets up two interrupt handlers for signals 1 and 2 and then goes into an infinite loop where it updates a counter

and sleeps for 1 s. [Figure 84.13](#) also shows a command line script with this program. Invoking the interrupt character from the command interpreter causes interrupt 2 to be sent to the process. The second invocation of the program causes it to be run in the background with a process id of 20822. The **kill** program is then used to send interrupts to the background process.

84.3.3 Classic Problems

Two classic synchronization problems — the critical region and bounded-buffer producer/consumer — have already been discussed. A slight variation of the producer/consumer problem is to use an unbounded buffer, in which case the producer never blocks because the buffer never fills. Many other classic synchronization problems have been proposed and solved. The following describes two such problems.

84.3.3.1 Readers/Writers Problem

The readers/writers problem occurs when multiple readers and writers want access to a shared object such as a database. The problem was introduced in Courtois et al. [1971]. In the problem, multiple readers are allowed to access the database simultaneously, but a writer must have exclusive access to the database before performing any updates for consistency. A practical example of this problem is an airline reservation system with many readers and an occasional update of the information.

[Figure 84.14](#) shows a solution to this problem for multiple reader and writer processes with semaphores. The solution allows multiple readers access to the database at a time. A writer process can gain access only after all reader processes have relinquished the database. The solution gives priority to reader processes, who can gain access to the database even if a writer process is already requesting access to the database. Solutions giving more balanced priority to each type of process can also be constructed, as discussed in Flynn and McHoes [1997].

84.3.3.2 Dining Philosophers Problem

The dining philosophers problem was proposed and solved by Dijkstra [1971]. It consists of five philosophers sitting at a round table. The philosophers each have a bowl of rice in front of them and there is a chopstick in between each bowl (alternately, the problem is described using plates of spaghetti and forks). The problem is illustrated in [Figure 84.15](#) with the philosophers' bowls labeled A through E and the chopsticks 1 through 5. These philosophers have two functions in life: (1) *think*, requiring no interaction with colleagues, and (2) *eat*, requiring the philosopher to pick up the chopstick on the left and right.

This classic synchronization problem has potential for both deadlock and starvation (literally!). The straightforward solution for a philosopher to eat is to first pick up the left chopstick and then the right chopstick. However, if all philosophers pick up their left chopstick at the same time, they will all deadlock when they go to pick up their right chopstick. A simple modification to this approach is for the philosophers to put down the left chopstick if the right chopstick is not available, wait for some time, and try again. However, there is still a chance that the philosophers will operate in lock step and no philosophers will acquire both chopsticks. This condition is called **livelock** and occurs when attempts by two or more processes (philosophers) to acquire a resource (the left and right chopsticks) run indefinitely without any process succeeding. The dining philosophers problem will be used as a guide in the following discussion on deadlock and starvation.

84.3.4 Deadlock and Starvation

Deadlock occurs when a set of processes using shared resources are permanently blocked trying to gain access to those resources. Classic papers on this topic are Coffman et al. [1971] and Holt [1972]. Zobel and Koch [1988] contains a more up-to-date annotated bibliography on the subject. Deadlock can occur with synchronization such as when two processes each need to gain access to two separate critical regions for execution. If one process gains access to the first critical region and the other process gains access to

```

int readercount = 0;    /* number of readers currently reading */
int readermutex;      /* semaphore mutex for reader count */
int dbaccess;         /* semaphore to control access to database */

main()
{
    readermutex = semcreate(1); /* mutex for reader count */
    dbaccess = semcreate(1);   /* mutex for database */
    CreateProcess(reader);     /* create a reader process */
    CreateProcess(writer);     /* create a writer process */
}

reader()
{
    while (TRUE) {
        semwait(readermutex); /* get access to readercount */
        readercount++;        /* increment count */
        if (readercount == 1) /* if first reader ... */
            semwait(dbaccess); /* gain access to database */
        semsignal(readermutex); /* done with count */
        /* read database */
        semwait(readermutex); /* get access to readercount */
        readercount--;        /* decrement count */
        if (readercount == 0) /* if last reader ... */
            semsignal(dbaccess); /* relinquish access to database */
        semsignal(readermutex); /* done with count */
        /* use data read */
    }
}

writer()
{
    while (TRUE) {
        /* generate new data */
        semwait(dbaccess); /* gain access to database */
        /* update database */
        semsignal(dbaccess); /* relinquish access to database */
    }
}

```

FIGURE 84.14 Solution to the readers/writers problem using semaphores.

the second critical region, then these two processes will be in deadlock when they attempt to acquire the other needed critical region.

There are four principles used for dealing with the issue of deadlock in operating systems. These principles are prevention, detection, avoidance, and recovery and are summarized in Isloor and Marsland [1980]. Solutions to the deadlock problem exemplifying these principles are described in the following. Each of these solutions prevents deadlock by precluding one or more of the four conditions for deadlock given in [Section 84.2](#). The solutions are characterized as being conservative or liberal, depending on the degree of concurrency they allow.

The most liberal solution is to allocate requested resources to processes if the resources are available. This approach was given as an initial solution when introducing the dining philosophers problem. As was shown,

FIGURE 84.15 Illustration of the dining philosophers problem.

it can lead to deadlock and requires that a deadlock detection process be periodically invoked. Deadlock detection involves detecting the circular wait condition through any algorithm for detecting cycles in directed graphs. Once deadlock occurs, a deadlock recovery method must be invoked, either to take away resources from a victim process or to terminate the process altogether. In the dining philosophers problem, a recovery method would be to take away a chopstick from one of the philosophers.

At the other extreme, the most conservative deadlock prevention solution is *serialization*. This deadlock prevention approach guarantees no deadlock by allowing only one process to acquire resources at a time. In the dining philosophers problem, this approach means that only one philosopher is allowed to eat at any time. The approach prevents any concurrency and can lead to starvation if a philosopher is constantly passed over in obtaining chopsticks.

Another solution that allows more concurrency but still prevents deadlock is *one-shot allocation*. This approach requires that a process obtain all of its resources at once. Using this approach, a dining philosopher must obtain both chopsticks at the same time. It avoids deadlock by preventing the hold and wait condition. This solution prevents deadlock but not starvation. It also requires that a process obtain all of its resources at the same time, even if it does not currently need all of them.

A still more liberal solution that prevents deadlock is *hierarchical allocation*. This solution requires that all resources have a number associated with them as in Figure 84.15. Hierarchical allocation prevents deadlock by requiring that processes can acquire only resources with a higher number than any resource it currently holds. Thus, in Figure 84.15, each philosopher must first acquire the left chopstick and then the right except for Philosopher E, who must first acquire the right chopstick. This solution is still conservative and requires processes to acquire resources not necessarily in the order they are needed but in the order resources are numbered. It avoids deadlock by preventing the circular wait condition.

As opposed to deadlock prevention, deadlock avoidance policies do not prevent deadlock *a priori*, but monitor the allocation requests as they are made so as not to allow deadlock to occur. A solution using this approach is the *bankers algorithm* (also called the advanced claim algorithm) introduced in Dijkstra [1968]. This solution is the most liberal that avoids deadlock but requires that each process know the maximum number from a class of resources that it may request at any time during execution. The algorithm performs as a banker, giving out loans of money in that any resource requests are granted only if they:

1. Do not exceed the total number of resources in a class
2. Do not exceed the maximum number of resources for that process
3. Lead to a *safe state* where a sequence of resource deallocations and allocations can allow all processes to complete without deadlock

84.4 Research Issues and Summary

The research issues in synchronization and IPC correspond to the movement toward multithreaded, message-based operating systems running in a multiprocessor environment. The adoption of traditional synchronization primitives for this environment and the exploration of better primitives are leading to work on hybrid approaches for synchronization. This work is also extending to distributed environments.

Research continues on extending synchronization primitives and defining new problems. Recent work has examined the semantics of strong and weak semaphores as well as extending semaphores to define tagged semaphores. The group mutual exclusion problem, a generalization of the mutual exclusion and readers/writers problems, has been recently posed with different solutions under investigation.

The issue of performance is a key area as researchers seek to minimize the cost of busy waiting in shared memory multiprocessors by using virtual memory to reduce memory access costs. Other research is investigating optimal trade-off between the use of busy waiting for a lock vs. suspending the thread or process. Performance is also a research issue for IPC mechanisms in client/server systems as they execute in intra- and inter-machine environments.

An ongoing research issue is correctness, particularly as the synchronization problems of modern operating systems become more complex. Using language constructs to better encapsulate the synchronization details is being explored, but this approach can lead to trade-offs with performance. Tools for detecting synchronization errors are also an ongoing area of research.

In summary, synchronization and IPC are fundamental to multiprogrammed operating system design. Many primitives to solve fundamental problems such as mutual exclusion and producer/consumer exist, ranging from software-only approaches to special hardware instructions, to primitives constructed by the operating system and programming languages. Many of the primitives are equivalent in terms of their semantics, and one can be implemented in terms of another. Examples include implementing monitors with semaphores or message passing with shared memory and semaphores. Modern operating systems are using hybrid approaches, which adaptively switch between techniques according to the runtime operating environment.

Defining Terms

Busy waiting: Situation in synchronization when a process continuously polls the status of a condition variable.

Critical region: Set of instructions for a process that access data shared with other processes. Only one process may execute its critical region at a time.

Deadlock: Condition when a set of processes using shared resources or communicating with each other are permanently blocked.

Interprocess communication (IPC): Communication between two (or more) processes directly aware of each other.

Livelock: Condition when attempts by two or more processes to acquire a resource run indefinitely without any process succeeding.

Mailbox: An operating system abstraction containing buffers to hold messages. Messages are sent to and received from the mailbox by processes.

Monitor: Programming language construct providing abstract data types and mutually exclusive access to a set of guard procedures.

Mutual exclusion: A synchronization problem requiring that two or more concurrent activities do not simultaneously access a shared resource.

Race condition: Situation where multiple processes access and manipulate shared data with the outcome dependent on the relative timing of these processes.

Semaphore: Synchronization primitive consisting of an identifier, a counter, and a queue where processes waiting on a semaphore are blocked and placed on the queue; processes signaling a semaphore may unblock and remove a process from the queue, and the counter maintains a count of waiting processes.

Spin lock: Mutual exclusion mechanism where a process spins in an infinite loop waiting for the value of a lock variable to indicate availability.

Starvation: Condition when a process is indefinitely denied access to a resource while other processes are granted access to the resource.

Synchronization: Situation when two or more processes coordinate their activities based upon a condition.

Further Information

Many good textbooks on operating systems, such as those by Silberschatz et al. [2002], Tanenbaum [2001], and Stallings [2000] exist, which describe problems, issues, and solutions for synchronization and IPC. The book *Principles of Concurrent and Distributed Programming* by M. Ben-Ari [1990] contains a number of problems and worked-out solutions for both concurrent and distributed programming. *Algorithms for Mutual Exclusion* by M. Raynal [1986] presents a comprehensive treatment of solutions for the mutual exclusion problem. “Concepts and Notations for Concurrent Programming” by Andrews and Schneider [1983] provides a survey of processes, synchronization, and interprocess communication.

The Association for Computing Machinery (ACM) Special Interest Group on Operating Systems (SIGOPS) publishes *Operating Systems Review* four times a year. This publication contains work on a variety of operating system topics, including synchronization. This group also sponsors the biennial ACM Symposium on Operating Systems Principles that covers the latest developments in the field of operating systems. Its proceedings are published in an issue of *Operating Systems Review*. Another ACM publication, the *ACM Transactions on Computer Systems* is good source for relevant work.

The USENIX Association sponsors a number of conferences on operating system-related topics. A general technical conference is sponsored each year. Two conferences, the Symposium on Operating Systems Design and Implementation (OSDI) and Workshop on Hot Topics in Operating Systems (HOTOS), are specific to operating system issues.

85.1 Introduction

Virtual memory, since the 1960s a standard feature of nearly every operating system and computer chip, is now invading the Internet through the **World Wide Web (WWW)**. Once the subject of intense controversy, it is now so ordinary that few people think much about it. That this has happened is one of the engineering triumphs of the computer age.

Virtual memory is the simulation of a storage space so large that software programmers and document authors do not need to rewrite their works when the internal structure of a program module, the capacity of a local memory, or the configuration of a network changes. The name, borrowed from optics, recalls the virtual images formed in mirrors and lenses: objects that are not there but behave as if they are. The story of virtual memory, from the Atlas Computer at the University of Manchester in the 1950s to the multicomputers and World Wide Web of the 2000s, is not simply a story of progress in automatic storage allocation; it is a fascinating story of machines helping programmers to protect information, reuse and share objects, and link software components.

Virtual memory is the first instance of caching, which is one of the great principles of information technology. Caching says that a computer will perform better if the most-used data is held in fast storage close to the processor and the least-used data is held in slow storage more distant from the processor. Caching works because all computations exhibit **locality**, a strong tendency to cluster references to subsets of address space within extended time intervals. Locality is a manifestation of how the human mind organizes to solve problems.

85.2 History

From their beginnings in the 1940s, electronic computers had two-level storage systems. The **main memory** was then magnetic cores and is now random access memories (**RAMs**); the secondary memory was then magnetic drums and is now disks and an array of other media including tapes, CDs, and remote servers in the Internet. The processor [central processing unit (**CPU**)] could address only the main memory.

A major part of a programmer's job was to devise a good way to divide a program into blocks and to schedule their moves between the levels. The blocks were called *segments* or *pages* and the movement operations *overlays* or *swaps*. This was a complex task even for small programs. The designers of the Atlas Computer at the University of Manchester invented virtual memory in the 1950s to eliminate two looming programming problems: (1) planning and scheduling data transfers between main and **secondary memory** and (2) recompiling programs for each change of size of main memory. They dreamt of automating it all.

In 1959, the Atlas computer system was the first working prototype of a virtual memory [Fotheringham 1961, Kilburn et al. 1962]. Its designers called it a *one-level storage system*. At the heart of their idea was a radical innovation: a distinction between *address* and *memory location*. It led them to three inventions: (1) they built hardware that automatically translated each address generated by the processor to its current memory location; (2) they devised **demand paging**, an interrupt mechanism triggered by the address translator that moved a missing page of data from secondary to main memory; and (3) they built the first replacement algorithm, a procedure to detect and move the least useful pages back to secondary memory.

Despite the success of the Atlas memory system, the literature of 1961 records a spirited debate about the feasibility of automatic storage allocation in general-purpose computers. By that time, Cobol, Algol, Fortran, and Lisp had become the first widely used higher level programming languages. These languages made storage allocation harder because programs were larger, more portable, more modular, and their dynamics more dependent on their input data. Through the 1960s there were dozens of experimental studies that sought to either affirm or deny the hypothesis that operating systems could do a better job at storage allocation than any compiler or programmer [Denning 1970]. The matter was finally laid to rest — in favor of automatic storage allocation — by an extensive study of system performance by an IBM research team led by David Sayre [Sayre 1969].

Convinced that virtual memory was the right way to go, the makers of major commercial computers adopted it in the 1960s; these included the IBM 360/67, CDC 7600, Burroughs 5500/6500, RCA Spectra/70, and Multics for the GE 645. By the mid-1970s the IBM 370, DEC VMS, DEC TENEX, and Unix had joined the crowd. These systems all used multiprogramming; their designers turned to virtual memory to solve not only the storage allocation problem, but also the more critical memory protection problem. To their designers' dismay, and to the delight of virtual memory's critics, these systems all exhibited **thrashing**, a condition of near-total performance collapse triggered when the multiprogrammed load became too high [Denning 1968]. Thrashing motivated a long line of experiments and models seeking to understand it and to design effective load control systems. This was finally accomplished by the late 1970s; near-optimal **throughput** will result when the virtual memory guarantees each active process just enough space to hold its working set [Denning 1980].

Virtual memory attracted hardware designers as well as software designers. In 1965, Maurice Wilkes proposed the *slave memory*, a small high-speed store included in the processor to hold, close by, a small number of most recently used blocks of program code and data. Slave memory used address translation, demand loading, and usage-based replacement. Wilkes said that, by eliminating many data transfers between processor and the main memory, slave memory would allow the system to run within a few percent of the full processor speed at a cost within a few percent of the main memory [Wilkes 1965]. The term *cache memory* replaced *slave memory* in 1968 when IBM introduced cache memory in its 360/85 machine. Cache memory is now a standard principle of computer architecture [Hennessey and Patterson 1990].

If it ended here, this story would already have guaranteed virtual memory a place in history. But the designers of the 1960s were no less inventive than those of the 1950s. Just as the designers of the 1950s sought a solution to the problem of storage allocation, the designers of the 1960s sought solutions to two new kinds of programming problems: (1) shareable, reusable, and recompilable program modules, and (2) packages of procedures hiding the internal structure of classes of objects (abstract data types). The first of these led to the **segmented address space**, the second to the architecture that was first called **capability-based addressing** and later **object-oriented programming**.

In 1965 the designers of Multics at the Massachusetts Institute of Technology (MIT) sought systems to support large programs built from separately compiled, shareable modules linked together on demand

[Dennis 1965, Organick 1972]. To them, virtual memory as a pure computational storage system was too restrictive; they held that **modular programming** would not become a reality as long as programmers had to manually bind the component files of an address space (by a linking loader or makefile program). Their innovation was to add a second dimension of addressing to the virtual address space, enabling it to span segment names as well as within-segment addresses. A program could refer to a variable *X* within a module *S* by the two-part name (*S, X*); the symbols *S* and *X* were retained by the compiler and converted to the hardware addresses for *S* and *X* by the virtual memory on first reference (a *linkage fault*). The Multics virtual memory demonstrated sophisticated forms of sharing, reuse, access control, and protection. This innovation, however, did not find its way beyond Multics; programmers were content with one private, linear address space and a handful of open files. As will be discussed, the World Wide Web [Berners-Lee 1996] is changing this: programs and documents contain *hypertext links* — symbolic pointers to other objects that are not linked until the program references them for the first time.

In 1966 Jack Dennis and Earl Van Horn published a prescient paper that initiated a new line of computer architectures: machines that help programmers create managers of classes of objects. They anticipated what is now called object-oriented programming. They were especially concerned that objects be freely reusable and shareable and, at the same time, be protected from internal access by anyone except their authorized managers. They proposed an extension of virtual memory that would map a process' local name for an object into an internal bit pattern called a *capability*; a capability contained a type indicator, an access code, and a unique name. Capability addressing offered an elegant solution to the problem of sharing and reusing modules. Several commercial and academic capability systems were built in the 1970s: notably the Plessey 250, IBM System 38, Cambridge CAP, Intel 432, SWARD, and Hydra. In these systems, capabilities were implemented as long addresses (e.g., 64 bits), which the hardware protected from alteration. (See Fabry [1974], Myers [1982], and Wilkes and Needham [1979].) The reduced instruction set computer (**RISC**) microprocessor, with its simplified instruction set, coupled with programming languages with type checking, rendered capability-managing hardware obsolete by the mid-1980s. But software-managed capabilities, now called **handles**, are indispensable in modern object-oriented programming systems, databases, and distributed operating systems [Chase et al. 1994]. The same conceptual structure has recently reappeared in a proposal to manage objects and intellectual property in the Internet [Kahn and Wilensky 1995]. It is a powerful structure indeed.

You may have wondered why virtual memory, so popular in the operating systems of the 1960s and 1970s, was not present in the personal computer (PC) operating systems of the 1980s. The pundits of the microcomputer revolution proclaimed bravely that personal computers would not succumb to the diseases of the large commercial operating systems; the personal computer would be simple, fast, and cheap. Bill Gates, who said that no user of a personal computer would ever need more than 640K of main memory, brought out the Microsoft Disk Operating System (DOS) in 1982 without most of the common operating system functions, including virtual memory. Over time, however, programmers of personal computers encountered exactly the same programming problems as their predecessors in the 1950s, 1960s, and 1970s. That put pressure on the major PC operating system makers (Apple, Microsoft, and IBM) to add multiprogramming and virtual memory to their operating systems. These makers were able to respond positively because the major chip makers had not lost faith; Intel offered virtual memory and cache in its 80386 chip in 1985; Motorola did likewise in its 68020 chip. Apple offered multiprogramming in its MultiFinder and virtual memory in its System 6 operating system. Microsoft offered multiprogramming in Windows 3.1 and virtual memory in Windows 95. IBM offered multiprogramming and virtual memory in OS/2.

A similar pattern appeared in the early development of distributed-memory multicomputers beginning in the mid-1980s. These machines allowed for a large number of computers, sharing a high-speed interconnection network, to work concurrently on a single problem. Around 1985, Intel and N-Cube introduced the first hypercube machines consisting of 128 component microcomputers. Shortly thereafter, Thinking Machines produced the first commercial supercomputer of this genre, the Connection Machine, with as many as 65,536 component computer chips. These machines soon challenged the traditional supercomputer by offering the same aggregate processing speed at a lower cost [Denning and Tichy 1990]. Their designers initially eschewed virtual memory, believing that address translation and page swapping

would seriously detract from the machine's performance. But they quickly encountered new programming problems having to do with synchronizing the **processes** on different computers and exchanging data among them. Without a common address space, their programmers had to pass data in messages. Message operations copy the same data three times: first from the sender's local memory to a local buffer, then across the network to a buffer in the receiver, and then to the receiver's local memory. The designers of these machines began to realize that virtual memory can reduce communication costs by as much as two thirds because it copies the data once at the time of reference. Tanenbaum [1995] describes a variety of implementations under the topic of distributed shared memory.

The WWW, started in 1991 by Tim Berners-Lee, extends virtual memory to the world. The Web allows an author to embed, anywhere in a document, a **uniform resource locator** (URL), which is an Internet address of a file. The WWW appeals to many people because it replaces the traditional **processor-centered view** of computing with a **data-centered view** that sees computational processes as navigators in an immense space of shared objects. To avoid the problem of URLs becoming invalid when the object's owner moves it to a new machine, Kahn and Wilensky proposed that objects be named by globally unique handles; handles are translated with a two-level mapping scheme first into a URL, and then into the machine hosting the object [Kahn and Wilensky 1995]. This scheme recalls the Dennis-Van-Horn object-oriented virtual memory of the 1960s but now with worldwide, decentralized mapping systems. With its Java language, Sun Microsystems has extended WWW links to address programs as well as documents; when a Java interpreter encounters the URL of another Java program, it brings a copy of that program to the local machine and executes it [Gilder 1995]. These technologies, now seen as essential for the Internet, vindicate the view of the Multics designers in 1965 — that many large-scale computations will consist of many processes roaming a large space of shared objects.

From time to time over the past 50 years, various people have argued that virtual memory is not really necessary because advancing memory technology would soon permit us to have all the random-access main memory we could possibly want. Each new generation of users has discovered that its ambitions for processing, memory, and sharing led it to virtual memory. It is unlikely that today's predictions of the passing of virtual memory will prove to be any more reliable than similar predictions made in 1960, 1965, 1970, 1975, 1980, 1985, 1990, 1995, and 2000. Virtual memory accommodates essential patterns in the way people use computers to communicate and share information. It will still be used when we are all gone.

85.3 Structure of Virtual Memory

Figure 85.1 shows a system consisting of a processor, main memory, and secondary memory. Main memory is typically RAM and secondary memory disk. The access time of the RAM is on the order of 0.1 to 0.01 μ s and of the disk 10 to 100 ms, giving speed ratios from 10^5 to 10^7 . In the early computers, the speed ratio was on the order of 10^4 . The penalty for referencing an item in secondary memory is even more severe than in the computers of the 1960s. This does not make virtual memory very attractive to those who believe that the primary purpose of virtual memory is to swap pages between main and secondary memory.

85.3.1 Paging

The computer hardware addresses bytes (8 bits of data). Data is usually stored and moved as blocks of contiguous bytes. In the simplest case, called paging, all the blocks are of the same size, say, 256 bytes. The main memory is divided similarly into blocks of **locations**, called **page frames**. Any page can be loaded in any page frame. We will consider first how a paged virtual memory works and then later examine variations that accommodate segments and other objects of variable sizes.

The set of addresses generatable by the processor is called the *address space*; all programs must be compiled to generate addresses within this space. Similarly, the set of main memory locations is called the *memory space*. The virtual memory system defines and maintains a dynamic map f from address to memory space, so that the hardware can quickly convert an address x to a memory location $y = f(x)$. The *page table* in which the map is stored has one entry for each page of the address space.

FIGURE 85.1 A processor executes a program from main memory. If the main memory is too small to hold the whole program, portions will be in secondary memory. Without virtual memory, the programmer would have to encode the commands to move blocks of data up and down the memory hierarchy.

FIGURE 85.2 To convert a virtual address from the process into a real address for the main memory, the mapper refers to a page table f . A presence bit P indicates that the page is present in main memory; if so, the bits in the field F indicate which frame. An access code field A tells whether the page can be read (r) or written (w). A translation lookaside buffer (TLB) accelerates mapping by bypassing the page table on repeat access to pages.

An example will clarify the relationships among these elements. Suppose that the virtual addresses are 32 bits, main memory addresses are 24 bits, and the page size is $256 = 2^8$ bytes. In any 32-bit virtual address, the 8 low-order bits select a byte within a page and the 24 high-order bits select a page. Thus, the address space contains 2^{24} (about 16.8 million) pages and the memory space contains 2^{16} (about 65,000) page frames. The page table f contains 2^{24} entries, each of which is a 16-bit word. During address translation, the 24 high-order bits of the virtual address are replaced with the corresponding 16 bits from the mapping table. All of this is illustrated in Figure 85.2.

A master copy of all the pages of the address space resides in the secondary memory; a subset of those pages will be in main memory. Any page modified by the processor will cease to be an exact copy of the

master; the operating system must write it back to the master before deleting it from main memory. To support this, each page table entry contains a *modified bit* that the mapper turns on automatically during any write to the page.

Sooner or later the processor will generate an address whose page number is not mapped (indicated by $P = 0$). The mapping unit will detect this and halt, issuing a signal called the *page fault*. In response, the operating system interrupts the running program and invokes a *page fault handler* routine that (1) locates the needed page in the secondary memory, (2) selects a frame of main memory to put that page in, (3) empties that frame, (4) copies the needed page into that frame, and then (5) restarts the interrupted program, allowing it to complete its reference.

The replacement policy (step 2) frees memory by removing pages. The objective is to minimize mistakes, that is, replacements that are quickly undone when the process recalls the page. This objective is met ideally when the page selected for replacement will not be used again for the longest time among all the loaded pages. To support this, each page table entry contains a *usage bit* that the mapper turns on automatically during any reference to the page. A variety of nonlookahead replacement policies have been studied extensively to see how close they come to this ideal in practice. When the memory space allocated to a process is fixed in size, this usually is least recently used (LRU); when space can vary, it is **working set** (WS) [Denning 1980].

The controller of the channel between main and secondary memory can accept commands of the form (*up*, a , b) and (*down*, a , b). The up command transfers a page from secondary memory frame b into main memory frame a . The down command transfers a page from main memory frame a to secondary memory frame b . The page fault handler routine automatically issues those commands when and as they are needed: in step 3, if the frame has been modified since being loaded, and in step 4.

This design makes address translation transparent to the programmer. Because the operating system maintains the contents of the map, it can alter the correspondence between addresses and locations dynamically. A program can now be executed on a wide range of system configurations, from small to large main memories, without recompiling it.

The main memory can also be partitioned among several executing programs. Each one has its own **address map** and can therefore refer only to its own pages. We will say more about multiprogramming later.

85.3.2 Translation Lookaside Buffer

The page tables, which can become quite numerous and large, cannot be stored economically in a local fast memory built in to the mapper. Instead, the mapper contains a pointer to the running process's page table stored in the main memory. This has the additional advantage of simplifying the processor **context-switch** operation because the entire memory state of a process is denoted by one register, the page table base. However, without some kind of accelerator, the mapper would generate two memory references for each virtual address, running the program at half-speed.

Virtual memory mappers use a small cache, called a **translation lookaside buffer** (TLB), as this accelerator. The TLB is a high-speed hardware associative memory that holds a small number of most recently mapped *paths*. A path consists of a page number (more generally, an object number) and the corresponding memory location: (a , $f(a)$). If the TLB already contains the path being attempted, the mapper bypasses the table lookups. In practice, small TLBs (e.g., 64 or 128 cells) give high enough hit ratios that average mapping speeds are within 1% to 3% of main memory speeds [Hennessey and Patterson 1990]. The TLB is a powerful and cost-effective performance accelerator. Without it, address mapping would be intolerably slow.

85.3.3 Cache Memories

The caching principle used in the translation lookaside buffer was first proposed by Wilkes [1965] as a direct hardware method for speeding up memory accesses (Figure 85.3). The main memory and cache are divided into equal-size blocks. The cache memory, which is attached directly to the processor, holds a subset of the blocks of the main memory; the block stored in a cache slot is indicated in a tag register associated with the slot. When the processor generates address (a , b) — meaning byte b of block a — the

FIGURE 85.3 In a cache memory, the indices of pages (blocks) stored in cache slots are held in tag registers. The address hardware searches the tag registers in parallel for a match on the addressed page, and then uses the remaining address bits to select a byte of that page. The search can be made faster by dividing the tags into 2^m sets, using the m low-order bits of the block number to select the set, and restricting the parallel search to that set. (The figure is drawn for $m = 0$.) This partitions the blocks equally among the sets and thereby limits the number of slots into which a given block may be placed. In the worst case, when 2^m equals the number of cache slots, the set size is 1 and each block can be loaded into one slot only.

addressing hardware searches all of the tag registers in parallel for a match on a . If there is a match, it addresses byte b of that slot. If not, the hardware copies block a into a slot, sets the slot's tag to a , and then addresses byte b of that slot. This is just like paging except that the page table is inverted — that is, the page numbers are the results obtained by looking up frame numbers. (Hennessey and Patterson [1990].)

Note how the caching principle appears twice in a virtual memory: once when a subset of address space is loaded into main memory, and again when a subset of address-paths are loaded into the TLB. Caching paths in the TLB enables fast address translation; caching pages in main memory enables fast program execution. The storage system will run at nearly full speed even when these caches are a fraction of their maximum potential size. Because the caching store is small compared to the total size of the data, its cost is fixed and controllable.

85.3.4 Object-Oriented Virtual Memory

Many computing environments offer abstractions and functions that require virtual addressing but are not easily accommodated by paging. These include program objects such as arrays, procedures, structures, processes, message buffers, files, and directories; concurrent processes (threads) with varying **permissions** sharing the same address space; modular programs; and very large address spaces containing many objects shared among many users. The designers of early virtual memories anticipated these uses with segmented and capability-based virtual memories [Dennis 1965, Dennis and Van Horn 1966, Fabry 1974]. The resulting storage systems are called object-oriented virtual memories.

The earliest form of object-oriented virtual memory was the segmented address space. It appeared as a collection of named blocks (segments) of various sizes. Each segment was a container for a program object. In the Burroughs B5000 and later series, for example, the Algol compiler created program segments containing procedures and data segments containing array rows [Organick 1973]. The compiler generated virtual addresses of the form (s, b) , meaning byte b of segment s . The size of each segment was explicitly

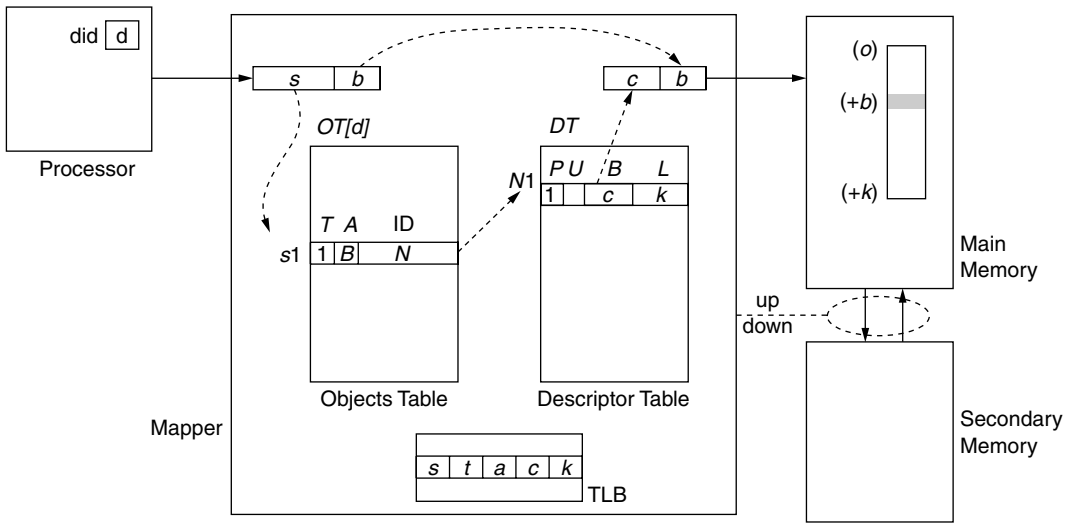

FIGURE 85.4 The mapping for object-oriented virtual memory operates in two levels. The first maps a local object number s of type t to an object unique identifier x , which in turn locates the object's descriptor in a descriptor table. An object's descriptor contains a presence bit P and a base-limit pair that designates a memory region of k bytes starting at address c . The byte number b must be less than k . A TLB that holds paths (s, t, a, c, k) accelerates the mapping. Different processes can have different segment numbers for the same segment: sharing of objects is possible without prior arrangements about the names each process will use internally. Shared objects can be relocated simply by updating the base address c in the descriptor.

recorded in the mapping table so that the mapper could reject out-of-bounds addresses b . Multics let the programmer, rather than the compiler, define the segments. In Multics PL/I, operands had symbolic two-part names (see earlier discussion); the operating system used a *linkage fault* to invoke a routine that mapped a symbolic (S, X) name-pair to its corresponding virtual address (s, b) as previously described [Organick 1972].

Multics also combined segmentation with paging by allowing each segment to be divided into pages. The offset into a segment was subdivided into a page and line number, and the page number mapped to a frame via the page table associated with the segment. This **two-level mapping** scheme made it easy to share segments: the first level of mapping would direct two users with different segment numbers to the same page table. The page table in turn mapped page numbers to page frames. Any changes made by the operating system to the page table would be seen immediately by all users sharing the segment. There would be no need for the operating system to locate all the users and update their segment tables.

Today's **object-oriented addressing** is the descendent of the Multics two-level segment address scheme. An object is stored in an address space segment. Each address space has an object table mapping object names to *descriptors*. A descriptor is a system object that contains all the information about the physical location of the object in the memory system. Two address spaces can assign different names to a shared object, which their object tables map to the object's single descriptor. Figure 85.4 shows the scheme. The mapper follows this routine:

```

processor places (s,b) in address register
if ((t,a,c,k) = LOOKUP(s) undefined)
then
    (t,a,x) := OT[d,s]
    (P,c,k) := DT[x]
    if (P = 0) then ADDRESS FAULT
    DT[x].U := 1

```

```

        LOAD(s, t, a, c, k)
    endif
    if (b ≥ k) then BOUNDS FAULT
    if (request not allowed by (t, a)) then PROTECTION FAULT
    place c+b in memory address register

```

The operation **LOOKUP(s)** scans all the TLB cells in parallel and returns the contents of the cell whose key matches **s**. The operation **LOAD** replaces the least recently used cell of TLB with **(s,t,a,c,k)**. The mapper sets the usage bit **U** to 1 whenever the entry is accessed so that the replacement algorithm can detect unused objects.

Object addressing creates a new problem of storage allocation in main memory: finding unused *holes* in which to place object-containing segments loaded from secondary memory. This is only a problem if the average size of an object is larger than about 10% of the memory size. In that case, the problem can be alleviated by paging each segment. In [Figure 85.4](#), this would be implemented by adding a third level of mapping: the base address *c* points to a page table, and offset *b* is mapped to a frame in the same way as with pure paging. The combination of segmentation and paging is not often used.

85.3.5 Protection

One of the fundamental requirements of an operating system is that users cannot interfere with each other. By default, they cannot see each other's address spaces. The virtual memory system plays an integral role in meeting this requirement. The images of address spaces are always in disjoint regions of main memory. This feature of virtual memory is called **logical partitioning**.

With virtual memory, a processor can address only the objects listed in its object table, and only then in accord with the **access codes** of the objects. In effect, the operating system walls off each process, giving it no chance to read or write the private objects of any other process. This has important benefits for system reliability. Should a process run amok, it can damage only its own objects: a program crash does not imply a system crash. This benefit is so important that many systems use virtual memory even if they allocate enough main memory to hold a process' entire address space.

85.3.6 Multiprogramming

Multiprogramming is a mode of operation in which the main memory is partitioned among the address spaces of different processes. Each user can start multiple processes. Multiprogramming allows users to switch among active programs such as word processor, spreadsheet, and print spooler. It also provides a supply of programs ready to be resumed next by the operating system, thus maintaining high processor unit efficiency. As noted in [Section 85.3.5](#), virtual memory confines each process to its assigned address space. Virtual memory provides an elegant and flexible way of partitioning a multiprogrammed memory.

Multiprogramming can be done with fixed or variable regions. Fixed regions are easier to implement but variable regions offer much better performance. With variable regions, the operating system can adjust the size of the region so that the rate of **address faults** stays within acceptable limits. The operating system can transfer space from processes with small memory needs to processes with large memory needs. Variable partitions often improve over fixed partitions even when the variation is random [Denning 1980]. System throughput will be near-optimal when the virtual memory guarantees each active process just enough space to hold its working set [Denning 1980].

85.3.7 Performance

Because most virtual memory systems represent objects with pages (one or more to an object), we can discuss performance of these systems in terms of decisions about loading, mapping, and replacing pages. Loading refers to the costs of bringing a page into main memory. Most systems load pages only on demand because no method of predicting future page use has proved reliable enough. However, because the time

to load a page is usually 4 to 6 orders of magnitude higher than the time to access a byte on a loaded page, a few bad guesses are more expensive than simply waiting for page faults.

Mapping refers to the cost of tracing address paths through the mapping tables. As noted, the translation lookaside buffer reduces these costs to a small percentage of the main memory access time.

Replacement refers to the costs of removing pages from main memory. Each removal has a cost because a modified page must be copied back to the master copy in secondary storage and because most pages will be recalled into main memory by future page references. Because this is an ongoing process — removal followed by recall — replacement is the major determinant of virtual memory performance.

The main metrics of system performance are **throughput** and **response time**, and the main metric of memory usage is **space-time**. Throughput is measured as jobs or transactions completed per second, response time as the average number of seconds to complete a job or transaction, and space-time as the total number of byte (or page) seconds accumulated by a job while it holds main memory. Space-time is a like “rent” paid by a job for memory usage. If n jobs complete in T seconds, the throughput is $X = n/T$. When the total memory is M bytes, the total space-time available in the system is MT , and therefore the space-time per job is $Y = MT/n$. These definitions imply:

$$M = XY$$

This invariant relation is fundamental: it says that minimizing space-time is the same as maximizing throughput for a given amount of main memory.

When a program has a fixed memory allocation, the minimum space-time occurs when the addressing faults are minimum. The ideal policy — let us call it MIN — replaces the page that will not be used again for the longest time. Unfortunately, such a policy cannot be implemented because the operating system cannot know the future reference pattern of a program. Among the implementable policies, LRU attempts to implement the MIN rule by predicting that time until next reference to an object is same as time since last reference. Although LRU is not as good as MIN, it has been found to be quite robust over a range of programs, typically doing as well or better than other nonlookahead policies, such as first-in-first-out (FIFO). LRU is often used in caches.

If we remove the constraints that memory size is fixed and that replacements occur only at page-fault times, we can do better than MIN. The ideal policy — let us call it variable-space MIN (VMIN) — operates as follows [Prievé and Fabry 1974]. After each object reference, VMIN looks ahead to the moment of the next reference to that page; if the time to that reference exceeds a threshold T , VMIN immediately replaces the page; otherwise, it retains the page in memory until that next reference. As T gets larger, VMIN retains more pages and generates fewer page faults. Thus, the parameter T gives a way to trade off the amount of memory used against the amount of paging generated. The reason no other policy can do as well is that VMIN minimizes space-time at every reference: VMIN retains a page only if the cost of recovering it by page-fault at the next reference exceeds the cost of retaining it.

Although we cannot implement VMIN because we cannot predict future page references, we can implement a good approximation. Simply define a process’s **working set** as the set of pages referenced in a window of size T looking *backwards* from the current time. The **working-set (WS) replacement policy** removes a page as soon as it leaves the working set. Under WS replacement, a page will cause a page fault at its next reference only if the time since previous reference exceeds T . In other words, WS replacement generates exactly the same faults as VMIN. The difference between WS and VMIN is due solely to WS’s retaining pages for T seconds after last use when VMIN would replace those pages. A long line of experimental studies in the 1970s showed that there is not much one can do about clipping off the memory “overshoot” of WS relative to VMIN. WS is about as good as one can do in a replacement policy [Denning 1980]. The working-set policy was first defined in 1967 [Denning 1968, 1970, 1980].

The WS replacement policy works especially well in a multiprogrammed system. Using a common window size T , the system measures every program’s working set dynamically. The scheduler admits waiting processes to the active state, one at a time, until the available memory space is filled with working sets. The window size can be adjusted empirically until it maximizes system throughput. System throughput

FIGURE 85.5 The system throughput is depicted as a function of the multiprogramming level N , which is the number of active programs among which main memory is partitioned. When N is too large, each program has so little space that it is forced toward a high paging rate. This makes the paging device the bottleneck, which slows down the system, producing thrashing. The ideal load control dynamically adjusts N to be constantly near the peak throughput.

may be improved further, but only by 5 to 10% at most, by measuring each running process with its own private window size [Denning 1980].

Many early systems using multiprogrammed virtual memory attempted to extend the LRU policy, which works very well in fixed partitions, by lumping all pages in main memory into a single global program managed by LRU. This strategy does not have the built-in load control of the working set policy: the scheduler can keep on activating more programs without limit. Each activation reduces the average space available to each program and increases the paging rate. These policies were therefore subject to thrashing (Figure 85.5). Thrashing can be avoided by limiting the multiprogramming level either by a fixed limit or by a working-set policy. The working-set policy generally leads to more stable performance with higher throughput.

85.4 Distributed Shared Memory

Starting in the mid-1980s, Sequent, Intel, Thinking Machines, N-Cube, and then later IBM, Cray, Kendall Square, and a few others introduced commercial multicomputers. These machines allowed for a large number of computers, sharing a high-speed interconnection network, to work concurrently on a single problem. They soon began to challenge the traditional supercomputer by offering the same aggregate processing speed at a lower cost [Denning and Tichy 1990]. But they also introduced a host of new programming problems having to do with synchronizing the processes on the different computers and exchanging data among them. Because these machines offered no common address space among all of the component computers, their programmers could share data only by copying it between machines. Not only does this complicate the job of programming the machine, but it also causes high message overhead.

It is possible to merge the address spaces of the component machines into a single global address space. The mapping mechanism uses a standard memory reference for a local object, or a message requesting data from the machine containing a nonlocal object. The resulting virtual memory is often referred to as **distributed shared memory** [Tanenbaum 1995].

The performance problems of distributed share memory are different because the other computers do not form a memory hierarchy, but are instead peers at the same level of memory hierarchy. Typical questions include: (1) Should a page be moved to the computer that most recently referenced it? Should it be moved only to the computer with the highest density of recent references to it? Should it be left in the

computer that obtained it by page fault? (2) How should a working set be defined when pages are shareable among many processes? How should the system ensure that this working set remains resident even while spread throughout the component memories? (3) How should duplicate copies (replicates) of pages be treated?

Questions like these can be answered only by experimenting with the alternatives. They are subjects of considerable attention among designers of these computers and their operating systems.

85.5 The World Wide Web: Virtualizing the Internet

The World Wide Web (WWW) extends virtual memory to the world. The WWW allows an author to embed, anywhere in a document, a uniform resource locator (URL), which is an Internet address of a file. By clicking the mouse on a URL string, the user triggers the operating system to map the URL to the file and then bring a copy of that file from the remote server to the local workstation for viewing. The WWW appeals to many people because it replaces the traditional processor-centered view of computing with a data-centered view that sees computational processes as navigators in an enormous space of shared objects.

A URL is invalidated when the object's owner moves or renames the object. To overcome this problem, Kahn and Wilensky [1995] have proposed a scheme that refers to mobile objects by location-independent handles and, with special servers, tracks the correspondence between handles and object locations. Their method is functionally similar to that described in Figure 85.4: first, it maps a URL to a handle and then it maps the handle to the Internet location of the object. Unlike Figure 85.4, however, their method does not rely on central databases to store the mapping information.

The WWW is being extended to programs as well as documents. Sun Microsystems has taken the lead with its Java language. The URL of a Java program can be embedded in another program; exercising the link brings the Java program to a local interpreter, which executes it. The Java interpreter is encapsulated so that imported programs cannot access local objects other than those given it as parameters. Java programs organized in this way are called applets.

85.6 Conclusion

Virtual memory systems are used to meet one or more of the following needs:

1. *Automatic storage allocation.* Solving the overlay problem that arises when a program exceeds the size of the computational store available to it. Also includes the problems of relocation and partitioning arising with multiprogramming.
2. *Protection.* Each process is given access to a limited set of objects, its protection domain. The operating system enforces the rights granted in a protection domain by restricting references to the memory regions in which objects are stored and by permitting only the types of reference stated for each object (e.g., read, write, or apply a function). These constraints are easily checked by the hardware in parallel with the main computation. These same principles are being used for efficient implementations of object-oriented programs.
3. *Modular programs.* Programmers should be able to combine separately compiled, reusable, and shareable components into programs without prior arrangements about anything other than interfaces, and without having to link the components manually into an address space.
4. *Object-oriented programs.* Programmers should be able to define managers of classes of objects and be assured that only the manager can access and modify the internal structures of objects [Myers 1982]. Objects should be freely shareable and reusable throughout a distributed system (Chase et al. 1994, Tanenbaum 1995). (This is an extension of the modular programming objective.)
5. *Data-centered programming.* Computations in the World Wide Web tend to consist of many processes navigating through a space of shared, mobile objects. Objects can be bound to a computation only on demand.

6. *Parallel computations on multicomputers.* Scalable algorithms that can be configured at runtime for any number of processors are essential to mastery of highly parallel computations on multicomputers. Virtual memory joins the memories of the component machines into a single address space and reduces communication costs by eliminating some of the copying inherent in message passing.

Virtual memory, once the subject of intense controversy, is now so ordinary that few people think much about it. That this has happened is one of the engineering triumphs of the computer age. Virtual memory accommodates essential patterns in the way people use computers.

Defining Terms

Access control: A means of allowing access to an object based on the type of access sought, the accessor's privileges, and the owner's wishes.

Address fault: An error that halts the mapper when it cannot locate a referenced object in main memory; it invokes an interrupt, whose handler corrects the condition by loading the missing object.

Address map: A table that associates an object (or page) number with the main memory locations containing the object.

Address space: The set of all addresses that a processor can issue while processing a program.

Bounds fault: An error that halts the mapper when it detects that the offset requested into an object exceeds the object's size; it invokes an interrupt that terminates the program.

Capability: A systemwide unique identifier for an object; the bits of a capability are protected from alteration.

Context-switch: An operation that switches the CPU from one process to another, by saving all of the CPU registers for the first and replacing them with the CPU registers for the second.

CPU: Central processing unit, or processor.

Data-centered view: A view of computing that emphasizes navigation of many concurrent processes within a large space of objects.

Handle: A systemwide unique identifier for an object, like a capability without the system guarantee of integrity.

Location: A memory register with its own address.

Logical partitioning: A property of virtual memory whereby the address spaces of different jobs are mapped into disjoint regions of memory.

Main memory: The highest level of the memory hierarchy; all CPU memory references are directed to main memory; CPU can access objects only when they are loaded in main memory.

Memory hierarchy: A system of memory devices of different speeds and capacities; allows for trading off between capacity and speed, and between volatility and persistence.

Memory space: The set of all hardware addresses of memory locations in RAM available to a given address space.

Modular programming: Programs are divided into parts that can be shared, reused, and recompiled without affecting other parts of the system as long as the interfaces to modules are unchanged.

Object-oriented addressing: A form of virtual addressing in which object numbers are mapped to memory regions and internal object references are mapped to offsets within an object's memory region.

Object-oriented programming: A form of programming in which data is organized into classes of objects, each with a specific set of functions that can be applied to the objects.

Page: a fixed size unit of storage and transfer in a memory hierarchy.

Page frame: A contiguous block of memory locations used to hold a page.

Paging: A method of virtual memory in which address space and memory space are paged.

Partition: A division of memory space into disjoint subsets of pages for each address space.

PC: Personal computer.

Permissions: Access rights granted by an object's owner and represented as bits in the object's access code.

Process: An abstraction of the execution of a program, usually represented as the sequence of values of its CPU state as the program traces through its instruction sequence.

Processor-centered view: A view of computing that emphasizes the work of a processor.

Protection fault: An error condition detected by the address mapper when the type of request is not permitted by the object's access code.

RAM: Random access memory.

Response time: The time from when a command is submitted to a computer until the computer responds with the result.

RISC: Reduced instruction set computer (e.g., PowerPC, Sun SPARC, DEC Alpha, MIPS).

Secondary memory: Lower, large-capacity level of a memory hierarchy, usually a set of disks.

Segmentation: An approach to virtual memory when the mapped objects were variable-size memory regions rather than fixed-size pages; superseded by object-oriented addressing.

Slave memory: A hardware cache attached to a CPU, enabling fast access to recently used pages and lowering traffic on the CPU-to-main-memory bus.

Space-time: The accumulated product of the amount of memory and the amount of time used by a process.

Thrashing: A condition of performance collapse in a multiprogramming system when the number of active programs gets too large.

Throughput: The number of jobs (or transactions) per second completed by a computer system.

TLB: Translation lookaside buffer, a cache that holds the most recently followed address paths in the mapper.

Two-level map: A two-tiered mapping scheme; the upper tier converts local object numbers into system unique handles, and the second tier converts handles to the memory regions containing the objects. Essential for sharing.

URL: Uniform resource locator (in the WWW).

Working set: The smallest subset of a program's pages that must be loaded into main memory to ensure acceptable processing efficiency; changes dynamically.

Working-set (WS) policy: A memory allocation strategy that regulates the amount of main memory allocated to a process, so that the process is guaranteed a minimum level of processing efficiency.

World Wide Web (WWW): A set of servers in the Internet and an access protocol that permits fetching documents by following hypertext links on demand.

86.1 Introduction

The memory on a computer is organized into a hierarchy of storage [Smith, 1981]. This storage ranges from small and fast to large and slow. [Figure 86.1](#) shows a typical hierarchy. It is composed of two main parts: the primary store and the secondary store.

The main components of this hierarchy include:

1. The first level of the primary store is the *cache memory*. It is often contained on the same chip as the central processing unit (CPU), or on other nearby chips that can be connected to the CPU with a minimum of delay. Because it must be able to run at close to the speed of the CPU, with access times of as little as a few nanoseconds, cache memory is typically small, rarely exceeding a few megabytes (Mbytes). The cache is never used for permanent storage; it holds values that are actively being processed by the CPU.
2. The second level of the primary store is the *main memory* on the computer. It currently runs with access times of 6 to 7 microseconds that may delay a CPU by 5 to 100 instruction cycles. The size of main memory ranges from a few hundred Mbytes up to several hundred gigabytes (Gbytes). Like the cache, main memory is not used for permanent storage; it holds the active part of running programs. Inactive parts of running programs are swapped out of the main memory to disk when the main memory becomes full. Thus, the size of a program is not constrained to the size of the main memory.
3. The first level of the secondary store is usually built from one or more *disk drives*. These disk drives are usually connected directly to the computer, although they may be located across a fast network on a central storage server. Disks are used for intermediate to long-term data storage. Access time for a fast disk is currently about 1 millisecond; thus, a CPU that needs to access data that is on disk will have to wait thousands of instruction cycles. Modern multitasking operating systems will suspend a program that awaits a disk access and run another program. Some time after the disk access has completed, the program that requested the data will begin to run again.

FIGURE 86.1 Computer memory hierarchy.

FIGURE 86.2 Construction of a magnetic disk.

4. The second level of the secondary store consists of *tape drives*. The tape drives are used for archival and backup storage. The access time to get to the start of and begin reading a file stored on a robotically managed tape system is several minutes. If a human operator must get involved, the access time takes longer. Historically, actively running programs directly manipulated data on tapes. Today, most applications arrange to have data read from tapes onto disk before beginning to access that data. Tapes are used primarily to archive data that is not currently accessed.

This chapter is concerned with the secondary part of the storage hierarchy; [Chapter 19](#) and [Chapter 108](#) discuss primary storage and its management. In particular, disks can be used as a temporary store when the main memory becomes full. This chapter considers disks solely from the perspective of their use as long-term storage media. The first half of this chapter discusses the hardware used to support secondary storage. The second half of the chapter discusses filesystem software used to access and manage secondary storage.

86.2 Secondary Storage Devices

Many types of hardware are used to support secondary storage. This section describes the most commonly used devices — magnetic disks, compact disk–read-only memory (CD-ROM) disks, and various types of tape devices.

86.2.1 Magnetic Disks

Disks are the most frequently used form of secondary storage. The most common type of disk is the magnetic disk [White, 1980]. Figure 86.2 shows the construction of a typical magnetic disk.

A disk is built from one or more metal platters coated on both sides with an iron oxide compound. The platters are mounted on a spindle connected to a motor that spins them. Data is read and written on the

platters by magnetic heads mounted in a head assembly that runs on a track that enables the heads to be moved between the inner and outer edges of the platter. The operation of moving the head assembly is referred to as a *seek*. Separate heads scan the top and bottom of each platter. Each platter is divided into a set of concentric circles referred to as *tracks*. Each track is subdivided into fixed-size blocks referred to as *sectors*. The set of all tracks that are accessible from a single seek position are referred to as a *cylinder*.

Moving a head to any particular location on the disk to read or write data is a two step process. First, the head assembly must be moved to the desired cylinder. Once the head assembly is located at the correct cylinder, the head for the requested track is enabled. The second step, called *rotational delay*, is to wait for the desired sector on the disk to rotate under the head. Reading is done by the head by measuring the polarization of the iron oxide. Writing is done by sending a current through the head to generate a magnetic field that polarizes the iron oxide.

The access time for a disk is a function of the seek time plus the rotational delay. If the entire contents of a chunk of data can be stored in the same cylinder as the current head position, then it can be accessed with no seek delay. If the data cannot be placed entirely within the same cylinder, it should be placed on nearby cylinders because seek time is a function of distance. Rotational delay can be minimized by placing data on contiguous sectors within a track. A disk can only read or write data from one head at a time; however, switching between heads is almost instantaneous. If the contents of a chunk of data can be stored contiguously on several tracks within a cylinder, it can be accessed without any rotational delay because the disk can switch between heads at the end of each track.

Early disk technology used platters up to a meter in diameter spinning at a few hundred revolutions per minute. Modern technology has been steadily shrinking the size of the platters so that today they are only a few centimeters in diameter. The smaller platters have allowed the head assemblies to shrink in size and mass. Because the lighter head assemblies can be moved more quickly and have shorter distances to travel, the seek times of modern disks are a hundredth that of early disks. The heads do not touch the disk surface; instead, they float on a cushion of air a few microns above the surface. The air cushion pushed ahead of the heads creates friction that must be dissipated as heat. Because the amount of friction rises by the cube of the speed of the platter, even a small increase in rotational speed causes the generation of a lot more heat. Over time, the speed of rotation has increased much more slowly than the seek speed. Access times on early disks were dominated by seek times while in modern disks, the rotational delay is the dominating factor.

Data is transferred between the main memory and the disk by a disk controller. Most disk controllers transfer data between the disk and main memory using direct memory access. The CPU issues a command specifying the range of main memory addresses to be written or read and the disk sectors to or from which they should be transferred. The controller is responsible for issuing a seek command to the disk if necessary, waiting for the desired sectors to rotate under the head, transferring the data between the specified main memory locations, and interrupting the CPU to signal that the transfer has been completed.

To improve performance, disk controllers often provide a *track cache*, which holds the contents of the track containing the currently requested sector. For example, consider a file that fits on one track of a disk. Suppose the disk controller has been requested to read the first part of the file, but when the seek completes, the head is sitting over the middle of the file half a rotation away from its beginning. Instead of waiting for the disk to rotate the beginning of the file into position, the controller immediately begins reading the track into its cache. As the beginning of the file passes under the head, it is transferred into the main memory as requested and the CPU is notified of its completion. Following the end of the requested data transfer, if there are no further requests awaiting the controller, it reads the remaining quarter of the track into its cache. Because files are often read sequentially, the controller will probably be asked to read the next quarter of the file. Instead of having to wait for the disk to rotate back into position, it can satisfy this request from its cache. Thus, after one disk revolution, the controller can produce any part of the file with no rotational delay. Because the controller can transfer data from its cache to main memory much faster than data is delivered by the disk, the disk cache produces an even greater performance gain than just that measured by eliminating rotational delay.

Using a cache to speed up disk writes is a bit more difficult. If the controller completes a seek half a rotation ahead of the spot that requests the write, there is nothing useful that it can do; it must wait for the requested position to rotate into place. Normally, the controller waits until the write completes before issuing a completion interrupt to the CPU. Typically, a millisecond or so of CPU processing occurs before it issues the next write request. If the next write request contiguously follows the previous write, then the disk head will have just missed the start of the block and will incur nearly an entire rotation's delay reaching the correct starting point. When writing a large contiguous file, the controller will consistently be delayed by a full rotation on each block, which leads to poor throughput. One approach to correcting this problem is to transfer the requested block into the controller cache and then issue the completion interrupt before the block has been placed entirely on the disk. Here, the CPU can prepare and issue the next request for the controller while the previous block is being written. With the new request in hand, the controller can start its transfer to the disk without loss of a revolution.

This approach has a serious failing if the controller does not have a non-volatile cache. Many applications such as databases depend on the completion interrupt to let them know that critical data such as a transaction log has been stored in a location that will survive a system failure. If the data is only in the volatile controller cache and the system fails before the cache is written to disk, then the database will be unable to recover. Thus, early completion interrupts must be used only if the controller cache uses non-volatile memory and has software to restart it and write out any incomplete blocks after a system failure.

A much better alternative is to use a technique called tag queuing. Here, several requests are given to the disk controller, each of which is identified with a unique tag. When a request has been written to the disk, an interrupt is generated which presents the tag of the completed transfer to the system. Tag queuing allows the disk to write contiguously without the need to depend on premature and possibly incomplete I/O. Thus, applications can reliably know that their data is on stable store. Unfortunately, tag queuing is available only on high-end SCSI disks and is not generally available on the cheaper and more ubiquitous IDA disks usually found on personal computers.

The capacity of disks has been rising steadily; single disks today hold hundreds of Gbytes of data. Unfortunately, disks are still able to transfer data from only one location at a time. As the amount of data on the disk grows, this serialized access has become more and more of a bottleneck. To compensate, some systems deliberately use smaller capacity disks to increase the total number of disks on the system, which allows more parallel data access.

86.2.2 Redundant Array of Inexpensive Disks (RAID)

The biggest problem with magnetic disks is dealing with their inevitable failures. Because the heads fly only microns above the disk surface and because of the need to dissipate the heat that this small gap produces, even the best-designed disks have a lifetime of only 5 to 7 years. On a large file server containing 50 to 100 disks, a disk failure is expected every few weeks. Traditionally, recovery from such failures were handled by use of a tape backup system. Every few weeks a complete copy of each disk would be made on tape. Each day, a backup would be made of everything that had changed since the last complete copy had been made. When a disk failed, it would be replaced with a new disk; then the contents of the complete copy, followed by all the daily changes, would be made to complete the recovery process.

There are three problems with this approach:

1. *Capacity limits.* As the capacity of disks has increased, the amount of data that must be backed up on tape has exploded. The large server above would have several terabytes (Tbytes) of disk space connected to it. Even with the high-density tapes available today, it would take hundreds of tapes to back it up. The server would require several tape drives running continuously just to keep up with the backups.
2. *Data loss.* At best, most systems can only schedule backups once per day. If the disk crashes shortly before it is scheduled for its daily backup, everything that was done that day will be lost. For many businesses, losing even a day's work is unacceptable.

3. *Recovery delay.* Replacing a disk and recovering its contents from backup tapes takes several hours. During the recovery period, the disk is completely unavailable. This recovery delay is often unacceptable for time-critical applications.

Two approaches have been taken to avoid these problems. The first of these approaches is a brute-force solution called *mirroring*. The number of disks on the system is doubled. Disks are paired off and each pair keeps a copy of its partner. Thus, each time an application does a write, the changed data is written to both disks in the pair. Reads can be done from either disk because they both contain the same data. If one disk in the pair fails, the other disk can continue servicing requests without interruption. When the failed disk is replaced, its initial contents are copied in from its operating partner. Although it may take an hour or two to do the replacement and contents copy, users are unaware of the delay because they are running from the remaining good drive. Additionally, no data is lost because there is no dependence on backup tapes for recovery. Mirroring has traditionally been used for time- or business-critical data such as that handled by banking and airline reservation systems where the extra cost can be justified.

The second approach to avoiding the tape backup problem is to collect several disks together and use one of them to store a parity of the others. Such an organization is referred to as a Redundant Array of Inexpensive Disks (RAID) [Patterson et al., 1988; Chen et al., 1994]. A typical RAID cluster will contain five disks. Four of the disks contain data and the fifth contains a parity of the data on the other four. Each time data is written to any of the other four disks, a new parity must be computed and written to the fifth disk. In practice, the parity is not stored entirely on one disk as it would become the bottleneck when trying to write to one of the other four disks. Instead, each disk in a five-disk RAID cluster would be divided so that 20% stores parity and 80% stores data that would be covered by parity on the other four disks.

Recovery from disk failure in a RAID cluster is not as transparent as it is with mirroring. Access to the RAID cluster can continue, but at about half of its regular access rate while the broken disk is replaced and rebuilt. The replacement disk is initialized by reading the other four disks in the cluster and computing what value should be put onto the new disk. In data communications, parity can be used to detect errors, but not to correct them. That is because in data communications, the receiver does not know which bit is in error. Parity can be used for error correction for a RAID cluster because the cluster knows which disk failed. Thus, it can recompute the correct value for the failed disk using the data on the other drives. Failure recovery on a RAID cluster typically takes one to two hours.

Once the recovery is complete, the cluster returns to the state it was in just before the disk failed. Thus, RAID clusters solve two of the three tape backups problems. They avoid the need for daily backups and they avoid losing data when they fail. While access to the data is slow during the recovery period, that period is typically about half the time required for a tape recovery. A RAID cluster is considerably cheaper than a mirroring strategy because there is only a 25% redundancy of hardware rather than a 100% redundancy. Thus, RAID cluster usage is increasing in less time-critical environments.

Even with RAID clusters, the need for tape backups is not completely eliminated. Full backups need to be taken and stored off-site for recovery if a major catastrophe such as a fire destroys the disks in a machine room. Tapes are also needed to recover from user errors where an important file is accidentally deleted. Neither of these problems can be handled by RAID clusters.

Mirroring can handle the catastrophic failure if the mirror disks are kept in physically separate locations. For genuine safety, the mirrors should be in different buildings that are several miles apart. The communication costs of the high-bandwidth network connection that is required usually makes a long-distance mirroring solution unacceptably expensive. And, distance mirroring does not provide recovery from user errors where an important file is accidentally deleted.

86.2.3 CD-ROM Disks

The ubiquitous CD-ROM plays a small but important role in computer systems today [Asthana, 1995]. Its primary use is as a software distribution medium where it has replaced tapes and floppy disks. It has the benefits of being cheap, reliable, and easily mass-produced. It has the random access features of a magnetic

disk that makes it much more convenient than a tape. Because the software is often used directly from the CD-ROM rather than being loaded onto the system disk, large software packages can be used on systems that are otherwise short of disk space.

The CD-ROM disks are more compact to store than tapes. They are expected to hold data reliably for 50 to 100 years, compared to tapes, which can only hold data reliably for 5 to 8 years.

86.2.4 Tapes

Tapes remain the most commonly used form of fourth level storage. Early tape technology used 12-inch reels of half-inch tape that stored a little over 100 Mbytes of data. Current tape technology uses DLT cartridges that store hundreds of Gbytes of data. The rule of thumb has been that the largest tapes hold about the same amount of data as the largest disks.

Data transfer to and from tapes tends to be slower than data transfer to and from disks. Random access to tapes is much slower than disks. Even modern DLT drives take about a minute to seek from one end of a tape to the other. The big benefit of tapes is that they are a tenth the cost of disks per Mbyte of storage. Also, by installing a robotic tape system with a capacity of several hundred tapes, it is possible to create a file store capable of storing 100 Tbytes of data. While the access time to the data may be a minute or two, it is far cheaper than storing a similar amount of data on disk.

In practice, tape store is generally used as the final repository for data. Recently accessed data is stored on disk where it is more readily available. When the disks become full, the least recently accessed data is copied to tape and deleted from the disk. If it is later needed, it is reloaded onto the disk, displacing other less recently accessed data. To maintain reasonable access times, most systems arrange to have enough disk space to keep data disk resident for at least a month.

86.3 Filesystems

Most applications that users run on their computer do not write data directly onto the disk. The operating system provides a filesystem that organizes the data into files. The filesystem is responsible for deciding where the file contents should be placed on the disk. The filesystem provides several important services:

- *Protection.* Most filesystems allow users to control access to their files. At a minimum, they can restrict access to themselves, a defined group of other users, or all other users of the system.
- *Organization.* Data in each file can be manipulated independently of data in other files. Data can be added or deleted from one file without affecting the data contained in other files. In particular, users need not be concerned that one file might run into another file on the disk as they would if they were directly placing the data on the disk themselves.
- *Multiple access.* Modern filesystems allow multiple files to be accessed at the same time and even allow separate programs to consistently access the same file. Consistent access means that if one application writes a file while another is reading the same part of the file, the reader will see the file either before the write has been started or after it has finished, but not in a partially written state.
- *Space management.* The filesystem tracks the used and free space on the disk. When any file in the filesystem needs to grow, the filesystem finds an appropriate-sized piece of free space and allocates it to the file. As long as there is free space left on the disk, the filesystem is prepared to allocate it to any file within the filesystem that wants to grow or to create a new file and allocate the space to that new file.

In addition, a filesystem is expected to optimize the use of disk bandwidth. Thus, it must not only find space to allocate to files, but it must also try to find space that is contiguous or at least rotationally close together to minimize the time that it takes to read and write the file. Issues of space management are discussed below.

FIGURE 86.3 A set of files and directories.

86.3.1 Directory Structure

Most filesystems allow files to be grouped together into directories. These directories can then be further grouped together into other directories. The files and directories are usually grouped together in a tree hierarchy; Figure 86.3 shows a typical filesystem hierarchy. The rounded boxes represent directories; the square boxes represent files. The top of the tree is referred to as the *filesystem root*. Files are accessed by giving the set of names of directories from the root of the tree down to the desired file, separated by forward slashes; this name is called the *pathname*. For example, access to the file *mydata* in Figure 86.3 would use the pathname */users/myhome/mydata* [IEEE, 1994].

Many filesystems maintain a current working directory for the user. Instead of having to always specify a file by its complete pathname, the system keeps track of which directory the user is currently referencing, and does all filename translation relative to that directory. The user initially specifies a current directory using a complete pathname. Using the filesystem shown in Figure 86.3, the user might request that the current directory be set to */users/myhome*. Thereafter, the reference to the file *mydata* can be used without specifying its entire path because it is resident in the current directory.

86.3.2 Describing a File on Disk

To allow both multiple file allocation and random access, most systems uses a data structure similar to that shown in Figure 86.4 to describe the contents of a file. This structure includes:

- Access permission for the file
- The file's owner
- The time the file was last read and written
- The size of the file in bytes

Notably missing in this structure is the filename. Filenames are usually maintained in directories rather than in this structure because a file may have many names, or links, and the name of a file may be large (often up to 255 bytes in length).

The file structure also contains an array of pointers to the blocks in the file. The system can convert from a *logical block* number to a *physical block* number by indexing into this array using the logical block number. A null array entry shows that no block has been allocated, and will cause a block of zeros to be returned on a read. On a write of such an entry, a new block is allocated, the array entry is updated with the new block number, and the data is written on that physical block of the disk.

Because the filesystem must support many files and most files that it stores are small, the file structure has a small array of pointers for efficient use of space. The first few array entries are allocated in the file structure itself. For typical filesystems, these array entries allow the first 100 Kbytes of data to be located directly using a simple indexed lookup.

For somewhat larger files, Figure 86.4 shows how the file structure contains a pointer to a single *indirect block* of pointers to data blocks. To find the hundredth logical block of a file, the system first fetches the

FIGURE 86.4 Extensible data structure used to describe a file.

block identified by the indirect pointer, then indexes into it by 100 minus the number of direct pointers, and fetches that data block.

For files that are larger than a few Mbytes, this single indirect block is eventually exhausted. These files must resort to using a double indirect block, which is a pointer to a block of pointers to pointers to data blocks. For files of multiple Gbytes, the system uses a triple indirect block, which contains three levels of pointers leading to the data block.

Although indirect blocks appear to increase the number of disk accesses required to reach a block of data, the overhead for this transfer is typically much lower. Most filesystems maintain a memory-based cache of recently read disk blocks. The first time that a block of indirect pointers is needed, it is brought into the filesystem cache. Further accesses to the indirect pointers find the block already resident in memory; thus, they require only a single disk access to reach the data.

The filesystem handles the allocation of new blocks to files as they grow. Simple filesystem implementations, such as those used by early microcomputer systems, allocate files contiguously, one after the next, until the files reach the end of the disk. As files are removed, gaps occur. To reuse this freed space, the system must compact the disk to move all the free space to the end. Files can be created only one at a time; to increase the size of a file (other than the last one on the disk), it must be copied to the end and then expanded. For the more complex file structure just described, the locations of the data blocks in each file are given by its block pointers. Although the filesystem may cluster the blocks of a file to improve I/O performance, the file structure can reference blocks scattered anywhere throughout the disk. Thus, multiple files can be written simultaneously, and all the disk space can be used without the need for compaction.

86.3.3 Filesystem Input/Output

The filesystem implementation converts the file from the user abstraction as an array of bytes to the structure imposed by the underlying physical medium. Consider a typical medium of a magnetic disk with fixed-size sectoring. Although the user may wish to write a single byte to a file, the disk supports reading

FIGURE 86.5 The block I/O system.

and writing only in multiples of sectors. Here, the system must read the sector containing the byte to be modified, replace the affected byte, and write the sector back to the disk. This operation of converting a random access within an array of bytes to reads and writes of disk sectors is called *block I/O*.

First, the system breaks the user's request into a set of operations to be done on logical blocks of the file. Logical blocks describe block-sized pieces of a file. The system calculates the logical blocks by dividing the array of bytes into filesystem-sized pieces. Thus, if a filesystem's block size is 8192 bytes, logical block 0 would contain bytes 0 to 8191, logical block 1 would contain bytes 8192 to 16383, etc.

Figure 86.5 shows the flow of information and work required to access the file on the disk. The abstraction shown to the user is an array of bytes. These bytes are collectively described by a file descriptor that refers to some location in the array. The user can request a write operation on the file by presenting the system with a pointer to a buffer, with a request for some number of bytes to be written. Figure 86.5 shows that the requested data need not be aligned with the beginning or end of a disk sector. Further, the size of the request is not constrained to a single disk sector. In the example shown, the user has requested data to be written to parts of logical blocks 1 and 2.

The data in each logical block is stored in a physical block on the disk. A physical block is the location on the disk to which the system maps a logical block. A physical disk block is constructed from one or more contiguous sectors. For a disk with 512-byte sectors, an 8192-byte filesystem block would be built from 16 contiguous sectors. Although the contents of a logical block are contiguous on disk, the logical blocks of the file need not be laid out contiguously.

Returning to our example in Figure 86.5, we now know which logical blocks are to be updated. Because the disk can transfer data only in multiples of sectors, the filesystem must first arrange to read in the data for any part of the block that is to be left unchanged. The system must arrange an intermediate staging area for the transfer. This staging is done through one or more *system-cache buffers*.

In our example, the user wishes to modify data in logical blocks 1 and 2. The operation iterates over five steps:

1. Allocate a system-cache buffer
2. Determine the location of the corresponding physical block on the disk

3. Request the disk controller to read the contents of the physical block into the system-cache buffer and wait for the transfer to complete
4. Do a memory-to-memory copy from the beginning of the user's I/O buffer to the appropriate portion of the system-cache buffer
5. Write the block to the disk

Because the user's request is incomplete, the process is repeated with the next logical block of the file. The system fetches logical block 2 and is able to complete the user's request. Had an entire block been written, the system could have skipped Step 3 by simply writing the data to the disk without first reading the old contents. This incremental filling of the write request is transparent to the user's process because that process is blocked from running during this entire operation. It is also transparent to other processes because the file is locked by this process; any attempted access to the file by any other process will be blocked until this write has completed.

86.3.4 Disk Space Management

The role of the filesystem code is not only to organize the data on a disk but also to minimize the time it takes to read and write that data. There are two important measurements of access time. The first is the time it takes to access the data contained within a particular file. The second is the time it takes to access the data contained within a collection of files that are accessed together.

Examples of collections of files accessed together include files that are collected together in a spool area such as those destined to be sent to a printer or those being batched to be sent as a collection of electronic mail messages. Another example might be a collection of files that make up the components of a spreadsheet, a document, or a program. Directories provide a strong clue that a set of files will be accessed together. Thus, many filesystems will try to allocate all the files contained within a directory in close physical proximity to each other on the disk. If they are accessed together, the disk will not need to make long or multiple seeks to get from one to the next.

Most filesystems put their greatest effort into optimizing the layout of individual files. The default assumption is that the files will be accessed sequentially, starting at their beginning. Certain files, such as those that contain a large database, may have randomly scattered accesses. The optimal layout for such files depends on their access patterns, which may be known only to the database or application program, or may not be known at all. For such files, the filesystem may allow the database or application to direct the layout of the file. Alternatively, it may simply layout the file sequentially, and assume that the database or application will attempt to cluster related information within the file to minimize the time it takes to seek between file locations.

For a sequentially accessed file, the usual strategy is to allocate a contiguous piece of space on the disk on which it is stored. When a disk is first put into service, doing sequential allocation for files is easy. The filesystem has a large area of contiguous physical free space, and allocates pieces out of that space for each new file. Unfortunately, this allocation approach quickly uses up all the physically contiguous space. As old files are deleted, they return the space that they were using. However, this unused space will be randomly scattered throughout the disk. Eventually, the disk will become completely fragmented, with no large contiguous pieces of space remaining, thus making it impossible for the filesystem to allocate new files contiguously.

Filesystems often use defensive algorithms to reduce the rate of fragmentation of the free space on the disk. A key to reducing fragmentation is to observe that most of the files within a filesystem are small. When a new file is created, the filesystem can assume that it will be small. Instead of allocating its initial disk space in a large contiguous area of the disk, the file will be allocated in a smaller fragment that may have been freed when another small file was deallocated. If the file turns out to be small as expected, then it will nicely fit in the small space that it was initially allocated. If it continues to grow, then the filesystem can move it to a fragment left by a somewhat larger file. Only when the file grows large is it finally relocated to the large contiguous space that the filesystem has now been able to hoard. By only allowing large files to be

allocated in the large contiguous space, the filesystem is better able to ensure that some large contiguous space will be available when it is needed.

Moving files around on the disk can be a potentially slow and expensive operation if the file must be read and rewritten every time the filesystem wants to move it. To reduce the relocation cost, the filesystem will attempt to defer writing the file until it has determined its final location on the disk. The deferral is done by holding blocks of the file in system-cache buffers until its size can be determined (see [Figure 86.5](#)). The steps involved in allocating space to a file are as follows:

- When the first block is written, a system-cache buffer is allocated. A single block-sized piece of free disk space is found, the address of that piece of disk space is assigned to the system-cache buffer, but the buffer is not written to the disk.
- If the file continues to grow, a second system-cache buffer is allocated. The filesystem finds a two block-sized piece of free space, frees the single block-sized piece of space originally assigned to the file, and assigns the addresses of the new, larger block to the two buffers. As before, neither buffer is written to the disk.
- This process continues until the file has grown to the maximum-sized block allowed (typically the size of a disk track) or the file has ceased to grow, at which point the buffers are written to their final destination.

If the system-cache buffers are needed for another purpose, or the application explicitly requests that the file be stored on disk (for example, it is a transaction log that must be in stable storage before the application can proceed), the system-cache buffers always have a location to which they can be written. The only implication of doing the write early is the loss of performance that comes from writing the data to disk more than once.

This algorithm has the additional benefit that it allows even slowly growing files to be written contiguously. If a file such as one holding accounting records grows at the rate of a few Kbytes per hour, it will be relocated to larger contiguous blocks periodically. Here, the relocation usually involves reading and rewriting the data, because the turnover in system-cache buffers causes them to be flushed before the new disk addresses for the data are assigned. Because the reallocation occurs only a few times per hour, the added I/O overhead does not adversely affect system performance.

To ensure successful layouts, a filesystem must have a quick method for finding contiguous and nearby free blocks on the disk and then allocating them. The most common data structure used for describing the free disk blocks is an array of bits. The blocks on the disk are sequentially numbered; the corresponding bit in the array is set to 1 if the block is being used and 0 if it is free. Block allocation involves setting the bits corresponding to the blocks being allocated; block deallocation involves clearing the bits corresponding to the blocks being freed. Finding other nearby blocks can be done by looking for 0 bits in the array near the location of the most recently allocated block in the file. Clusters of blocks can be identified by looking for strings of 0 bits in the array.

The free disk block array is large for a big disk. Exhaustive searches of the array (for example, when the disk is nearly full and there are few free blocks remaining) would slow filesystem performance unacceptably. Consequently, most filesystems maintain auxiliary data structures that summarize the contents of subranges of this bit array. Such summaries include the number of free blocks and the maximum-sized contiguous piece within each subrange of the bitmap. When looking for a block or a cluster of blocks, the filesystem first scans the summary information to find a subrange of the bitmap that has the necessary free space. Once it finds the needed space, the filesystem can narrow its search to that subrange of the bitmap rather than searching the whole space.

86.3.5 Log-Based Systems

Logging has long been used in database systems to provide recovery after a system failure [Date, 1995]. The database periodically does a *checkpoint* of its on-disk data structures to ensure that they are in a

consistent state. Following the checkpoint, the database keeps a log of every change that it commits. The log is usually written serially onto a disk that is dedicated to the log. Thus, the log can be written quickly because the disk head is always within no more than a rotational delay from the next location to be written.

If the system fails, the log is used to do a *roll forward* operation on the database to bring it back to consistency. The roll forward works by going through the log and ensuring that all the changes that it lists are reflected in the on-disk database state. The time required to recover the database after a system failure is bounded by the frequency of checkpoints. By checkpointing the database and resetting the log every few minutes, the recovery time for a disk failure can be kept to a few minutes or less.

The idea of using a log to recover a database has also been applied to filesystems. Like a database, the filesystem periodically checkpoints its state. It then writes all changes after that point, both to its log and to the filesystem itself. When the log becomes full or a time limit is reached, the filesystem checkpoints itself again and resets its log. As with the database, the log is rolled forward after a system failure to ensure that all the changes made since the checkpoint are reflected in the filesystem. The log only needs to record modifications to the filesystem. While it has no effect on the speed with which data can be read from the filesystem, logging does introduce additional overhead when files are written. However, if the log is stored on a separate disk from the rest of the filesystem, writing to the log is seldom the limiting function on the speed with which data are placed into the filesystem.

Although a log provides fast recovery after a system failure, it does not provide the data recovery of mirroring or RAID that can recover from catastrophic disk failure. The reason that logging does not help with catastrophic disk failure is that data may be lost from parts of the disk that the filesystem thinks are stable and hence did not enter in the log.

A more recent filesystem design has taken the use of a log to its logical conclusion. Instead of using a log as an adjunct to an existing filesystem implementation, the entire filesystem is implemented as a log [Rosenblum and Ousterhout, 1992]. The log-structured filesystem is being used in commercial products [Wilkes et al., 1995]. The fundamental idea of a log-structured filesystem is to improve filesystem performance by storing all filesystem data in a single, contiguous log. A log-structured filesystem is optimized for writing, and no seek is required between writes, regardless of the file to which the writes belong. It is also optimized for reading files written in their entirety over a brief period of time (as is the norm in workstation environments), because the files are placed contiguously on disk. A log-structured filesystem places files created at the same time together on disk. If an application reads a set of files written at different times, the filesystem potentially will have to seek around on the disk to read them. Log-structured filesystems expect to avoid the need for many seeks when reading files because they assume that all files that are actively being read will reside in the system cache.

The underlying structure of a log-structured filesystem is that of a sequential, append-only log. The disk is statically partitioned into fixed-size contiguous segments that are generally 0.5 to 1 Mbyte. In ideal operation, a log-structured filesystem accumulates *dirty blocks* in memory. When enough blocks have been accumulated to fill a segment, they are written to the disk in a single, contiguous I/O operation. All writes to the disk are appended to the logical end of the log.

Although the log logically grows forever, portions of the log that have already been written must be made available periodically for reuse because the disk is not infinite in length. This process is called *cleaning*, and the utility that performs this reclamation is called the *cleaner*. The need for cleaning is the reason that the disk is logically divided into segments. Because the disk has reasonably large static areas, it is easy to segregate the portions of the disk that are currently being written from those that are currently being cleaned. The logical order of the log is not fixed, and the log can be viewed as a linked-list of segments, with segments being periodically cleaned, detached from their current position in the log, and reattached after the end of the log.

As a log-structured filesystem writes dirty data blocks to the logical end of the log (that is, into the next available segment), modified blocks will be written to the disk in locations different from those of the original blocks. This behavior is called a *no-overwrite policy*, and it is the responsibility of the cleaner to reclaim space resulting from deleted or rewritten blocks. Generally, the cleaner reclaims space in the

filesystem by reading a segment, discarding dead blocks (blocks that belong to deleted files or that have been superseded by rewritten blocks), and rewriting any live blocks to the end of the log.

Cleaning must be done often enough that the filesystem does not fill up; however, the cleaner can have a devastating effect on performance. One study shows that cleaning segments while a log-structured filesystem is active (i.e., writing other segments) can result in a performance degradation of about 35 to 40% for some transaction-processing-oriented applications. This degradation is largely unaffected by how full the filesystem is; it occurs even when the filesystem is half empty [Seltzer et al., 1995]. Another study shows that typical workstation workloads can permit cleaning during disk idle periods without introducing any user-noticeable latency [Blackwell et al., 1995]. The effect of filesystem cleaning on performance is still hotly debated.

Like a conventional filesystem that has a log associated with it, a log-structured filesystem must periodically do a checkpoint that synchronizes the information on disk so that all disk data structures are completely consistent. The frequency with which checkpoints are done affects the time needed to recover the filesystem after system failure. The more frequently they are done, the shorter the time it takes to recover. Checkpoints must also be taken whenever an application requests that one of its files be moved to stable storage. For example, an editor will usually request that a new version of a file be moved to stable storage before it deletes the old copy of the file. A conventional filesystem must be checkpointed whenever its logging disk becomes full. In the absence of application-requested checkpoints, a log-structured filesystem is only required to checkpoint a segment between the time that it is last written and the time that it is cleaned.

Recovery after a system failure is handled by rolling the filesystem log forward from the last checkpoint. In a conventional filesystem, the changes listed in the log are applied to the filesystem data structures. In a log-structured filesystem, the filesystem is the log, so rolling it forward simply means discarding any incomplete operations.

86.3.6 Versioning Systems

Users often want to retain previous versions of files, such as released versions of programs or documents. Usually they use a revision control utility that maintains a database which stores and retrieves the selected versions. Most version control systems only keep a complete copy of the original file. Each successive version is then stored as a set of differences from the previous version. Some version control systems operate by storing each version in a separate file, allowing fast and easy access to older versions (because it is just a matter of finding and reading the desired version). However, this method of version control is wasteful of space, especially if the file being versioned is large and the changes between versions are minimal.

The whole file copy version of revision control can be done by the filesystem itself. Each time a file is opened for writing, the contents of the old file are saved instead of being overwritten. The old file is kept around until the filesystem runs out of space. When additional space is needed for new files, the user must either explicitly delete unneeded earlier versions of files or request the filesystem to reclaim the space from the oldest of the earlier file versions. Log-structured filesystems are particularly good at providing versioning because they never overwrite data in files. Older versions of files can be retrieved by going backward through the log. Space reclamation in a log-structure filesystem is done only by the cleaner process. Thus, an application can control when old versions are reclaimed by controlling when the cleaner process runs. The cleaner process can also be customized to skip over older versions of selected files that the user wishes to retain for a longer period of time.

The user interface for accessing older files may simply provide a list of different versions that are available and allow the user to specify the one that they want. Or it may be more sophisticated, allowing the user travel in time. For example, the user might be able to request all the files making up a particular program as they existed at the release date for the program.

Another variant of versioning involves taking a *snapshot* of the filesystem. Logically, the snapshot represents a frozen copy of the filesystem as it existed at the time that the snapshot was taken. Snapshots

are typically compact, as they reference the filesystem on a copy-on-write basis. So, the snapshot only needs to make copies of the disk blocks that are modified. Thus, it is possible to take a snapshot of a filesystem every few hours during the day. Often, the snapshots are put in a location accessible to the users so that they can go retrieve older versions of their files without the intervention of a system administrator. Thus, if a user wrote a file in the morning and accidentally overwrote it in the afternoon, he could retrieve the original copy from the late-morning snapshot.

Defining Terms

Block I/O: The conversion of application reads and writes of records with arbitrary numbers of bytes into reads and writes that can be done based on the block size and alignment required by the underlying hardware.

Checkpoint: The writing of all modified data associated with a filesystem to stable storage (either non-volatile memory or the disk). A checkpoint ensures that all operations completed before the checkpoint will be recovered following a system failure.

Dirty blocks: In computer systems, modified. A system usually tracks whether or not an object has been modified — is dirty — because it needs to save the object's contents before reusing the space held by the object. For example, in the filesystem, a system-cache buffer is dirty if its contents have been modified. Dirty buffers must be written back to the disk before they are reused.

Filesystem root: The starting point for all absolute pathnames.

Indirect block: A filesystem data structure composed of an array of pointers to disk blocks used to locate the data blocks associated with a file.

Logging: Writing data to a file where existing data are never overwritten; the system thus modifies the file only by appending new data.

Logical block: The sequential fixed-size pieces of a file. The logical block associated with a given byte offset in a file is calculated by dividing the offset by the filesystem block size. For example, byte 20000 is located in the third logical block of a file residing on a filesystem with 8-Kbyte blocks.

No-overwrite policy: The filesystem never rewrites existing data in a file. New data is always written into a new location on the disk.

Physical block: The disk sector addresses associated with a logical block of a file. The filesystem finds the contents of a logical block in a file using the logical block number as an index into an indirect block to find the disk sector address holding the requested data.

Roll forward: Used to recover after a system failure. The operation of rerunning the update operations stored in a log file against a filesystem or database to bring it to a consistent state as of the last update completed in the log.

System-cache buffers: System memory used to hold recently used data. For example, in the filesystem, system-cache buffers are used to hold recently accessed disk blocks.

Further Information

A good overview of filesystems can be found in Chapter 3 of Silberschatz and Galvin [1994]. Most operating systems today use filesystem designs similar to those found in McKusick et al. [1996]. This chapter summarizes information on file layout on disk described in Section 2 of Chapter 7; filesystem naming described in Section 3 of Chapter 7; the traditional disk space management described in Section 2 of Chapter 8; and a log-structured filesystem described in Section 3 of Chapter 8.

87.1 Introduction

The advent of distributed systems came hand in hand with that of workstations and personal computers. The presence of many computers interconnected by a network opened up several new possibilities:

1. Every user could have personal dedicated computing cycles, while the network still allowed sharing data or devices through centralized file servers, printers, etc.
2. Reliability could be increased by arranging for computers to take over from each other in the case of crashes.
3. Performance could be increased by allowing software to make use of many processors in parallel.
4. Systems could grow incrementally by adding computers one at a time.

These possibilities triggered research in the new field of *distributed and network operating systems*. The first projects started in the middle 1970s, but the bulk of activity in the area took place in the 1980s. Now, halfway through the 1990s, the activity in distributed systems research seems to be declining.

A distinction between distributed operating systems on the one hand and network operating systems on the other has sometimes been made. A network operating system is essentially a centralized operating system whose components have been distributed over multiple nodes, whereas a distributed system is one in which this distribution, combined with replication, plays a role in achieving fault tolerance as well.

The distribution of components of an operating system over multiple nodes requires splitting up the traditional operating system into its constituent components, leaving only a small amount of machine-dependent and resource-protecting code in a *microkernel* [Accetta et al. 1986, Mullender et al. 1990, Rozier et al. 1988]. Microkernels can thus, to some extent, be viewed as a consequence of introducing network operating system or distributing operating system functionality.

Another distinction is necessary between distributed systems and *parallel* systems. In parallel systems research, the focus is very much on completing computations in minimal time, by exploiting the presence

of multiple processing nodes. Distributed systems also exploit parallelism, but there is at least as much concentration on fault tolerance.

Early research in distributed systems focused very much on functionality: better mechanisms for sharing, fault tolerance, communication, and parallelism. Later, attention shifted to keeping the same functionality while improving performance. The declining interest in distributed-systems research today may have a lot to do with the rapid increase in reliability of hardware components during the past 10 years.

87.2 Survey of Distributed Systems Research

In this section we survey the contributions that important projects have made for the distributed systems research community. Only a few of these projects have resulted in complete systems that are in use, but most of them have contributed from their key features to commercial operating systems. It is because of this that we do not survey the important projects one by one, but that, instead, we survey them area by area.

In the following sections we look at some of the important projects in the areas of naming, communication, transactions, and group communication. We do not discuss security in this chapter, even though fault tolerance properly implies security as well. The subject of security is in a separate chapter in this handbook. Research on distributed shared memory has also been left out: distributed shared memory (DSM) makes parallel programs run better, but does not contribute to fault tolerance — it does the opposite, if anything. DSM has been delegated to the parallel processing chapter.

87.2.1 Naming

87.2.1.1 Amoeba

Amoeba was a research project, initially only of the Vrije Universiteit, later also of CWI, the Centre for Mathematics and Computer Science, both in Amsterdam [Mullender 1985, Mullender et al. 1990, Mullender and Tanenbaum 1986, Tanenbaum et al. 1990]. Together with the V-system [Cheriton 1988], it was one of the first standalone distributed systems.

Amoeba has two levels of naming, which were both innovative. At the system's level, all objects are named using *capabilities*, which are managed in user space. A capability consists of four fields, as illustrated in Figure 87.1. The *service* field, also known as the service's *port*, identifies the service that manages the object. This field is used by the remote-operations protocol to deliver messages to a server process (see the communication subsection). The *object* field identifies the object to the service, and the *rights* (Rts) field indicates what operations the holder of the capability may carry out on the object. The *check* field prevents forging capabilities; it is calculated by the server, using a *secure hash* of object and rights fields, plus possibly a per-object secret *random number* maintained by the service.

Service ports are 48-b random numbers and, if you know a service's port, you can send messages to it. Services can be made private by keeping their ports secret.

Amoeba uses *request/reply* communication between *clients* and *servers*. A request contains a capability whose port names a service, while its remainder names an object maintained by that service. The Amoeba system finds a server for the service by broadcasting the port and waiting for location information from the servers (clients maintain a server-location cache to save broadcasts). When a server has been found, the request is sent to it; the server processes the request and returns a reply. Replies are addressed to the client's port.

FIGURE 87.1 Layout of an Amoeba capability.

In Amoeba, ports and capabilities are the names for services and objects, respectively. At the operating-system's application programmer's interface (API), they are the only names supported. For operating system and application software development, these fixed-length names are quite convenient.

For human beings, a directory service is available which maps hierarchical path names onto capabilities. A directory entry consists of a name and a *list* of capabilities. Normally, these capabilities all refer to the same object, but carry different rights; they are not all equally powerful. Depending on the rights in the capability of a directory, a client will be allowed to retrieve subsets of the capabilities in its entries. A powerful capability to a directory allows a client to see most or all of the capabilities, a weak capability allows it to see only small or empty subsets of, presumably, weak capabilities.

87.2.1.2 DEC Global Name Server (GNS)

The DEC global name server (GNS) [Lampson 1986] is an example of a design that was intended to be scalable to worldwide size and millions of nodes.

The members of the design team (Andrew Birrell, Butler Lampson, Roger Needham, and Michael Schroeder) had been involved with Grapevine, Xerox's name server [Birrell et al. 1982]. One could say that Grapevine succumbed under its own success: its popularity caused it to grow to a size for which it had not been designed, revealing several deficiencies in its scalability [Birrell et al. 1984].

GNS was designed to scale both in size and, as it were, in time. Scaling in size means that the naming database must be able to grow to billions of entries stored at millions of nodes. Scaling in time means that the name space can cope with large structural changes at any level in the naming tree (as, for instance, the unification of East and West Germany and the split up of Czechoslovakia).

The name space of GNS is necessarily hierarchical; no other structure could scale to the desired size. The hierarchy is not necessarily geographically determined; GNS has no problems coping with multinational organizations. Each directory entry is essentially a list of attribute *{name, value}* pairs. An entry */nl/utwente/cs/sape* could describe a user and have attributes such as **mailbox** and **certificate**. A user's public-key certificate could then be retrieved under the name */nl/utwente/cs/sape/certificate*.

Each directory has a unique *directory identifier* (DI). A directory is referred to by its parent via a *directory reference* (DR), which contains a DI. A *full name* in GNS consists of a DI and a *pathname*; the pathname is resolved starting at the directory named by the DI.

The naming database is organized such that every system can retrieve the directories it controls and all parent directories up to the global root by their DIs. However, the flat — and *pure** — name space of DIs alone cannot be used to find directories elsewhere in the naming tree. For this purpose, a DR not only contains the DI of the named directory, but also a list of servers that store copies of the directory. Server names are stored as full names also, and, if one is not careful, looking them up can result in endless lookup loops.

The designers of GNS recognized that availability of the name server is of crucial importance. Directories that are essential for the operation of a system must be available locally. As a consequence, directories near the root of the naming tree will be very highly replicated indeed; the root will be replicated everywhere. With such high degrees of replication, consistent update is not possible.

GNS, therefore, defines a form of loose consistency that may be formulated as follows: "If the supply of updates stops, there will eventually be glorious consistency" [Needham 1993]. This is achieved by making sure that updates have the following properties:

1. Every update eventually reaches every replica.
2. Two updates can be applied in any order and yield identical results (the *set* of updates matters, not the order in which they are made).
3. Updates are *idempotent*: applying an update twice has the same effect as applying it only once.

To achieve property 1, updates are distributed among the copies of a directory by a *sweep algorithm*: A sweep operation visits every directory copy, collects a complete set of updates, and then writes this set

*Pure names are explained in a subsequent section on naming (Section 87.3).

back to every copy. Property 3 implies that directory replicas need not keep track of the identity of every update received.

Achieving property 2 is subtle: Normally, you cannot update a directory before it has been created, and so the order of directory-create and directory-update operations does seem to matter. This is solved by the following ruse: If you update an item and it, or one of the directories on its path, does not exist, then that directory is created and updated, but it is marked *absent*. When a create operation is performed, the item is created if it does not exist, and it is marked *present*. Queries will only find and traverse paths with *present* items.

Furthermore, updates are *time stamped* so that conflicting updates yield the result of the one with the highest time stamp. This also causes the desired idempotency.

DEC GNS was used initially within DEC only, but since it has been adopted by the Open Software Foundation as part of its Distributed Computing Environment, it is becoming more widespread.

87.2.1.3 Domain Name Server (DNS)

The Domain Name Server [RFC-1035, RFC-1034] is the world's most widely distributed name service. It is used to name and locate hosts, services, and mailboxes on the Internet. It uses a hierarchical name space and pathnames with components separated by dots. Like postal addresses, but unlike most computer-related naming hierarchies, DNS puts the highest level domain at the end to give names, such as **amstel.cs.utwente.nl**, for a machine called Amstel in the Computer-Science Department of the University of Twente in The Netherlands.

Pathnames (at most 255 characters) are composed of a sequence of labels (of at most 63 characters) separated by dots (the character “.”). The root of the name space has an empty name, and so full names end in a dot. Relative names are resolved starting at the current domain. Names that cannot be resolved relative to the current domain are resolved as full names (by appending an imaginary dot).

DNS was designed to scale with the number of hosts and users in the global Internet. Most of the data in the system is expected to change very slowly, but small subsets of the name space may change rapidly, e.g., on the order of seconds to minutes, and DNS should be capable of keeping up with those changes. In doing this, however, DNS depends on the rapidly changing subset being small; if it were large, the update traffic would saturate the Internet.

DNS has a worldwide distributed implementation. Obviously, not all servers can be trusted. Clients can indicate which name servers they trust and name servers in this trusted set are always consulted before any others. Just like GNS, DNS is also based on the assumption that old data are better than no data; consistency guarantees are sacrificed to obtain maximum availability.

Queries are first sent to one of the local name servers. Servers only contain subsets of the name space, and so most names can only be resolved by consulting several servers. Normally, servers do not query other servers on behalf of clients, but they pass the partially resolved query back to the client and let the client resolve the query by iterating over multiple servers. Thus, clients can build up a cache that can tell them which servers serve a particular subdomain of the name space.

Each domain has an administrator who maintains a master naming database. The master database also identifies the master databases of each of the subdomains. An *authoritative* answer to a query is obtained by consulting master databases. Servers not only maintain master databases, but they also cache information from other servers. The system allows administrators to configure their servers to cache certain information from other servers permanently. This mechanism allows names to be resolved even though the domain cannot be reached or the authoritative server is down.

The naming database is maintained by a set of servers. A program which is called a *resolver* queries one or more servers in order to resolve a name. Clients give their queries to a resolver; thus, they do not have to iterate over multiple servers themselves.

Each internal node or leaf node in the name space corresponds to a *resource set*, which is stored by one or more name servers. The name servers make no distinction between internal nodes and leaf nodes (but resolvers do). A resource set contains zero or more *resource records*. A resource record consists of a *type*, a *class*, a *time to live* (TTL), and *type-dependent* (and sometimes also *class-dependent*) *data*.

Types and classes are represented by 16 b. Types and classes are defined per domain (including all subdomains). A new global type or class can only be introduced by the administrator of the root domain. This is the Network Information Center (NIC).

Important types are **A** for host addresses, **CNAME** for naming aliases, **HINFO** for host information [central processing unit (CPU) and operating system], **MX** for mail-handling agents, and **NS** for the authoritative name server for a domain. There are more types. Classes can be used to distinguish between different (sub)networks.

The time to live entry in a resource record tells name servers and resolvers how long it is safe to cache the resource record. When a resource record is cached, the authoritative server is not consulted, and so updates are not seen until the TTL has expired. Administrators must choose the TTL to balance between the two evils of increased name server traffic caused by rapid expiry of caches and increased inconsistency caused by slow expiry.

Queries are for {*name, type*} pairs. To find a mail handler for **sape@cs.utwente.nl**, one posts a query for {**cs.utwente.nl, MX**}. This query will yield a list of mail handlers, for instance:

```
cs.utwente.nl           preference = 0,
                        mail exchanger = utrhcs.cs.utwente.nl
cs.utwente.nl           preference = 10,
                        mail exchanger = driene.student.utwente.nl
utrhcs.cs.utwente.nl    inet address = 130.89.10.247
driene.student.utwente.nl inet address = 130.89.220.2
```

In this case, two possible mail handlers are produced, the first one being preferred over the second, and for each one, the **A**-type record is also produced — a useful optimization, since the Internet address will be needed to send the mail message.

The Domain Name Service must be one of the most heavily used distributed applications in the world (along with e-mail, the World Wide Web, and net news) and it works remarkably well. This is quite surprising given the sheer size of the worldwide DNS database today, and the unavoidable variations in professionalism of the administrators. The reliability and scalability of DNS show off the skill of its designers.

87.2.1.4 Plan 9

The group that designed Unix in the late 1960s and early 1970s has built a new operating system named Plan 9 from Bell Laboratories. It is an elegant little system available on CD for academic and noncommercial use [Harcourt 1995]. The Unix philosophy of using the filename space for naming everything* has been preserved and developed further which resulted in a very elegant design.

In Plan 9, each server can export a name space. Clients can refer to objects maintained by such a server by name. These name spaces are hierarchical and singly rooted. A process can access the name spaces of several servers by *grafting* them onto its own name space. This grafting is called *mounting*. A *mount table* maintains which server name spaces are mounted where in the naming tree. This resembles the way in which Sun Network File System (NFS) servers can be mounted in Unix.

But where Unix maintains a single mount table per machine, Plan 9 can have a mount table per process. When a process is created, it normally inherits its parent's mount table and then shares it with its parent. However, processes can also inherit a *copy* of the mount table so that mount and unmount operations of the parent are not visible by the child and vice versa. They do this by starting a new *process group*; Plan 9 maintains a mount table per process group. Here, the analogy with Unix file descriptors is enlightening: normally, children inherit the open files from the parent, but, if the parent so chooses, it can modify the set of open files between *fork* and *exec* (using *close*, *open*, and *dup*, usually). This can be done with mount tables in an analogous way (using *newpgrp*, followed by *mount* and *unmount* operations).

*The addition of networking and environment variables to Unix has diluted this philosophy to some extent.

As a result, each process group can create its own private name space. A parent can, for instance, *encapsulate* a child process by mounting an encapsulation server in its root directory before starting it. The encapsulation server can monitor all of the child's file input/output (I/O) requests and name space operations and process (some of) them in the parent's name space. Such encapsulation servers can be very useful for debugging, collecting statistics on application file usage, or for checking out imported software for anomalies such as Trojan horses.

The handle that specifies the server to be mounted is a *connection* in Plan 9 (identified by a file descriptor). Connections to local servers are essentially *pipes*; connections to remote ones are network connections.

There is a standard protocol for accessing the objects maintained by a server. This protocol contains operations normally associated with files: *open*, *close*, *read*, *write*, *seek*, etc. However, they need not be files. The Domain Name Server in Plan 9, for instance, can present itself as a file system that allows users to open and read a file such as **com/bell-labs/plan 9**. The mouse server implements a file **mouse** which is conventionally mounted as **/dev/mouse** and can be read to give the position of the mouse.

The Plan 9 window system, known as 8^{1/2},* illustrates the use of the Plan 9 name space very elegantly. The device drivers for screen, keyboard, and mouse are represented by files mounted in **/dev**: **/dev/bitblt** (for bit-blit operations to write to the screen), **/dev/keyboard** and **/dev/mouse**. The window manager, 8^{1/2}, uses these devices. When 8^{1/2} creates a window, it forks the child process that runs in that window, and gives the process a new mount table (by creating a new process group for it); 8^{1/2} then mounts itself as a service onto the new process's **/dev** where it implements new versions of **/dev/bitblt**, **/dev/keyboard** and **/dev/mouse**. A process running in a window, thus, does not read from the hardware mouse directly, but from one synthesized by the window manager. The window manager only gives it the mouse clicks and movements related to a particular window. A happy consequence of this organization is that the window manager can run as a window in itself. X-window applications run on Plan 9, through an X server running in an 8^{1/2} window.**

Plan 9 does not support a global name space in the sense that all objects have the same name everywhere. In fact, it makes explicit use of the fact that different objects have the same name in different places (e.g., **/dev/mouse** in different windows). Rob Pike, a principal designer of Plan 9, claims that, even in global naming schemes, sharing only becomes practical if everybody adheres to certain naming conventions. Naming conventions allow you to find things in the name space by guessing. Plan 9 uses naming conventions explicitly; the user who mounts **/dev/mouse** as **/dev/keyboard** should not be surprised if certain things fail to work properly.

87.2.2 Communication

It is likely that the research into efficient communication for distributed systems in the late 1970s came as a reaction to the cumbersomeness of the standards being developed by the International Organization for Standardization and the Consultative Committee on International Telephony and Telegraphy (CCITT). In any case, the early 1980s saw a race by a number of research groups to develop the fastest protocols for supporting remote procedure call. Early participants in the race were the V systems group at Stanford, led by Cheriton [1988]; and the Amoeba group at the Vrije Universiteit Amsterdam, where van Renesse et al. [1988] made their record attempts for fastest remote procedure call (RPC).

In the mid-1980s, Schroeder and Burrows [1989] thoroughly analyzed the performance of the RPC implementation of DEC Systems Research Center's (SRC's) Firefly multiprocessor. This resulted in a significantly better understanding of the design issues for interprocess communication. Hutchinson and Peterson [1988] at the University of Arizona then designed an extremely flexible framework for building efficient protocol stacks, the *x*-kernel. This is now widely used by researchers in a large number of research systems.

*Also after a movie.

**It was noticed that X servers were not designed to deal gracefully with resize operations of what they perceive to be their screen.

87.2.2.1 The V System

The V system, during its heyday, ran on SUN workstations connected by an Ethernet. It is believed that the multicast capability of Ethernets inspired a communications infrastructure that made heavy use of it for delivering requests to replicated services.

V uses remote operations for all communication. The common form is a remote operation between two processes, but there is also a form where a request is *multicast* to a set of processes with multiple replies as a result. Requests can thus be addressed to individual processes or to *process groups*.

Processes and process groups in V share a name space; clients sending requests to a process group multicast the request to all its members. The reliability of the multicast is that of the underlying hardware multicast mechanism (i.e., the reliability of Ethernet multicast). A few of the servers, therefore, may not receive the request, but this is viewed as normal and replicated services must take this into account. One, several, or all of the servers can return a response; this is up to the service designer.

The request and reply messages in V consist of a 32-byte *fixed-size message* with an optional *data segment* that can be as large as 16 kilobytes. A minimal message consists of just the fixed-size message. This separation of data into two kinds is useful because it can prevent quite a lot of copying and allows *scatter-gather* operations to collect the data to be sent or to deliver the data to be received. Amoeba does this too.

In the V system, a request is sent and a reply is received with one operation, called *send*. A single system call thus suffices to complete a remote operation, which, in V, is called a *message transaction*. All other interactions with the operation system take place using message transactions.

87.2.2.2 Amoeba

Amoeba [Mullender 1985, Mullender et al. 1990, Tanenbaum et al. 1990] was designed and implemented as a general-purpose distributed operating system combining fault tolerance to high performance. Its interprocess-communication mechanisms were based on the exclusive use of *remote operations* for all communication: In a remote operation, one process, the client, sends a request to a *service*; exactly one of the service's server processes receives and processes the request and returns a reply.

Requests and replies in Amoeba consist of two parts, a parameter area and a body part, very similar to V. Messages can be of arbitrary length so that a wide range of service types can easily be realized. Also, Amoeba implemented *at-most-once* semantics for its remote operations. Under this regime, requests will normally be executed exactly once. When a failure occurs, however, no reply reaches the client, while the request may not have been carried out at all, or it may have been carried out partially, or even completely. A failure can be caused by a crash of the server process, a crash of the server host or operating system, or a network failure. Sometimes, for instance, when a server cannot be reached, it is possible to provide exact feedback to the client about whether or not its request was acted on, but in most cases a client must find out using indirect means.

In this respect, Amoeba differs from both SUN RPC and V: SUN RPC implements an *at-least-once* strategy in that it retransmits a request until it gets a reply; in the process, it is possible that the request will be executed partially or wholly multiple times. V multicasts a request to multiple servers, with the possibility of multiple, parallel executions.

SUN RPC and V message transactions have the advantage of achieving a higher probability of success, but applications have to use requests with *idempotent* semantics; that is, semantics where executing a request partially or wholly several times, followed by a final, complete execution has the same result as exactly one complete execution. Reading from a file is an example of an idempotent operation: as long as you get the data in the end, semantically, it does not matter if you tried in vain a couple of times.

Amoeba's *at-most-once* semantics also allows nonidempotent requests to be used (e.g., transfer \$10 from my account to that of the Red Cross). The reason for putting so much emphasis on these subtle differences in semantics for different communication mechanisms is that one cannot move an application from a system that implements *at-most-once* to one that implements *at-least-once* with impunity. Program correctness can crucially depend on the difference.

Guaranteeing *at-most-once* behavior during communication with a replicated service requires some care: Suppose a request is sent to one of the servers, but no reply is received. The client may not retransmit

to a different server, because the absence of a reply does not indicate that the request was not acted on (the server may have crashed after executing it). At the same time, Amoeba does have to deal with *migrating* server (and client) processes, and so, although retransmissions may not be sent to a different server, it is possible that they are sent to the same server on a different *host*.

Making this work requires individual servers to be named. Therefore, in addition to the *service port* (see preceding section), server processes also have a *unique port*. When a client initiates a remote operation, the system locates a server by broadcasting a *locate message* that contains the server port. Servers respond with a message containing their location and their unique port. After selecting a server (typically by using the first response to arrive), the system commits to that particular server for the duration of the remote operation. If the server migrates, the new location can be found by broadcasting a locate message containing the server's unique port.

Mappings from server port to unique port to current location are, of course, cached. When a host receives a message for a port no longer serviced by it, it returns a not-here reply which invalidates the cache. When a not-here response arrives for the initial transmission of a request, the client may try to locate another server; when it arrives for a retransmission or a control message, the client must try to relocate the server at another address.

87.2.2.3 Firefly Remote Procedure Call

The Firefly was a shared-memory multiprocessor workstation built at the DEC Systems Research Center in the early 1980s. Its operating system, Taos, implemented a remote-procedure-call mechanism that was used for all communication. When one takes the speed of its processors into account, Firefly RPC may have had the lowest latency implementation of its day. Its performance was the result of carefully crafting the interactions among application threads, kernel threads, and interrupt routines. Schroeder and Burrows [1989] measured and analyzed the performance and their report has provided useful insights into high-performance communication architectures for later generations.

Firefly RPC allows request and reply messages of at most one Ethernet packet in size. The packets must also contain user datagram protocol (UDP) and Internet protocol (IP) headers, so the payload could not exceed 1440 bytes. Remote procedure calls with more data were split up into a sequence of RPCs. To take advantage of the multiprocessor capability of the Firefly, it was common practice to carry out large-data transfers with multiple parallel threads making multiple single-packet RPCs in parallel. The resulting throughput is a significant fraction of the capacity of the Ethernet, but it is achieved by loading five processors at each end almost to capacity. Amoeba, Sprite, and V achieved similar throughput on much less loaded uniprocessors (but with processors that ran three to five times faster).

In their paper, Schroeder and Burrows [1989] measured the performance of a *null RPC* (minimum-size request and reply) and of a *maxresult RPC* (minimum-size request, maximum-size reply). The roundtrip latencies for these were 2.66 ms and 6.35 ms, respectively. With four threads doing maxresult RPCs in parallel, the throughput is 4.65 Mb/s.

A remote procedure call can be separated into four activities, *marshalling*, *protocol processing*, *hardware processing*, and *synchronization*.

The code for marshalling parameters into and out of network packets is produced by a *stub compiler* and runs in the application address space. The time needed for marshalling depends on the complexity and size of the parameters to be marshalled. The latency of 6.35 ms for a maxresult RPC was achieved with a (Modula-2) **var array[0..1439] of char** parameter that took 550 μ s to marshal; that is, some 10 percent of the RPC latency. For complex parameters of the same size, the marshalling time can be a multiple of this. As more and more 10-Mb/s local area networks (LANs) are now being replaced by much faster networks, the significance of marshalling times will increase. It is, thus, worthwhile to invest in well-designed RPC type systems that use carefully tuned stub compilers.

The protocol processing consists of filling in IP and UDP headers and calculating the UDP checksum. This costs between 50 and 450 μ s, depending on packet size. UDP-checksum verification costs the same amount of time.

The hardware processing time can be divided in two parts: the time the driver takes to enqueue the packets and process the interrupt, and the time the hardware itself needs to transmit the packets. The driver time was some 240 μs , and the hardware time 210 μs for a minimum packet and 2880 μs for a maximum packet of 1500 bytes.

Finally, time is needed for synchronization: A user thread must be woken up when its data have arrived and, on the Firefly, an interprocessor interrupt is needed to activate the processor that operates the Ethernet device. The time for this is on the order of 350 μs , where the bulk of the time is used to wake up the receiving thread.

An important thing to notice is that the time the hardware uses to transmit the packets in an RPC call makes up only half of the RPC latency; the other half of the time is spent in software. With faster networks, the software overhead will increase even more. Protocols that spend a large amount of effort to optimize the use of the network hardware are, therefore, in many cases self-defeating. In local-area networks, it pays to use protocols that are as lightweight and simple as possible. The next section describes an excellent project on streamlining protocol stacks.

87.2.2.4 The x -Kernel

The x -kernel is a configurable operating system kernel designed specifically to simplify the process of implementing network protocols [Hutchinson et al. 1989]. Its structure allows flexible configuration of protocol stacks, if necessary even at run time, and combines this with excellent performance. This has made it popular in the operating systems research community and, since it became available to researchers, it has been incorporated into several distributed systems.

The x -kernel derives its flexibility and performance from several features. The first, and most important, is that there is a uniform interface to all protocol layers. This allows layers to be stacked arbitrarily (although there are, of course, many protocol combinations that make no semantic sense) and it allows one layer in a stack to be replaced by another.

Protocol layers can be *bound late*; that is, a protocol stack can be constructed at run time, when a connection is established. Late binding is exploited through the use of *virtual protocols*. Virtual IP (VIP), for instance, is a protocol layer that provides an IP interface, but uses dynamic binding to other protocol layers to achieve the actual transport. For destinations on the Internet, VIP would use IP itself, but for destinations on the local Ethernet, or dial-up telephone lines, other protocols can be used which provide the best possible performance for the media used.

Another technique exploiting late binding is decomposing protocols into sublayers. A single protocol often combines several functions, for example, *(de)multiplexing*, *fragmentation*, and *(re)transmission*. Sometimes, higher layers only require a subset of these functions. By decomposing a protocol in separate (dynamically bindable) sublayers, protocol stacks can be composed that have no unnecessary functions or header fields.

Using late binding, a transport protocol can use different lower level protocols, depending on which network is used to reach the destination. An RPC transport protocol, for instance, can use UDP/IP for its data transport when the destination has to be reached over the Internet, but use Ethernet packets directly when the destination is on the same Ethernet. Late binding allows network-dependent optimizations without any loss in flexibility.

Protocol layers in the x -kernel have a simple procedural interface. One thread of control can traverse several protocol layers in order to send or deliver packets. This reduces the number of context switches and enhances performance.

87.2.3 Transactions

87.2.3.1 Locus

The Locus operating system [Walker et al. 1983], developed at the University of California, Los Angeles, (UCLA) in the early 1980s, represents an important advance in distributed systems. It demonstrated that a standard Unix interface can be implemented on a fault-tolerant distributed platform, so that

unmodified Unix applications can exploit many of the advantages of an operating system that masks failures.

Two basic mechanisms in Locus are used to assist in failure recovery. One is a replicated storage facility, the other is a nested-transaction mechanism. Replicated storage allows data to survive system and media failures. Transactions allow applications to recover from system crashes.

The system does not replicate computations, so a crash will stop all application processes on a machine. Crash recovery is, therefore, necessary, but the transaction mechanisms can be used to leave the system in a consistent state when the crash occurs.

Replicated files are normally updated consistently, but, when a failure partitions the network, separating replicas, then updates are allowed on the accessible subset of the replicas. This can cause inconsistencies among the replicas. These are detected when the network becomes whole again and then reconciled.

The automatic reconciliation mechanism tries to repair inconsistencies. When it cannot do so for lack of relevant information, it refers the reconciliation up to a mechanism at a higher level. At higher levels, the reconciliation mechanisms become more specialized and distinguish between directories, mailboxes, database files, and other files. Semantic knowledge of a file type allows more reconciliations to happen. Remaining inconsistencies are referred to the human owner of the file, who is considered to be the ultimate reconciliator.

Locus provides nested transactions [Mueller et al. 1983] for failure atomicity. Nested transactions are transactions within other transactions. The outermost transaction is the *top-level transaction*. When a transaction commits, the resulting state is only visible in the enveloping transaction. When a top-level transaction commits, its effects and the effects of all committed subtransactions become globally visible.

Transactions modify files. Files opened as part of a transaction are locked by that transaction and unlocked when the transaction aborts, or the enveloping top-level transaction either commits or aborts. When a transaction commits, its locks are thus inherited by its supertransaction.

Partitions form a complicating factor in the realization of transactions, because the transaction coordinator may become separated from some of the files that form part of the transaction. Subtransactions, when they are separated from their callers, are simply aborted, and the supertransaction is informed. Transactions are also aborted when they are separated away from a file for which they hold a lock and no other replica of the file is accessible.

If the owner of a transaction is separated from the transaction coordinator, then the owner cannot find out the fate of the transaction until the partition is repaired. Thus, under certain circumstances, applications will be blocked waiting for communication to be restored. This blocking problem occurs in all transaction systems, but in some it is worse than in others.

Locus has been in use as a general-purpose fault-tolerant Unix system for a number of years and it has had a significant influence on many other systems, including Quicksilver.

87.2.3.2 Quicksilver

The Quicksilver project of the IBM Almaden Research Center [Cabrera and Wyllie 1987, Haskin et al. 1988, Schmuck and Wyllie 1991] has demonstrated that it is possible to build general-purpose support in distributed systems for fault tolerance. The design of Quicksilver was guided by the following principles [Haskin et al. 1988]:

1. Servers and other applications should be resilient to external failures and be able to recover the resources associated with failed components.
2. The operating system should not contain any code to aid the error recovery for particular servers: each server should contain its own recovery code.
3. The point in item 2 notwithstanding, the system should offer a systemwide uniform error recovery architecture to prevent ad hoc proliferation of error recovery mechanisms.
4. There is a mechanism that allows a client to perform a group of logically related activities in interaction with a set of different servers as a single *atomic* operation (all of the activities should succeed, or none).

With respect to fault tolerance, four categories of applications are recognized in Quicksilver: (1) Those that manage volatile internal state that does not have to be recovered in a crash; after a crash, the server is simply started afresh (example: window servers). (2) Servers that manage replicated volatile state; when a single server crashes, it can recover from one of its replicas; when all servers crash, e.g., in a systemwide power failure, they are started afresh (example: the Quicksilver binding agent where servers register themselves so that clients can find them; after a systemwide crash, all servers must reregister). (3) Servers that manage a recoverable state; that is, a state that may not be lost as the result of a crash (example: the file system). (4) Long-running applications that need periodic checkpointing to make their state recoverable (example: simulations).

Quicksilver offers mechanisms for *atomic transactions* to these applications, very similar to the atomic transactions of database systems. Application classes 1 and 2 only use a subset of the mechanisms described subsequently; the others can use the full set.

There are servers that make transaction-based recovery possible:

1. The *transaction manager* is replicated over all nodes and coordinates transaction commit by communicating with other transaction managers.
2. The *log manager* implements a recovery log for the transaction manager's commit log and for servers' recovery data.
3. The *deadlock detector* detects global deadlocks and resolves them by judiciously aborting transactions.

The messages used by clients to communicate with servers carry a *transaction identifier (tid)*. Servers thus know to which transaction a client request belongs; they can tag the state information they keep with the associated tids. The interprocess communication (IPC) protocols keep track of the servers addressed as part of a particular transaction so that the appropriate transaction managers can be invoked at commit.

The commit protocol messages are used as a mechanism both for transaction synchronization and for failure notification. Before commit, servers maintaining recoverable state make use of the log manager to store the recoverable data.

These three services make up the *recovery manager*: with this recovery manager, Quicksilver concentrates the recovery functions in one place; servers can use them or not use them, according to their needs; applications can choose between transaction-protocol variants, such as one-phase or two-phase, as appropriate to their function.

Servers communicate with their local recovery manager. The recovery managers at different nodes communicate among themselves to achieve atomicity or recovery.

Processes using transactions use the primitives *begin*, *commit*, and *abort* to manage them. *Begin* allocates a new tid and makes the invoked transaction manager the coordinator for the transaction just begun.

Transactions in Quicksilver typically have an overhead of between 5 and 100 ms above the time required for the operations that were done as part of the transaction.* This overhead is a very acceptable price to pay for an excellent, well-structured, fault-tolerant mechanism.

87.2.4 Group Management

The technique of replicating computations over multiple, independently failing processing nodes is not new. It has been in use for a long time in safety-critical real-time applications, such as fly-by-wire aircraft control. In real-time environments, the processors are dedicated to running the application and the replicated computation runs in lock step.

Important techniques for managing fault-tolerance for *non-real-time* applications by replicating computations in more relaxed synchrony were first explored by Birman [1985] in the ISIS system [Birman and Joseph 1987, Joseph and Birman 1986]. The ISIS project has inspired research on the theoretical

*On an RT-PC.

foundations of replicated computations, causality and virtual synchrony, and models of fault tolerance. This has made it one of the most important projects in distributed systems research.

87.2.4.1 ISIS

The goal of the ISIS project is to provide a system that automates the “transformation of fault-*intolerant* program specifications into fault-tolerant implementations” [Birman 1985]. This is done by taking a sequential program and replicating its code and data over a number of nodes.

The failure model underlying ISIS is *fail-silent*, that is, processors fail by stopping, not by giving wrong results. The surviving processes find out about the crash using a *failure detector* (which uses *time out* to detect processors that are no longer responding). Network failures are transformed into processor failures by declaring unreachable processors crashed; when the network is repaired, such processors learn about their crash and execute a crash-recovery protocol to synchronize themselves to the rest of the replicated computation again.

Computations manipulate *objects* which are made *resilient* by replicating them over multiple sites. *K*-resiliency means that the replicated object behaves like its nondistributed, sequential counterpart running to completion; that, when *k* or fewer replicas fail, the object continues to accept and process requests and does not block, and that recovering replicas can rejoin the group of replicas; and that, when there are more than *k* failures, the replicas restart when all failures are repaired.

Applications can group operations on objects into (nested) atomic transactions. For this purpose, the system provides operations for starting, committing, and aborting transactions and for locking objects.

Replicated objects coordinate their actions by *broadcasting* the relevant information. The broadcast operations are all *reliable*; that is, if one working replica receives the broadcast, all of them will (see subsection “Group Communication,” or Hadzilacos and Toueg [1993]). There are three types of reliable broadcast; they are called *Bcast*, *OBcast*, and *GBcast* and they differ in the *ordering* semantics; that is, in the way delivery of broadcast messages is ordered relative to the delivery of other broadcast messages.

The *Bcast* primitive achieves a total ordering of broadcast deliveries: if a broadcast message is delivered at one site before another, then it is also delivered before the other at all of the other sites. Such a broadcast operation is known as *atomic reliable broadcast* (see subsection “Group Communication,” or Hadzilacos and Toueg [1993]) for details).

The ordering semantics of the *Bcast* primitive are quite strong: two totally unrelated broadcasts are still forced to be processed in the same order everywhere. Relaxed ordering semantics can be implemented more efficiently. The *OBcast* primitive is one that does not induce a total order, but instead induces order only on broadcasts that could be related in a cause-and-effect manner. Such broadcast primitives, known as *causal broadcast*, use a logical-time stamp on each message and deliver them in increasing time-stamp order. The logical clock, from which the logical-time stamps are derived, is maintained independently by each process; it is incremented on every broadcast operation and always set to a value that is higher than that in received broadcast messages.*

Finally, there is a *GBcast* primitive which is used to inform the members of a broadcast group (that is, the collection of processes receiving the broadcast messages) of changes in the composition of the group. When a replica joins, it tells the rest of the group with the *GBcast* operation; when a replica crashes, one of the remaining processes will notice and send a *GBcast* message on behalf of the crashed process. The *GBcast* broadcasts are ordered with respect to other broadcast messages: a *GBcast* message informing of a crash will be delivered after all extant broadcasts (of any kind) from the crashed process have been delivered and a *GBcast* announcing the joining of the group will be delivered before any messages from the new member. Thus, *GBcast* messages are totally ordered with respect to group = membership changes; they are also totally ordered with respect to other *GBcasts*.

*Logical clocks are but one way of enforcing causality. Since clock values are rarely the same, most messages will still have a delivery order forced on them even if they are not causally related. A better way to maintain time stamps is the maintenance of *vector clocks* (see Hadzilacos and Toueg [1993] for details).

ISIS uses OBCast wherever it can, because the extra asynchrony allowed by it causes less waiting of processes for each other. It thus provides for more concurrency. Crashes are rare, so the GBcast operation will only rarely be invoked.

ISIS applications are built using an object-oriented style of programming. Each object can receive requests from other objects, which are processed and responded to. Each replica of a replicated object will receive all requests (via one of the broadcast primitives) and will also coordinate with the other replicas using broadcast messages.

Knowing which primitive to use in a particular situation is not trivial and ISIS has been criticized for this [Cheriton and Skeen 1993]. There are claims that transactions can be used to manage replicated objects just as well. This may be the case, but the fact remains that ISIS has been more influential in the development of distributed-systems theory and in increasing the understanding of concurrency, fault tolerance, and causality than any other system. The commercial success of ISIS in stock-market applications proves that ISIS certainly is not a toy.

87.3 Best Practice

Most computers are connected to networks now so that all systems are becoming, to a greater or lesser extent, distributed. Most system builders, therefore, need some knowledge of distributed systems in their baggage and distributed-systems research is becoming mixed with other research areas.

A major — probably the major — motivation for distributed systems research used to be the quest for dependable systems, systems that would tolerate failures in order to become more reliable than their parts. This quest has largely succeeded in that we now have a wide range of techniques and algorithms that work.

However, the subsequent integration of such techniques and algorithms in everyday systems has largely failed. We find two important causes for this. One is the reliability of current computer hardware, the other is the difficulty to change systems that have become accepted as standards.

Computer hardware is now very reliable. Disk manufacturers claim mean times between failure of 200,000 h and more so that very few disks ever fail during their operational lifetime. Because of this, in most situations, there is little need for replicated data storage. Highly distributed services, such as electronic mail and the domain name service, have their specialized fault-tolerance mechanisms. In the World Wide Web no fault tolerance exists at the moment, but some replication will likely occur in the next few years. It appears that only a small set of specialized applications and application domains need mechanisms that provide reliability beyond what networked, but nondistributed, systems can give today.

The other reason is that the world is currently burdened with a few operating system standards that cannot easily be extended with fault-tolerance mechanisms without major change. There is such an investment in existing software that any short-term changes are unlikely. In any case, the world's most widely used operating systems have many, more urgent problems to solve before increased fault tolerance will be noticeable.

87.3.1 Failure Models

Distributed systems can grow to a very large size. But large systems tend to be more complicated than small ones and the consequence of a fault is more difficult to control. One of the most desirable properties for a distributed system is that the failure of any component does not cause other components to fail as well.

Fault-tolerant applications must be distributed over multiple processors so that the crash of one or a few processors does not bring down the application as a whole. The state that the application maintains must be distributed as well, with enough added redundancy to recover from failures.

A *failure model* describes what failures are expected to occur. If it is assumed, for instance, that nodes fail by crashing, then recovery is usually simpler than when they can fail by producing erroneous data. In safety-critical applications, such as a fly-by-wire system or a system controlling railway signalling, the failure model typically assumes that a limited number of *arbitrary* failures may occur. Arbitrary failures are also known as *Byzantine* failures — after the problem of the Byzantine generals [Lamport et al.

1982] — or *malicious* failures. For other applications, however, a *fail-stop* model is common: processors fail by stopping. For a more detailed discussion of failure models we refer to Schneider [1993].

87.3.2 Naming

Without a naming mechanism to allow information sharing, a distributed system cannot exist. Names provide a level of indirection in referring to objects, processes, services, and data that is crucial when entities can be relocated or replicated.

Needham [1993] distinguishes between *pure* names and names of the other sort, *impure* names. A pure name only identifies, an impure name also guides: File names (`/usr/bin/sort`), URLs (<http://www.pegasus.esprit.ec.org/sape>), and IP addresses (130.89.181.118) are all examples of impure names, because they lead a system toward the location of the named thing. Impure names have the disadvantage that moving an object often requires renaming it.

Pure names do not have this problem. If a name only identifies, there is no relationship between an object's location and its name. Unfortunately, the scale of many systems makes the use of pure names impractical; in the best case, finding the location of an object requires an $O(\sqrt{n})$ search, where n is the number of possible locations [Mullender and Vitányi 1988]. This makes using a pure name from Europe to locate a file in Australia very expensive.

Distributed systems are, for this reason, forced to use impure names. However, some names are impurer than others. While one name space, because of its structure, fixes the location of objects in exactly one location, another name space might allow objects to move within an organization, a local-area network, or a group of nodes.

Name services should be among the most available services in a distributed system. Availability is an even more important requirement for a name service than correctness: When name resolution does not work, not much else can work either, but if a name service occasionally gives wrong or outdated answers, an application might be guided to the wrong place where the error will usually be discovered.

To be very available, a name service usually is highly replicated. Particularly, name services that are accessible worldwide tend to be enormously replicated. The list of top-level domains of the Internet, for example, is replicated at practically every site; that is, hundreds of thousands of times. Under such massive replication, maintaining consistency is impossible.

Most of the data in large name spaces is fairly static, so inconsistencies will be rare. Smaller name spaces, such as a name space for a distributed file system, will have much higher rates of change. Consistency is also more of an issue in such name spaces. Fortunately, the limited size and replication of such name spaces make it easier to maintain consistency.

Schroeder [1993] claims that “an object should have the same name everywhere” so that sharing becomes possible. Pike et al. [1993] have countered that sharing is facilitated primarily by *naming conventions*: Usually, sharing is achieved by knowing where to look for the shared object; that is, you guess most of its name; it is only sometimes that somebody tells you.

The hierarchical name spaces of Digital's GNS, X.500, and DNS are singly rooted; one name has the same meaning everywhere. Plan 9 [Presotto et al. 1991] uses a two-level naming scheme. One name space names *servers*, each server maintains a local name space, and applications construct a name space by *mounting* some of these servers in a private name space. The servers are named in a global name space (which Plan 9 defined somewhat ad hoc), and conventions play an important role in deciding where users are expected to mount certain servers. The result is a name space in which, for the objects that matter, objects have the same name everywhere.

Amoeba [Mullender et al. 1990] was one of the few systems to use pure names. In this system, services were named using 48-b *ports*. Ports were located using broadcast. As a result, Amoeba did not scale to a size beyond a local network composed of bridged Ethernet segments. Within an Amoeba system, however, objects could be arbitrarily relocated, and processes could be migrated without naming inconsistencies.

An excellent example of a very large-scale name service is the design of Digital's Global Name Service [Lampson 1986]. The update operations in GNS were carefully chosen to be commutative and idempotent.

Commutativity lets only the set of updates determine the state of the naming database, not the order in which they are applied. The idempotency allows updates to be carried out more than once without effect in the state, so that the distribution of updates does not have to happen too carefully.

87.3.3 Communication

The primary function of the interprocess communication mechanisms in distributed systems is to transport information between processes on the nodes of a distributed system. Processes on the same node can also interact in other ways, such as through shared memory. But even within a node, it is useful to use network communication mechanisms between processes. Doing this achieves three things:

1. The system can be reconfigured in such a way that processes, previously running on one node can run on different nodes.
2. Crashes of one process do not have to bring down another.
3. The message-passing interface between processes provides a convenient place for carrying out sanity checks on the data transmitted.

In effect, the interprocess communication mechanism also functions as a *fire wall* that protects one process from bad influences from another. This fire-wall function is an important one in distributed systems, because it helps to get the property of independent failure, it helps to hide the location of a process or function and, thus, it helps the realization of fault tolerance.

It is almost always assumed that networks can fail. They lose and corrupt packets, and sometimes network links may fail altogether. Corrupted packets are detected by making use of checksums; and they are then treated as lost.

Recovery from lost packets can simply be done by numbering the packets, detecting gaps in the number sequence of received packets, and requesting retransmission. When a connection is set up, packet numbers are usually initialized at zero. It is important that packets from one connection cannot mistakenly be received as part of another. There is this risk especially when a connection is set up to replace one that broke in a host or network crash.

Host and network crashes bring about fundamental uncertainty about the state of the system in the surviving nodes. When receipt of messages is acknowledged by a receiving host which crashes, can the sending host deduce from the receipt of an acknowledgment that its message was acted on? The answer is no, because the recipient may have crashed the microsecond after sending the acknowledgment. Can a host deduce anything from *not* receiving an acknowledgment then? Again, the answer is no; the acknowledgment may have been lost.

When an operation is executed remotely, acknowledgments for the arrival of packets or messages are not useful. The only truly useful information is a message that the operation was completed. This is the *end-to-end argument* of Saltzer et al. [1984] who stated that, in a protocol stack, lower layers can never be used to recover from all of the faults and crashes of higher layers. In other words: the highest level of protocol, which necessarily is in the application domain, must have some error recovery if the application is to be fault tolerant.

The opposite is not true; on the contrary: higher layers of protocol are always used to recover from some of the faults in lower layers: when an IP packet is corrupted, TCP will do the recovery.

The end-to-end argument suggests treating the messages belonging to the execution of a remote operation as belonging together in a single protocol unit, directly used by the application, and this is exactly what most distributed systems do. The protocols that handle such groups are known as *message transaction* [Cheriton 1988, Mullender and Tanenbaum 1986], *remote operations*, or *remote procedure call* [Birrell and Nelson 1984].

The basic idea is that activities in a distributed system are structured around the notion of sending a *request* to carry out an operation to a server and receiving a *response* from that server when the operation is completed. The response serves as the fundamental acknowledgment that the request was carried out. Acknowledgments for message arrival may also be used, but they should be viewed as optimizations only.

FIGURE 87.2 Structure of remote procedure call.

Amoeba [Mullender et al. 1990] and the V system [Cheriton 1986] were among the first systems to enter the race for implementing remote operations with very low-response times [Nordmark and Cheriton 1989, van Renesse et al. 1988]. The race was joined by many others, but the most interesting work was published by Schroeder and Burrows [1989], who gave an excellent account for where an implementation spends its time and Hutchinson et al. [1989] who built a framework for high-performance protocol stacks that is still being incorporated in many research systems and some commercial ones.

When remote operations are adorned with a mechanism to pass parameters between caller and callee, one has the ingredients for remote procedure call [Birrell and Nelson 1984]. The mechanism is illustrated in Figure 87.2. On the left is a normal procedure call: The procedure is called at point A by the processor's *call-subroutine* instruction sequence. At point Z, the called procedure returns control to the caller, using the processor's *return-from-subroutine* instruction sequence.

On the right of Figure 87.2, one can see how remote procedure call works. In the address space of the caller, a *client stub* is linked in, and in the address space of the called procedure, a *server stub* is linked in. On the server side, the server stub begins executing at P; it announces its presence to its clients (presumably via a name server, we shall discuss the mechanisms for this presently) and, at point Q, it asks the system for incoming client messages and blocks.

On the client side, the caller calls the stub at point A, just as it would have called the procedure in the normal procedure-call case. The stub retrieves the parameters from the stack, puts them in a request message, and sends that to the server at point B. This is called *parameter marshalling*. After marshalling, the client stub blocks itself awaiting the reply message.

This unblocks the server stub. The server stub *unmarshals* the parameters — it takes the parameters from the request message, and pushes them onto the stack — and calls the remote procedure at C, using the standard calling sequence. The procedure returns at point X, the server stub retrieves the return parameters, puts them in a reply message, and sends it back to the client at point Y. The server stub does not block at this point. It carries out some clean-up operations, if necessary, and, at point R, it could jump back to point P or Q to await the next client request.

The arrival of the reply message unblocks the client stub, which then retrieves the return parameters for the reply message and it uses them to make a normal return from procedure at point *Z*.

From the point of view of the calling program and the called procedure, calling a remote procedure appears to be exactly the same as calling a conventional one. This is not the case, however. When remote procedures are used across address space or even machine boundaries, crashes need only affect the caller or the callee. Thus, when remote procedures are used callers must anticipate the possibility that the procedure does not return a value as expected, but that a crash, or communication failure is reported instead.

Another difference between calls within an address space and calls between address spaces is that in the latter case, it is pointless for caller and callee to exchange a pointer to an object in a call. A pointer refers to a different thing in a different address space. Remote procedure call thus imposes restrictions on the kinds of parameters that can be passed that normal procedure-calling sequences do not have.

When remote procedures are used between hosts with different architectures, or between processes written in different programming languages, stubs can be used to convert between the different representations that the parameters may have. This conversion can only be carried out when the parameter types are known.

Given a procedure *signature*,* client and server stubs can be built automatically from an interface definition specified in an *interface definition language* (IDL). Interface definition languages are an almost vital tool in building large distributed applications. They specify the interfaces at module boundaries, the fire walls where type checking is so very important.

Examples of IDLs are HP/Apollo's NCS which is now part of the Distributed Computing Environment (DCE) of the Open Software Foundation, SUN RPC [Sun 1985], Mercury [Liskov et al. 1987], Flume [Birrell et al. 1984], Courier [Xerox 1981], and Middl [Roscoe 1994].

In client/server settings, it can be useful to put some of the server functionality in the client stubs. The client stubs then no longer provide a direct mapping of client calls to the stub and remote calls to the server's procedure. When this is the case, we use the term *clerk* or *agent* rather than the word stub.

Clerks can help with the implementation of automatic rebinding, should a server crash [Schroeder 1993]. The clerk provides a good point for this, because semantic knowledge of the service's behavior can be built into it. Alternatively, clerks can try to provide a (degraded) service while a server is down. A name-server stub, for instance, can provide information for its cache which may be obsolete; clients are better off with old data than no data in this case.

Clerks can also help with performance improvements through caching. A client-side cache for a file server can be viewed as a clerk for the file server. Clients make calls to the clerk and the clerk passes some of them on to the server.

87.3.4 Binding

In a distributed system, services do not always have to reside in one location. Reconfiguration can cause services to be moved, or a service can be restarted on a different machine when the original crashes.

Binding and naming are closely related. Binding is the process of mapping the name of a *service* onto a connection with a provider of that service, a *server*.** The service can be anything: a mail-delivery service for a particular user, a service that can get a file printed nearby, or another part of a distributed application. A name can vary from something as specific as an IP address plus port number to something as vague as the nearest printer that can render PostScript.

Thus, when a binding is created, a specification of a service is converted into a connection to a particular server. A service can be characterized by two things: one is what it can do for its clients, the service's *function*, the other is how its clients can make it do those things, the service's *interface*.

*The signature of a procedure is the procedure's name and type: the number and type of parameters and the type of the return value.

**We exercise some care in distinguishing *service* and *server*. Service represents the abstract notion of a set of operations that can be carried out on a set of objects. Server represents a processing entity (a process or processor) that can carry these operations out.

A service has a *state* and, through the service interface, clients can query or modify that state. The interface describes the syntax and semantics of the interactions between client and service. The semantics describe how the operations that the service can carry out modify the state and what values will be returned.

In the binding process, a service is usually sought that has a particular interface and a distinguished state: When delivering mail, we look for a mail service whose state indicates that it works for a particular user; when connecting to a file service, we want one whose state contains the file we aim to read.

A mechanism is needed to *name* the things one binds to, explicitly or implicitly. An example of explicit naming occurs in binding to an NFS file server, the name of the service corresponds directly to the server.* Slightly more implicit is the way one names a mail box, `sape@cs.utwente.nl`, for instance. This name does not directly name a particular server, but a *set* of them. During the binding process, the servers in the set are tried until a binding is established. Bindings can be named even more implicitly: The ANSA Trader [API 1989] allows associative names; for instance, one can name a printer with certain properties: it should be on the fourth floor and it should be capable of printing dvi files.

The binding process consists of three stages. First, a set of servers must be found that implement the service. Then, a connection must be created between client and one of these servers, and finally client and server must initialize their mutual binding state. We shall discuss these in turn.

Finding a server for a service can be done by clients and servers themselves, or with the help of a separate *binding agent*. The V system [Cheriton 1988] and Amoeba [Mullender 1985] are examples of systems where clients locate servers without a separate binding agent. Both systems were designed for use in a local network, and clients found servers by *broadcasting* for the service on the local network. In the V system, service requests were broadcast and, if there were multiple servers for the service, it was up to these servers to decide which one would respond; in some cases all servers would respond. In Amoeba, before a request was sent a *locate* message was broadcast and the first server to respond would be chosen to send the request to.

In far-flung systems, usage of broadcast for the location of a server is not doable. A service with the function of broker is needed to bind clients to servers. The idea is that servers, when they become active, notify the broker service of the service they perform and their location. Naturally, most bindings between clients and servers take place within a node or a local network, but bindings that span the globe occur too. For efficiency, it is common practice to make use of a hierarchy of brokers in such a way that the brokers needed to bring about a binding are as near to client and server as they are to each other.

Binding in large systems cannot be done by making use of a pure** name space for the identification of services. Brokerage is best done with a hierarchically organized set of broker services. The Domain Name Service [RFC-1035, RFC-1034] is the almost universally used broker service at the moment.

Binding to the broker presents a bootstrapping problem that is solved by putting the broker at a well-known address, or providing the addresses of a set of brokers in a (well-known) file.

After a server has been found, the second step in the binding process is setting up a connection. This is straightforward and does not need further discussion.

When a connection exists between client and server, negotiation can take place concerning protocol parameters, such as packet sizes, window sizes, network data representations, etc. A step that is becoming increasingly important now that most hosts are connected to the Internet is carrying out an authentication handshake and, if necessary, establishing encryption keys. When all of this is done, a binding exists, and clients can start sending requests to the server.

Client or server crashes result in broken bindings. The role of a server is usually such that, when a client crashes, no attempt is made to create a new binding. The server may, of course, use the report of a broken binding to clean up the connection state. When a server crashes, a client may attempt to bind to another server for the same service in order to be able to continue getting service.

* Provided the server is up; if it is down, binding will fail.

** Cf. [Section 87.3](#) subsection on naming.

87.3.5 Transactions

Process and node crashes can leave the state of a distributed computation in an inconsistent, unknown state. When a process in a distributed application crashes, the others must find out where that process got to when it crashed in order to do recovery. Consider, as a trivial example, a request made to the bank's computer to transfer a sum of money from one account to another. If that computer fails, it can leave the database in at least four states: (1) nothing was done yet, (2) the money was removed from one account but not yet added to the other, (3) the money was added to one account but not yet removed from the other, and (4) the transaction was completed.

Without maintaining extra administration, it is not possible to find out how much of a mess a crashed process leaves behind in a system. This administration could be maintained in an application-dependent manner, but, as it turns out, there are excellent general-purpose mechanisms as well.

In this section and in the next, we discuss these general-purpose mechanisms. In "Group Communication," we show how computations can be replicated and how communication can be structured so that all replicas are guaranteed to receive all relevant information in the correct order.

The mechanisms discussed in this section are based on the notion that distributed applications query and modify a distributed database of some sort and that they structure the update operations in such a manner that, after a crash, a consistent state of the system can always be restored.

The database is organized in such way that updates on it succeed completely or fail completely; that is, if an update fails, it leaves the database in the state it had before the update started. We can call such updates *atomic updates*, because they appear to happen all at once.

Atomicity is also an important structuring mechanism for the management of multiple simultaneous updates. Suppose that, in our bank-account example, two updates on a single bank account happen simultaneously, one depositing and one withdrawing. The updates both proceed by reading the balance, computing the new balance, and writing it back. When the two updates both read before the first writes back, the balance of the account becomes inconsistent, a euphemism for wrong.

The update consists of a group of operations that belong together (a read operation and a write operation, in the example). We call such a group a *transaction*. Database systems usually have operations *transaction-begin* and *transaction-end* to allow applications to indicate the grouping.

By making transactions be — or appear to be — atomic, the effect of simultaneous transactions is to *serialize* the updates; that is, the result would be exactly the same if one transaction finished before the other started. Thus, applications do not have to be aware of concurrent transactions, which makes programming them much simpler.

Transactions have, what is often called, the ACID property: they are *atomic*, *consistent*, *isolated*, and *durable*. By consistency, we mean that, provided each transaction by itself maintains consistency, the combination of multiple, concurrent transactions also maintains consistency. Isolation means that transactions do not interfere with each other, they are serialized so that the effect is that of one transaction finishing before the next one starts. Finally, durability means that the updates made by a transaction last: when a transaction finishes successfully, all updates are safely stored on stable media.

So far, all of this is just as relevant to centralized systems as it is to distributed ones. In distributed systems, however, the additional problem is to realize atomic transactions also in the face of failures: host crashes, communication failures, or media failures.

To deal with media failures, data can be replicated. Full replication can be done by *disk mirroring*: storing all data on two, identical, disks. Another popular replication technique is redundant array of inexpensive disks (RAID) [Chen et al. 1988]. Here, a parity disk is added to a small number of disks (say, four) and the blocks on the parity disk consist of the exclusive-or of the corresponding blocks on the data disks. When (a block on) a single disk fails, its contents can be calculated by computing the XOR of the corresponding blocks of the other disks.

Node crashes or communication failures can make it impossible to finish a transaction successfully: a node may store information that is needed to complete the transaction, for instance. Transactions that cannot be completed are *aborted*. Those that can are *committed*.

Atomicity of transactions, like so many other things in computer science, is made possible by introducing a level of indirection: a pointer refers to the data. Updates are made by copying a portion of the databases and modifying it. The updates are then committed by changing the pointer to point to the modified data. The rewrite of a single pointer is an atomic operation (Lampson and Sproull [1979] describe how atomic operations can be implemented on replicated disks); since all data are accessed via the pointer, the whole database undergoes atomic modification as well.

In distributed systems the technique for atomic update is quite similar to the one previously described. The pointers, of course, must be implemented as {server name, data pointer} pairs so that they can refer to remote objects as well as local ones.

A technique known as *two-phase commit* (2PC) works as follows. The database is distributed over a number of servers. A client, wishing to make an update, contacts one of the servers and issues a transaction-begin operation. The client receives a *transaction identifier* and makes read and write requests, labeled with the transaction identifier, to the various database servers. One of the database servers becomes the transaction coordinator; it forms the point where the decision is made to commit or abort the transaction.

All the database servers make their updates as described earlier: both the old state and the new state are stored and the flipping of a pointer will switch between the old and the new contents of the data involved in the transaction. In the distributed case, a *lock* is added. This lock is used to synchronize the commit operations of all of the participants: first all servers lock the data, denying access from outside the transaction, then the pointers are flipped, committing each participant to the transaction's updates, and finally, the participants unlock the data again.

Two-phase locking uses this mechanism as follows. If the client aborts the transaction, the coordinator only has to tell the other servers that the transaction has been aborted. They can then do garbage collection. If the client asks for a commit, the coordinator sends a prepare-to-commit request to all participants. The participants write all buffered data to disk to get ready to flip their pointer, they lock the database, and they send an *okay* reply to the coordinator. Naturally, if a server or a network connection fails, no okay message will be forthcoming.

When the coordinator has received the okay from all participants, it commits the transaction locally (by flipping the pointer) and sends a commit message to all participants. The participants also commit and they can unlock.

This is how transactions are committed using 2PC in normal failure-free circumstances. Let us now consider what havoc failures wreak. Suppose a participant crashes before sending its okay message. In this case, the coordinator will receive one okay too few and refuse to complete the commit. The coordinator will broadcast an abort message to the participants, which leaves them in the state before the transaction started. Now, suppose that the participant crashes after sending the okay. Sending an okay implies that both old and new data are on stable storage, so the transaction can (and probably will) still be committed. The coordinator commits and broadcasts the commit message. When the crashed participant comes back up, it finds its database still locked (the locks are also on stable storage) and it can find out from the coordinator, or another participant, what the outcome of the commit operation was.

Now, suppose the coordinator fails. If it fails before sending the prepare message, the transaction can be aborted without further ado. If it crashes after sending out (some) of the prepare messages, the remaining participants can compare notes. If there is at least one that has not responded okay, then it is safe to abort the transaction. But if all remaining participants have sent their okay, then it is not known whether or not the coordinator had already committed internally. The other participants can only wait until the coordinator comes back up. If the coordinator crashes after sending at least one commit message, then, of course, the other participants can finish the transaction, knowing the coordinator must have already committed internally.

Two-phase commit, thus, can *block* on the failure of the coordinator. The probability that this happens is reasonably small, because the time between receiving the last okay and sending the first commit can be kept quite short.

A technique that further reduces the probability of blocking requires an extra round of communication and is therefore known as *three-phase commit* [Skeen 1982].

Two-phase and three-phase commits are important techniques for making updates in distributed databases atomic. In addition to atomicity mechanisms, however, we also need mechanisms to *serialize* the updates; that is, make sure that the effect of two concurrent updates will be the same as that of either first doing one and then the other, or vice versa.

There are two important approaches to causing serializability, one is based on locking out all access that can cause nonserializable access, the other is to check for serializability at commit time and aborting in case of nonserializability. These approaches are widely known as *pessimistic* and *optimistic*, respectively. Locking out access is pessimistic because it also locks out some accesses which, in retrospect, could be serializable after all; checking at commit time is optimistic because it is used under the assumption that serializability conflicts are rare.

A serializability conflict between two transactions can only occur when they access the same data; otherwise, they are independent and it is obvious that, carrying out the two transactions one after the other or concurrently makes no difference. One transaction only influences another if the former writes data that the latter reads.

This observation suggests a simple test for making the decision whether to allow a transaction to commit in an optimistic setting [Kung and Robinson 1981, Schlageter 1981, Strom and Yemini 1985]: When a transaction is about to commit, a test is made to see if the intersection of the data read by the current transaction (its *read set*) with the data written by transactions that committed after the start of the current transaction is empty. If it is empty, the current transaction has not read any data that was modified afterwards; therefore, the current transaction would have proceeded no differently if the other transactions had already committed before the current one started and, thus, the current transaction is serializable after the other ones. Transactions under optimistic concurrency control are serialized in commit order.

In pessimistic concurrency control, locking is used to make sure that no transaction proceeds beyond the point where serializability is endangered.

A perfectly safe way of locking is to acquire all of the necessary locks when the transaction begins and to release them when it commits or aborts. This is not possible, however, when it is only during the course of the transaction that the dataset accessed by the transaction becomes known. Transactions thus need to acquire locks dynamically. Locks cannot, however, also be released dynamically, at least not carelessly: Suppose one transaction first modifies datum *a* and then datum *b*, while another transaction does the same in the opposite order. If both transactions acquire and release locks on datum *a* or *b* before acquiring the locks for the other datum, they deadlock.

A technique for dynamic locking that guarantees serializability is *two-phase locking* (2PL), not to be confused with two-phase commit: every transaction consists of two phases, one in which locks are acquired and one in which they are released. No lock may be acquired if even a single one has already been released. As long as it is not known whether more locks are needed, none should be released, so that many transaction systems do not release locks until commit (or abort).

The alternatives of total success or total failure that transactions provide are not always desirable. When a participant in a transaction fails, it is sometimes possible to use an alternative participant without having the whole transaction abort. Mechanisms that support splitting up large transactions into smaller ones are *nested transactions* [Reed 1978]. Subtransactions can commit or abort inside the main transaction. When the main transaction aborts, however, all of its subtransactions are aborted as well. When it successfully commits, however, only the committed subtransactions stay committed.

The ACID properties of transactions make structuring fault-tolerant systems much easier. Transactions have not only been found useful in distributed and centralized databases, but also in distributed file systems and even in operating systems. Examples of systems with atomic properties are Argus from MIT [Liskov and Scheifler 1983], Clouds from Georgia Institute of Technology [McKendry 1984], the Amoeba file system [Mullender and Tanenbaum 1985], Camelot and Avalon from Carnegie-Mellon University (CMU) [Eppinger et al. 1991], and Quicksilver from IBM Almaden [Haskin et al. 1988].

For more information on distributed databases and transactions we refer to books by Bernstein et al. [1987] and by Gray and Reuter [1992]. A compact introduction to distributed transactions can be found in Weihl [1993] and a rigorously formal treatment in Lynch et al. [1993].

87.3.6 Group Communication

In the previous section, we showed how distributed databases can be kept consistent by using transactions that atomically transform the database from one consistent state to another. Many applications can benefit from this way of structuring updates, but not all.

Transactions keep stably stored data consistent, but when applications must manage dynamic data structures consistently and reliably, or deliver exactly the same information to multiple locations, other mechanisms are required.

Group communication forms a class of mechanisms that allows delivering messages to groups of processes or machines. We shall see that group communication allows many more semantic variations than point-to-point communication and that different forms of group communication can be used to solve problems in very different settings.

As a first example, consider the design of a safety-critical control application, such as a fly-by-wire control system. Safety-critical systems must continue to function in the face of processor and communication failures of all kinds, not merely crash failures, but Byzantine failures.

The way in which this is typically done is to run the identical control program on a number of processors. Each of the processors starts out from exactly the same state and is fed with exactly the same information. Consequently, each of the processors will normally produce exactly the same results. These are compared and, if one result differs from the others, the processor with the dissenting result must have failed.

The minimum number of processors for this approach is three — with two processors, when the results differ, one cannot tell which one is wrong — and such an arrangement of three processors is known as *triple-modular redundancy* (TMR). When more processors are used, the configuration is usually labeled *n-modular redundancy* (NMR).

An NMR-based control system will get its inputs from a number of sources (*sensors*) and deliver its outputs to a number of destinations (*actuators*). Each of the sensors will deliver its data to all of the processors, but this, by itself, is not enough to guarantee that the processors will run in lock step. Additionally, all processors must receive the data from the sensors in exactly the same order.

The broadcast system that delivers sensor readings to all processors is known as an atomic broadcast system, because it happens indivisibly: no other broadcast or message delivery can break in and be delivered between the reception of the broadcast by one processor and another.

Another example of an application that uses broadcast is the system that broadcasts the Internet news worldwide. Anyone, anywhere in the world, can send messages and everyone, anywhere, can read them. A news message is labeled with a broad subject classification, the *news group* and with a *subject line* that is supposed to give some clue to its contents. When somebody reacts to a message, they send a *follow-up* message which contains a reference to the original message. Discussions on news net can create long chains of follow-up messages.

When reading the news, it makes sense to read messages in the order in which they follow one another up. It can be confusing to read somebody's reaction to something you have not seen yet. For news delivery, a broadcast system that maintains *causal order* makes much sense. Two messages sent independently can then arrive at different sites in a different order, but a message that causes a follow up must be delivered before the follow up everywhere.

Replicated systems that must withstand crash failures can use broadcast protocols, such as causal broadcast, to organize the communication between replicas and with clients. The participants are then organized as a group of processes, and both communication and membership changes are ordered according to the semantics chosen.

The earliest system that experimented with group communication was ISIS, developed at Cornell under the supervision of Birman [1985]. The idea in ISIS and in follow-up projects worldwide is to create, through reliable, ordered communication an illusion of synchrony: *virtual synchrony*. Examples of other well-known projects that make use of group communication and virtual synchrony are Paralex [Babaoglu et al. 1991], Relacs [Babaoglu et al. 1995], Delta-4 [Veríssimo et al. 1991], and Horus [van Renesse et al. 1995].

Broadcast protocols can be classified according to their ordering semantics, their reliability semantics, and their timing semantics. Ordering is established by making message *reception* and message *delivery* separate operations, so that after a message has been received it is possible to postpone delivery until other messages can be delivered.

Basically, a broadcast protocol is reliable when the following properties are satisfied: (1) If a correct process broadcasts message m , then all correct processes eventually deliver m (*validity*); (2) if a correct process delivers m , then all correct processes eventually deliver m (*agreement*); (3) for any message m , every correct process delivers m at most once, and only if some process broadcasts m (*integrity*) [Hadzilacos and Toueg 1993].

Reliability, as defined here, is only concerned with *correct* processes; these are the processes that correctly and completely execute the reliable-broadcast protocol at hand. It is thus possible that a process delivers a message m and crashes immediately afterwards so that no other process delivers m . This process may even act on the information in m before crashing. In some cases this is undesirable and, in such cases, reliability can be extended with *uniformity*, where the agreement rule changes into: if a process (correct or not) delivers a message, then all correct processes do so too; and the integrity rule changes into: any message is delivered to a process (correct or faulty) at most once, and only if it was broadcast by a process (correct or faulty).

The ordering semantics can be classified as (1) *no order*; (2) *first-in-first-out (FIFO) order*: if a process broadcasts m before m' , then no correct process delivers m' before m ; (3) *causal order*: if the broadcast of m causally precedes* the broadcast of m' , then no correct process delivers m' before m ; (4) *atomic broadcast*: if correct processes p and q both deliver m and m' , then p delivers m before m' if and only if q delivers m before m' .

Atomic broadcast does not relate broadcast ordering to delivery order; but it does say that the delivery order must be the same everywhere. Thus, atomicity can be combined with FIFO order, FIFO atomic broadcast, or with causal order, causal atomic broadcast, (causality does imply FIFO, by the way).

Real-time applications require messages being delivered within a bounded time after the broadcast. A protocol that does this is a **timed broadcast protocol**.

Reliability, ordering, and timing requirements can be combined to make, for example, *uniform timed causal atomic broadcast*.

A set of processes in a distributed application can use an appropriate broadcast protocol to maintain a replicated state. When a process crashes, the others must be informed reliably. It is often particularly important that the surviving processes agree on the moment of the crash with respect to the broadcasts made.

The combination of a set of protocols for broadcast (multicast) and a set of protocols to maintain membership state of a group of communicating processes is referred to as group communication. ISIS was the earliest group-communication system and it is still the best known.

Other groups have taken this work further. The Relacs system of Babaoglu et al. [1995] was designed to overcome the problems of scale that were present in ISIS. The Delta-4 project [Powell 1991] has explored group communication in the context of dependable computing.

88.1 Introduction

This chapter discusses CPU scheduling in parallel and distributed systems. CPU scheduling is part of a broader class of resource allocation problems, and is probably the most carefully studied such problem. The main motivation for multiprocessor scheduling is the desire for increased speed in the execution of a workload. Parts of the workload, called *tasks*, can be spread across several processors and thus be executed more quickly than on a single processor. In this chapter we examine techniques for providing this facility.

The scheduling problem for multiprocessor systems can be generally stated as: “How can we execute a set of tasks T on a set of processors P subject to some set of optimizing criteria C ?” The most common goal of scheduling is to minimize the expected runtime of a task set. Examples of other scheduling criteria include minimizing the cost, minimizing communication delay, giving priority to certain users’ processes, or needs for specialized hardware devices. The scheduling policy for a multiprocessor system usually embodies a mixture of several of these criteria.

[Section 88.2](#) outlines general issues in multiprocessor scheduling and gives background material, including issues specific to either parallel or distributed scheduling. [Section 88.3](#) describes the best practices from prior work in the area, including a broad survey of existing scheduling algorithms and mechanisms. [Section 88.4](#) outlines research issues and gives a summary. [Section 88.5](#) lists the terms defined in this chapter, and is followed by references to important research publications in the area.

88.2 Issues in Multiprocessor Scheduling

There are several issues that arise when considering scheduling for multiprocessor systems. First, we must distinguish between **policy** and **mechanism**. Mechanism gives us the ability to perform an action, while policy decides what we do with the mechanism. Most automobiles have the power to travel at speeds over 150 kilometers per hour or 90 miles per hour (the mechanism), but legal speed limits are usually set well below that (the policy). We will see examples of both scheduling mechanisms and scheduling policies.

Next, we distinguish between **distributed** and **parallel** systems. Past distinctions have been based on whether an interrupt is required to access some portion of memory; in other words, whether communication between processors is via shared memory (also known as **tight coupling**) or via message passing (also known as **loose coupling**). Unfortunately, while this categorization applies well to systems such as shared-memory symmetric multiprocessors (obviously parallel) and networks of workstations (obviously distributed), it breaks down for message-passing multiprocessors such as hypercubes. By common understanding, the hypercube is a parallel machine; but by the memory test, it is a distributed system.

The true test of whether a system is parallel or distributed is the support for **autonomy** of the individual nodes. Distributed systems support autonomy, while parallel systems do not. A node is autonomous if it is free to behave differently than other nodes within the system.* By this test, a hypercube is classified as a parallel machine. There are four components to the autonomy of a multiprocessor system: **design autonomy**, **communication autonomy**, **execution autonomy**, and **administrative autonomy**.

Design autonomy frees the designers of individual systems from being bound by other architectures; they can design their hardware and software to their own specifications and needs. Design autonomy gives rise to heterogeneous systems, both at the level of the operating system software and at the underlying hardware level. Communication autonomy allows each node to choose what information to send, and when to send it. Execution autonomy permits each processor to decide whether it will honor a request to execute a task. Furthermore, the processor has the right to stop executing a task it had previously accepted. With administrative autonomy, each system sets its own resource allocation policies, independent of the policies of other systems. The local policy decides what resources are to be shared. In effect, execution autonomy allows each processor to have a local scheduling policy; administrative autonomy allows that policy to be different from other processors within the system.

A **task** is the unit of computation in our computing systems, and several tasks working toward a common goal are called a **job**. There are two levels of scheduling in a multiprocessor system: **global** scheduling and **local** scheduling [Casavant and Kuhl, 1988]. Global scheduling involves assigning a task to a particular processor within the system. This is also known as **mapping**, **task placement**, and **matching**. Local scheduling determines which of the set of available tasks at a processor runs next on that processor.

Global scheduling takes place before local scheduling, although **task migration**, or dynamic reassignment, can change the global mapping by moving a task to a new processor. To migrate a task, the system freezes the task, saves its state, transfers the saved state to a new processor, and restarts the task. There is substantial overhead involved in migrating a running task.

Given that we have several jobs, each composed of many tasks, competing for CPU service on a fixed set of processors, we have two choices as to how we allocate the tasks to the processors. We can assign several processors to a single job, or we can assign several tasks to a single processor. The former is known as **space sharing** and the latter is called **time sharing**.

Under space sharing, we usually arrange things so that the job has as many processors as it has tasks. This allows all the tasks to run to completion, without any tasks from competing jobs being run on the processors assigned to this job. In many ways, space sharing is similar to old-fashioned batch processing, applied to multiprocessor systems. Under time sharing, tasks may be periodically preempted to allow other tasks to run. The tasks may be from a single job or from multiple jobs. Generally speaking, space sharing is a function of the global scheduling policy, while timesharing is a function of local scheduling.

*We speak of behavior at the operating system level, not at the application level.

One of the main uses of global scheduling is to perform **load sharing** between processors. Load sharing allows busy processors to offload some of their work to less busy, or even idle, processors. **Load balancing** is a special case of load sharing, in which the goal of the global scheduling algorithm is to keep the load even (or balanced) across all processors. **Sender-initiated** load sharing occurs when busy processors try to find idle processors to offload some work. **Receiver-initiated** load sharing occurs when idle processors seek busy processors. It is now accepted wisdom that, while load *sharing* is worthwhile, load *balancing* is generally not worth the extra effort, as the small gain in execution time of the tasks is more than offset by the effort expended in maintaining the balanced load.

A global scheduling policy may be thought of as having four distinct parts: the **transfer policy**, the **selection policy**, the **location policy**, and the **information policy**. The transfer policy decides when a node should migrate a task, and the selection policy decides which task to migrate. The location policy determines a partner node for the task migration, and the information policy determines how node state information is disseminated among the processors in the system. For a complete discussion of these components, see [Singhal and Shivaratri, 1994, Chap. 11].

An important feature of the selection policy is whether it restricts the candidate set of tasks to new tasks that have not yet run, or allows the transfer of tasks that have begun execution. **Nonpreemptive** policies only transfer new jobs, while **preemptive** policies will transfer running jobs as well. Preemptive policies have a larger set of candidates for transfer, but the overhead of migrating a job that has begun execution is higher than for a new job because of the accumulated state of the running job (such as open file descriptors, allocated memory, etc.).

As the system runs, new tasks arrive while old tasks complete execution (or, equivalently, are served). If the arrival rate is greater than the service rate, then the process waiting queues within the system will grow without bound and the system is said to be **unstable**. If, however, tasks are serviced at least as fast as they arrive, the queues in the system will have bounded length and the system is said to be **stable**. If the arrival rate is just slightly less than the service rate for a system, it is possible for the additional overhead of load sharing to push the system into instability. A stable scheduling policy does not have this property, and will never make a stable system unstable.

88.2.1 Distributed Scheduling

In most cases, work in distributed scheduling concentrates on global scheduling because of the architecture of the underlying system. Casavant and Kuhl [1988] define a taxonomy of task placement algorithms for distributed systems, which we have partially reproduced in Figure 88.1. The two major categories of global algorithms are static and dynamic.

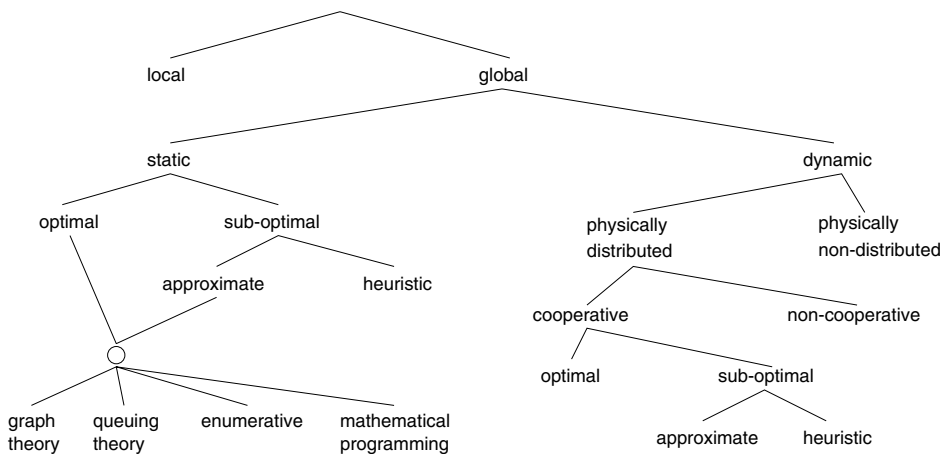

FIGURE 88.1 A taxonomy of distributed scheduling algorithms.

Static algorithms make scheduling decisions based purely on information available at compilation time. For example, the typical input to a static algorithm would include the machine configuration and the number of tasks and estimates of their running time. Dynamic algorithms, on the other hand, take factors into account such as the current load on each processor. Adaptive algorithms are a special subclass of dynamic algorithms, and are important enough that they are often discussed separately. Adaptive algorithms go one step further than dynamic algorithms, in that they may change the policy based on dynamic information. A dynamic load-sharing algorithm might use the current system state information to seek out a lightly loaded host, while an adaptive algorithm might switch from sender-initiated to receiver-initiated load sharing if the system load rises above a threshold.

In **physically non-distributed**, or centralized, scheduling policies, a single processor makes all decisions regarding task placement — this has obvious implications for the autonomy of the participating systems. Under **physically distributed** algorithms, the logical authority for the decision-making process is distributed among the processors that constitute the system.

Under **non-cooperative** distributed scheduling policies, individual processors make scheduling choices independent of the choices made by other processors. With **cooperative** scheduling, the processors subordinate local autonomy to the achievement of a common goal.

Both static and cooperative distributed scheduling have **optimal** and **suboptimal** branches. Optimal assignments can be reached if complete information describing the system and the task force is available. Suboptimal algorithms are either **approximate** or **heuristic**. Heuristic algorithms use guiding principles, such as assigning tasks with heavy inter-task communication to the same processor, or placing large jobs first. Approximate solutions use the same computational methods as optimal solutions, but use solutions that are within an acceptable range, according to an algorithm-dependent metric.

Approximate and optimal algorithms employ techniques based on one of four computational approaches: (1) enumeration of all possible solutions, (2) graph theory, (3) mathematical programming, or (4) queuing theory. In the taxonomy, the subtree appearing below optimal and approximate in the static branch is also present under the optimal and approximate nodes on the dynamic branch; it is elided in [Figure 88.1](#) to save space.

In subsequent sections, we examine several scheduling algorithms from the literature in light of this taxonomy.

88.2.2 Scheduling for Shared-Memory Parallel Systems

Researchers working on shared-memory parallel systems have concentrated on local scheduling because of the ability to trivially move processes between processors. There are two main causes of artificial delay that can be introduced by local scheduling in these systems: cache corruption and preemption of processes holding locks.

1. **Cache corruption.** As a process runs, the operating system caches several types of information for the process, including its working set and recently read file blocks. If this information is not accessed frequently, the operating system will replace it with cache information from other processes.
2. **Lock preemption.** Spin locks, a form of busy waiting, are often used in parallel operating systems when contention for a critical section is expected to be low and the critical section is short. The problem of lock preemption occurs when a process that holds the lock is preempted on one processor, while another process waiting to enter the lock is running on a different processor. Until the first process runs again and releases the lock, all of the CPU time used by the second process is wasted.

In an upcoming section, we examine methods to alleviate or avoid these delays.

88.3 Best Practices

In this section we examine the current state-of-the-art in multiprocessor scheduling. We first consider the techniques used in parallel systems and then examine scheduling algorithms for message-passing systems. Finally, we study scheduling support mechanisms and algorithms for distributed systems, including computational grids.

88.3.1 Parallel Scheduling

We examine three aspects of scheduling for parallel systems: local scheduling for shared-memory systems such as the SGI Altix family; static analysis tools that are beneficial for producing global schedules for parallel systems; and dynamic scheduling for distributed-memory systems.

88.3.1.1 Local Scheduling for Parallel Systems

For most shared-memory timesharing systems, there is no explicit global placement: all processors share the same ready queue, and so any task can be run on any processor. In contrast, local scheduling is crucial for these systems, while it is nonexistent in space-sharing systems. We examine several local scheduling techniques for parallel systems. In general, these techniques are attempting to eliminate one of the causes of delay mentioned previously. All of these techniques are discussed in Chapter 17 of Singhal and Shivaratri [1994].

Co-scheduling, or gang scheduling, schedules the entire pool of subtasks for a single task simultaneously. This can work well with fine-grained applications where communication dominates computation, so that substantial work can be accomplished in a single time slice. Without co-scheduling, it is easy to fall into a pattern where subtasks are run on a processor, only to immediately block waiting for communication. In this way, co-scheduling combines aspects of both space sharing and time sharing.

Smart scheduling tries to avoid the preemption of a task that holds a lock on a critical section. Under smart scheduling, a process sets a flag when it acquires a lock. If a process has its flag set, it will not be preempted by the operating system. When a process leaves a critical section, it resets its flag.

The Mach operating system uses scheduler hints to inform the system of the expected behavior of a process. Discouragement hints inform the system that the current thread should not run for awhile, and hand-off hints are similar to co-routines in that they “hand off” the processor to a specific thread.

In affinity-based scheduling, a task is said to have an affinity for the processor on which it last ran. If possible, a task is rescheduled to run on the processor for which it has affinity. This can ameliorate the effects of cache corruption. The disadvantage of this scheme is that it diminishes the chances of successfully doing load sharing because of the desire to retain a job on its current processor. In effect, affinity-based scheduling injects a measure of global scheduling into the local scheduling policy.

88.3.1.2 Static Analysis

There are several systems that perform static analysis on a task set and generate a static task mapping for a particular architecture. Examples of such systems include Parallax, Hypertool, Prep-P, Oregami, and Pyrros (see Shirazi et al. [1995] for individual articles on these systems). Each of these tools represents the task set as a directed acyclic graph, with the nodes in the graph representing computation steps. Edges in the graph represent data dependencies or communication, where the result of one node is made ready as input for another node. These tools attempt to map the static task graph onto a given machine according to an optimizing criterion (usually, minimal execution time, although other constraints such as minimizing the number of processors used can also be included). The scheduling algorithm then uses some heuristic to generate a near-optimal mapping.

Parallax (Lewis and El-Rewini) is a partitioning and scheduling system that implements seven different heuristic policies. The input to the system is a graph representing the structure of the tasks and a

user-selectable representation of the machine architecture. Parallax will then generate schedules based on each of the available heuristics, and present the expected results to the user. This system is unique in its ability to permit the user to explore different combinations of scheduling heuristics and machine architecture for a given task set.

Hypertool (Wu and Gajski) takes as input C source code and generates the task graph representing the program. This is distinct from Parallax, where the user must supply the task graph (and may therefore study the behavior of algorithms that have not been explicitly expressed in any particular programming language). Hypertool then schedules the derived task graph on a hypercube.

Sarkar and Hennessy built one of the first tools to extract parallelism from a functional program, partition the individual tasks into jobs, and then place the jobs on a multiprocessor. They developed a new representation for parallel computation called Macro-Dataflow, and applied their work to programs written in SISAL for the VAX.

Prep-P (Berman and Stramm) is a mapping tool that runs in conjunction with the Poker programming environment for the Pringle machine. Prep-P was one of the earliest program mapping tools, and uses a Graph Description Language as input to describe the program structure. Prep-P uses an iterative partitioning algorithm, wherein an initial partitioning is derived and the system repeatedly attempts to improve upon the partition by moving a task from one partition into another. Whenever the proposed move results in a lower-cost schedule, the move is kept.

Oregami (Lo et al.) is similar to Prep-P in functionality, with the addition of a new model for representing the computation called the Temporal Communications Graph (TCG). The TCG represents each event (computation, message send, or message receipt) as a node within a directed acyclic graph. Thus, it represents a combination of the static task graph with Lamport's process-time graphs.

In many ways, Pyrros (Yang and Gersoulis) represents a merger between several ideas from earlier static scheduling systems. Pyrros uses Sarkar and Hennessy's Macro-Dataflow model, and is targeted for a hypercube architecture. The system takes a Macro-Dataflow graph as input, and then performs partitioning and scheduling. It can produce optimal schedules for several restricted classes of algorithms.

88.3.1.3 Distributed-Memory Systems

In distributed-memory systems, such as hypercube systems, global scheduling is done. Most hypercube systems use space sharing, in that they reserve subcubes of the larger hypercube for use by a single application. Several algorithms have been proposed for this, including that found in Huang et al. [1989]. A typical algorithm maintains a binary tree listing the various sizes of hypercubes available in the system. When a request for an m -dimensional cube is made, the scheduling system searches the tree to see if a hypercube of that exact size is available, and if so, allocates it. If no such hypercube is available, the system splits the smallest hypercube of dimension greater than m into multiple hypercubes, allocates one, and updates the binary tree to reflect the new set of available hypercubes.

For example, consider a request for four processors from a 16-processor hypercube, with all nodes currently free. Four processors comprise a two-dimensional hypercube (a square). The scheduling system would split the 16 processors into two 8-processor cubes, and then split one of the 8-processor cubes into two 4-processor squares. One of the squares would be allocated to the job, leaving one two-dimensional and one three-dimensional hypercube for other jobs.

It is interesting to examine the coexistence of space sharing and time sharing on a single machine. The ASCI Red machine at Sandia National Laboratories is a distributed-memory system that divides its nodes into two partitions: a service partition that runs a general-purpose, full-featured operating system (Unix), and a compute partition that runs a special-purpose, highly efficient operating system (Cougar). The service partition runs in time-sharing mode, while Cougar provides low-latency communication under a mixed space-sharing and time-sharing paradigm (nodes are dedicated to a single job, but that job can run multiple tasks on a single node). Users launch their jobs from the service partition, and the scheduling system reserves a portion of the compute partition to run the tasks for those jobs.

88.3.2 Distributed Scheduling Algorithms

Many researchers have devised algorithms for task placement in distributed systems. This section categorizes several of these techniques in terms of the taxonomy presented earlier.

Table 88.1 displays information garnered from a survey of existing scheduling algorithms. For each algorithm, an entry indicates whether the method is distributed or centralized, supports heterogeneity, minimizes overhead, or supports scalability. Entries are either *Y*, *N*, *P*, or *x*, indicating that the answer is yes, no, partially, or not applicable. The remainder of this section contains a brief description of each method, with a discussion of its place in the taxonomy and its salient properties. Interested readers are referred to the cited publications to obtain full details about the algorithms.

88.3.2.1 Dynamic, Distributed, Cooperative, Suboptimal Algorithms

Blake [1992] describe four suboptimal, heuristic algorithms. Under the first algorithm, Non-Scheduling (NS), a task is run where it is submitted. The second algorithm is Random Scheduling (RS), wherein a processor is selected at random and is forced to run a task. The third algorithm is Arrival Balanced Scheduling (ABS), in which the task is assigned to the processor that will complete it first, as estimated by the scheduling host. The fourth method uses receiver-initiated load balancing, and is called End Balanced Scheduling (EBS). NS, RS, and ABS use one-time assignment; EBS uses dynamic reassignment.

Casavant and Kuhl [1984] describe a distributed task execution environment for Unix System 7, with the primary goal of load balancing without altering the user interface to the operating system. As such,

the system combines mechanism and policy. This system supports execution autonomy, but not communication autonomy or administrative autonomy.

Ghafoor and Ahmad [1990] describe a bidding system that combines mechanism and policy. A module called an Information Collector/Dispatcher runs on each node and monitors the local load and that of the node's neighbors. The system passes a task between nodes until either a node accepts the task or the task reaches its transfer limit, in which case the current node accepts the task. This algorithm assumes homogeneous processors and has limited support for execution autonomy.

Van Tilborg and Wittie [1984] present Wave Scheduling for hierarchical virtual machines. The task force is recursively subdivided and the processing flows through the virtual machine like a wave, hence the name. Wave Scheduling combines a non-extensible mechanism with policy, and assumes the processors are homogeneous.

Ni and Abani [1981] present two dynamic methods for load balancing on systems connected by local area networks: Least Expected Delay and Shortest Queue. Least Expected Delay assigns the task to the host with the smallest expected completion time, as estimated from data describing the task and the processors. Shortest Queue assigns the task to the host with the fewest number of waiting jobs. These two methods are not scalable because they use information broadcasting to ensure complete information at all nodes. Ni and Abani [1981] also present an optimal stochastic strategy using mathematical programming.

The method described in Stankovic and Sidhu [1984] uses task clusters and distributed groups. Task clusters are sets of tasks with heavy inter-task communication that should be on the same host. Distributed groups also have inter-task communication but execute faster when spread across separate hosts. This method is a bidding strategy and uses non-extensible system and task description messages.

Stankovic [1985] lists two scheduling methods. The first is adaptive with dynamic reassignment, and is based on broadcast messages and stochastic learning automata. This method uses a system of rewards and penalties as a feedback mechanism to tune the policy. The second method uses bidding and one-time assignment in a real-time environment.

Andrews et al. [1982] describes a bidding method with dynamic reassignment based on three types of servers: free, preferred, and retentive. Free server allocation will choose any available server from an identical pool. Preferred server allocation asks for a server with a particular characteristic, but will take any server if none is available with the characteristic. Retentive server allocation asks for particular characteristics, and if no matching server is found, a server, busy or free, must fulfill the request.

Chowdhury [1990] describes the Greedy load-sharing algorithm. The Greedy algorithm uses system load to decide where a job should be placed. This algorithm is non-cooperative in the sense that decisions are made for the local good, but it is cooperative because scheduling assignments are always accepted and all systems are working toward a global load balancing policy.

Gao et al. [1984] describe two load-balancing algorithms using broadcast information. The first algorithm balances arrival rates, with the assumption that all jobs take the same time. The second algorithm balances unfinished work. Stankovic [1984] gives three variants of load-balancing algorithms based on point-to-point communication that compare the local load to the load on remote processors. Chou and Abraham [1983] describe a class of load-redistribution algorithms for processor-failure recovery in distributed systems.

The work presented in Bryant and Finkel [1981] combines load balancing, dynamic reassignment, and probabilistic scheduling to ensure stability under task migration. This method uses neighbor-to-neighbor communication and forced acceptance to load balance between pairs of machines.

Casey [1981] gives an earlier and less complete version of the Casavant and Kuhl taxonomy, with the term *centralised* replacing *non-distributed* and *decentralised* substituting for *distributed*. This article also lists three methods for load balancing — Dipstick, Bidding, and Adaptive Learning — and then describes a load-balancing system wherein each processor includes a 2-byte status update with each message sent. The Dipstick method is the same as the traditional watermark processing found in many operating systems. The Adaptive Learning algorithm uses a feedback mechanism based on the run queue length at each processor.

88.3.2.2 Dynamic Non-cooperative Algorithms

Klappholz and Park [1984] describe Deliberate Random Scheduling (DRS) as a probabilistic, one-time assignment method to accomplish load balancing in heavily loaded systems. Under DRS, when a task is spawned, a processor is randomly selected from the set of ready processors, and the task is assigned to the selected processor. DRS dictates a priority scheme for time-slicing, and is thus a mixture of local and global scheduling. There is no administrative autonomy or execution autonomy with this system because DRS is intended for parallel machines.

Reif and Spirakis [1982] present a Resource Granting System (RGS) based on probabilities and using broadcast communication. This work assumes the existence of either an underlying handshaking mechanism or of shared variables to negotiate task placement. The use of broadcast communication to keep all resource providers updated with the status of computations in progress limits the scalability of this algorithm.

88.3.2.3 Dynamic Non-distributed Algorithms

Ousterhout et al. (see [Singhal and Shivaratri, 1994]) describe Medusa, a distributed operating system for the Cm* multiprocessor. Medusa uses static assignment and centralized decision making, making it a combined policy and mechanism. It neither supports autonomy, nor is the mechanism scalable.

In addition to the four distributed algorithms already mentioned, Blake [1992] describes a fifth method called Continual Balanced Scheduling (CBS) that uses a centralized scheduler. Each time a task arrives, CBS generates a mapping within two time quanta of the optimum, and causes tasks to be migrated accordingly. The centralized scheduler limits the scalability of this approach.

88.3.2.4 Static Algorithms

All the algorithms in this section are static and, as such, are centralized and without support for autonomy. They are generally intended for distributed-memory parallel machines, in which a single user can obtain control of multiple nodes through space sharing. However, they can be implemented on fully distributed systems.

Hochbaum and Shmoys [1988] describes a polynomial-time, approximate, enumerative scheduling technique for processors with different processing speeds, called the dual-approximation algorithm. This algorithm solves a relaxed form of the bin packing problem to produce a schedule within a parameterized factor, ϵ , of optimal. That is, the total runtime is bounded by $(1 + \epsilon)$ times the optimal run time.

Hsu et al. [1989] describe an approximation technique called the critical sink underestimate method. The task force is represented as a directed acyclic graph, with vertices representing tasks and edges representing execution dependencies. If an edge (α, β) appears in the graph, then α must execute before β . A node with no incoming edges is called a *source*, and a node with no outgoing edges is a *sink*. When the last task represented by a sink finishes, the computation is complete; this last task is called the critical sink. The mapping is derived through an enumerative state space search with pruning, which results in an underestimate of the running time for a partially mapped computation and, hence, the name critical sink underestimate.

Stone [1977] describes a method for optimal assignment on a two-processor system based on a Max Flow/Min Cut algorithm for sources and sinks in a weighted directed graph. A maximum flow is one that moves the maximum quantity of goods along the edges from sources to sinks. A minimum cutset for a network is the set of edges with the smallest combined weighting, which, when removed from the graph, disconnects all sources from all sinks. The algorithm relates task assignment to commodity flows in networks, and shows that deriving a Max Flow/Min Cut provides for optimal mapping.

Lo [1988] describes a method based on Stone's Max Flow/Min Cut algorithm for scheduling in heterogeneous systems. This method utilizes a set of heuristics to map from a general system representation to a two-processor system so that Stone's work applies.

Price and Salama [1990] describe three heuristics for assigning precedence-constrained tasks to a network of identical processors. With the first heuristic, the tasks are sorted in increasing order of communication, and then are iteratively assigned so as to minimize total communication time. The second heuristic creates pairs of tasks that communicate, sorts the pairs in decreasing order of communication, then groups the pairs into clusters. The third method, simulated annealing, starts with a mapping and uses probability-based functions to move toward an optimal mapping.

Ramakrishnan et al. [1991] present a refinement of the A* algorithm that can be used either to find optimal mappings or to find approximate mappings. The algorithm uses several heuristics based on the sum of communication costs for a task, the task's estimated mean processing cost, a combination of communication costs and mean processing cost, and the difference between the minimum and maximum processing costs for a task. The algorithm also uses ϵ -relaxation similar to the dual-approximation algorithm of Hochbaum and Shmoys [1988].

Sarkar and Hennessy (in Shirazi et al. [1995]) describe the GR graph representation and static partitioning and scheduling algorithms for single-assignment programs based on the SISAL language. In GR, nodes represent tasks and edges represent communication. The algorithm consists of four steps: cost assignment, graph expansion, internalization, and processor assignment. The cost assignment step estimates the execution cost of nodes within the graph, and communication costs of edges. The graph expansion step expands complex nodes (e.g. loops) to ensure that sufficient parallelism exists in the graph to keep all processors busy. The internalization step performs clustering on the tasks, and the processor assignment phase assigns clusters to processors so as to minimize the parallel execution time.

88.3.3 Wide-Area Distributed Scheduling: The Grid

Recent advances in distributed scheduling algorithms have occurred in a distributed computing environment known as the Grid, an ensemble of shared, geographically dispersed computers that may not be fully under the control of a single scheduler.

Scheduling in a Computational Grid environment introduces several challenges that go beyond that of traditional distributed system schedulers: heterogeneity, scale, and ownership. In a Grid, resources are highly heterogeneous, ranging from supercomputers to PCs, from high-end mass storage devices to low-end disks. Grid resources may number in hundreds or thousands making efficient run-time scheduling more difficult. Finally, in a Grid, resources may be under the control of resource owners, putting constraints on how schedulers can use them. The scheduling approaches described below deal with these issues in different ways and to differing degrees.

88.3.3.1 Messiahs

The first scheduling system for grids, then called metasytems, was the MESSIAHS (Mechanism Effecting Scheduling Support In Autonomous, Heterogeneous Systems) system [Chapin and Spafford, 1994]. MESSIAHS provided extensive support for autonomy, using hierarchically structured systems based on administrative domains. This structuring was based on an observation of a social aspect of computing: people are willing to allow outside utilization of their unused resources, as long as they maintain control of the system. This means that the local systems are autonomous and the local administrators can set their own access policies. An example distributed autonomous system is illustrated in Figure 88.2.

Each node within the MESSIAHS system is a **virtual system**, which represents a subset of the resources of one or more real systems, and has a hierarchical structure modeling the administrative hierarchies of computer systems and institutional organization. Virtual systems can be combined into encapsulating virtual systems. For example, in Figure 88.2, the University, National Laboratory, and Industry are each virtual systems, and are collected into a single large distributed (virtual) system. Within the University, National Lab, and Industry virtual systems are other virtual systems, giving a hierarchical structure. These intermediate groupings may correspond to divisions that contain departments, and the departments may contain research groups, etc. At the lowest level of grouping, each virtual system typically consists of a subset of the capabilities of a single machine. Together, these virtual systems form a directed acyclic graph topology.

FIGURE 88.2 A sample virtual system.

There is no centralized resource management in MESSIAHS. Instead, each virtual system runs a **scheduling module**, which maintains the system description information for that node. The scheduling module also exchanges service requests with neighboring virtual systems within the hierarchy, and is responsible for starting and stopping jobs.

MESSIAHS provides two interfaces with which administrators can define the scheduling policy for a system: an interpreted language called the MESSIAHS Interface Language (MIL) dedicated to implementing schedulers, and a library of functions for the C programming language. Using these interfaces, administrators write small event handlers that are linked into the scheduling system. Thus, MESSIAHS has extensive support for autonomy.

88.3.3.2 Matchmaking

Matchmaking is a highly distributed scheduling process that accounts for the heterogeneity of resources and the distribution of ownership. This approach consists of a semi-structured data model that combines schema, data, and query in a specification language, and a separation of matching and claiming phases of resource allocation. Both resources and jobs use a mechanism known as classads to specify attributes and constraints (Figure 88.3). A classad is a mapping from attribute names to expressions. This mechanism allows the heterogeneity and ownership issues inherent to the Grid to be addressed. Issues of scale are not addressed by this mechanism, and the locality of resources is not captured by classads.

Scheduling is accomplished by a matchmaker that matches resource classads to job classads, satisfying the constraints of both. The implementation of the decision is negotiated between the resource and the job using matchmaking and resource claiming protocols. The matching (aka scheduling) algorithm first determines feasible matches (schedules) by determining compatible resource and job classads via the Constraint expression. The next phase of the algorithm is to choose among compatible matches by maximizing the Rank attribute of the job. This scheme has been designed for localized resources within a single Grid site.

88.3.3.3 AppLeS

The AppLeS scheduling approach is a conceptual framework for the design of Grid schedulers tuned specifically for the application. The goal is to select a potentially efficient configuration of resources based on load and availability, evaluate the potential performance of such configurations based on application-specific performance criteria, and interact with the relevant resource management systems to carry out

Machine Classad	Job Classad
<pre>[Type = "Machine"; Activity = "Idle"; DayTime = 36107; KeyboardIdle = 1432; Disk = 323496; Memory = 64; State = "Unclaimed"; LoadAvg = 0.042969; Mips = 104; Arch = "INTEL"; OpSys = "SOLARIS251"; KFlops = 21893; Name = "leonardo.cs.wisc.edu"; ResearchGroup = { "raman", "miron", "solomon", "jbasney" }; Friends = { "tannenba", "wright" }; Untrusted = { "rival", "riffraff" }; Rank = member(other.Owner, ResearchGroup) *10+member(other.Owner, Friends); Constraint = !member(other.Owner, Untrusted) && Rank >= 10 ? true : Rank > 0 ? LoadAvg<0.3 && KeyboardIdle>15*60 : DayTime < 8*60*60 DayTime > 18*60*60;]</pre>	<pre>[Type = "Job"; QDate = 886799469; // Submit time secs. past 1/1/1970 CompletionDate = 0; Owner = "raman"; Cmd = "run_sim"; WantRemoteSysCalls = 1; WantCheckpoint = 1; Iwd = "/usr/raman/sim2"; Args = "-Q 17 3200 10"; Memory = 31; Rank = KFlops/1E3 + other.Memory/32; Constraint = other.Type == "Machine" && Arch == "INTEL" && OpSys == "SOLARIS251" && Disk >= 10000 && other.Memory >= self.Memory;]</pre>

FIGURE 88.3 Classads describing a machine and a job.

the decision. AppLeS agents perform the scheduling task for the user and exploit several generic components such as the Network Weather Service [NWS, 1999] which provides resource load predictions. Specific AppLeS scheduling agents have been developed for tightly-coupled parallel scientific computations [Berman et al., 1996], data replica selection [Su et al., 1999], parameter sweeps [Casanova et al., 2000], and gene sequence comparison [Spring and Wolski, 1998]. These AppLeS agents address the issue of Grid scale by considering a subset of Grid resources and the issue of heterogeneity by dynamic cost modeling via static and dynamic cost functions. An example of an AppLeS scheduling algorithm is shown in [Figure 88.4](#). The issue of ownership is not addressed. The more recent thrust in this project is to generalize the AppLeS approach to build template schedulers applicable to a wider class of applications. Templates have been constructed for master-slave applications and parameter sweep applications [Casanova et al., 2000].

88.3.3.4 Prophet and Gallop

Data parallel applications are a large and important class of parallel scientific applications. Efficiently scheduling these applications in a Grid is difficult due to the potential sharing and heterogeneity of resources. In addition, selecting the appropriate number of processors and data domain decomposition are all difficult problems that depend on the available resources, their load and heterogeneity, network load, and problem characteristics. Most systems leave this complex problem up to the end user. Even if the user figures out the best resource combination by running an application multiple times, this same resource combination may not be available all the time due to resource sharing; and even if it was, it is unlikely to be best for a different problem instance of the same application. Finally, such optimizations are tailored to

Resource Selection

Let *locus* = machine having the maximum criterion value
Let *list* = a sort of the remaining machines according to their logical distance

begin for $k = 0$ **to** $I - 1$

let $S = \text{locus} +$ the first k elements of *list*
parameterize C_i and P_i for $1 \leq i \leq |S|$
with Weather Service forecasts
solve linear system of equations using this parameterization

if (not all $A_i > 0$)

the specific application and are not available to another user's application. Prophet [Weissman, 1999] is an automated scheduler for data parallel applications that utilizes a performance model for predicting application performance on different resource combinations that automates processor selection, task placement, and data domain decomposition for data parallel applications. Prophet uses a callback mechanism to allow the runtime scheduler to obtain application-specific information to construct cost functions.

Gallop [Weissman, 1998] is a wide-area Grid scheduling system that provides a federated scheduling model across different sites in a Grid. In the Gallop model, each site can run its own local scheduler, and decide which resources are to be made available to Gallop. Gallop utilizes a bid-based distributed scheduling algorithm to decide which site to select from among a network of sites (see Figure 88.5.) A multi-site Gallop testbed was constructed in which the local sites each ran a version of Prophet to provide performance prediction estimates for using their resources. Gallop demonstrated that the overhead of remote execution can be tolerated for applications of sufficiently large granularity in the Grid. It achieved performance gains up to 25% over local site execution for a range of applications: a Poisson solver, an image processing pipeline, and a genomic sequence comparison.

88.3.3.5 Stochastic Scheduling

Stochastic scheduling [Schopf and Berman, 1999] harnesses the variability inherent in Grid computing to produce performance-efficient schedules. Stochastic scheduling models the performance variance of a resource using a stochastic value (i.e., distribution) and then proposes scheduling heuristics that use this value. By parameterizing models with stochastic information, the resulting performance prediction is also a stochastic value. Such information can be more useful to a scheduler than point predictions with an unknown range of accuracy. The authors introduce a tuning factor that represents the variability of the system as a whole as some constant number of standard deviations away from a mean value. Resource platforms with a smaller variability are given scheduling priority in this scheme. Extensions of well-known scheduling methods such as time-balancing are shown to achieve better performance under stochastic time-balancing.

88.3.3.6 Co-allocation

Resource co-allocation of multiple resources introduces a new scheduling problem for Grid applications. In the co-allocation model, the Grid application requires access to a specific set of resources concurrently. Several approaches for addressing this problem have been proposed [Chapin et al., 1999, Foster et al., 1999]. Scheduling techniques include atomic all-or-nothing semantics in which either all resources are acquired and the application starts, or it must wait. If the application starts and one or more resources are taken away or fail, then the application must abort. Another approach is advanced reservations in which resources can be locked at some future time so that they are available together. Co-allocation-based reservation schemes usually try to provide the soonest time a reservation of the desired length can be accommodated across all desired resources (see Algorithm 88.1).

```
begin
  rh-a ← CreateReservation(contact-a, “&(reservation_type=compute)
  (start_time=“10:30pm”) (duration=“1 hour”) (nodes=32)”);
  if rh-a is null then exit;
  repeat
    (contact-b, id-b, contact-net) ← FindNextCandidate();
    rh-b ← CreateReservations (contact-b, “&(reservation_type=compute)
    (start_time=“10:30pm”) (duration=“1 hour”) (percent_cpu=75)”);
    if rh-b is null then continue;
    rh-net ← CreateReservation(contact-net, “&(reservation_type=network)
    (start_time=“10:30pm”) (duration=“1 hour”) (bandwidth=200)
    (endpoint-a=id-a)(endpoint-b=id-b)”);
    if rh-net is null then CancelReservation(rh-b);
  until rh-b and rh-net are defined;
  if rh-b is null then signal that search failed;
end
```

Algorithm 88.1: Pseudo-code for a ReserveResources subroutine.

Legion [Chapin et al., 1999] provided the first co-allocation system for the Grid, and supports both co-allocation and advanced reservations. Legion provides full autonomy support, allowing a scheduling request to return a scheduling token, which is later redeemed when the job is actually started. Legion supports multiple simultaneous schedulers, including per-application, per-user, and default schedulers; these can in fact implement the techniques described here, such as Prophet or stochastic scheduling. Under Legion, schedulers produce a list of proposed target schedules ranked by desirability, and an Enactor component is responsible for verifying that the resources are in fact available and implementing the schedule. This allows maximum flexibility and support for autonomy.

88.4 Research Issues and Summary

The central problem in distributed scheduling is assigning a set of tasks to a set of processors in accordance with one or more optimizing criteria. We have reviewed many of the algorithms and mechanisms developed thus far to solve this problem. However, much work remains to be done.

88.4.1 Algorithms

Until now, scheduling algorithms have concentrated mainly on systems of homogeneous processors. This has worked well for parallel machines, but has proved to be unrealistically simple for distributed systems. Some of the simplifying assumptions made include constant-time or even free inter-task communication, processors with the same instruction set, uniformity of available files and devices, and the existence of plentiful primary and secondary memory. In fact, the vast majority of algorithms listed in the survey model the underlying system only in terms of CPU speed and a simplified estimate of interprocessor communication time.

These simple algorithms work moderately well to perform load balancing on networks of workstations that are, in most senses, homogeneous. However, as we look to the future and attempt to build wide-area distributed systems composed of thousands of heterogeneous nodes, we will need policies capable of making good scheduling decisions in such complex environments.

88.4.2 Distributed Scheduling Mechanisms

As we have seen, current scheduling systems do a good job of meeting the technical challenges of supporting the relatively simplistic scheduling policies that have been developed to date. Future work will expand in new directions, especially in the areas of heterogeneity, security, and the social aspects of distributed computing.

Just as scheduling algorithms have not considered heterogeneity, distributed scheduling mechanisms have only just begun to support scheduling in heterogeneous systems. Some of the major obstacles to be overcome include differences in the file spaces, speeds of the processors, processor architectures (and possible task migration between them), operating systems and installed software, devices, and memory. Future support mechanisms will have to make this information available to scheduling algorithms to fully utilize a large, heterogeneous distributed system.

The challenges in the preceding list are purely technical. Another set of problems arises from the social aspects of distributed computing. Large-scale systems will be composed of machines from different administrative domains; the social challenge will be to ensure that computations that cross administrative boundaries do not compromise the security or comfort of users inside each domain. To be successful, a distributed scheduling system must provide security, both for the foreign task and for the local system; neither should be able to inflict harm upon the other. In addition, the scheduling system will have to assure users that their local rules for use of their machines will be followed. Otherwise, the computing paradigm will break down, and the large system will disintegrate into several smaller systems under single administrative domains.

Defining Terms

Autonomy: The freedom to be different or behave differently than other nodes within the system.

Centralized mechanisms: Mechanisms in which data is stored at a single node, or which pass all data to a single node for a decision.

Distributed mechanisms: Mechanisms in which decisions are made on the local system, based on data located on that system.

Distributed memory: A system in which processors have different views of memory. Often, each processor has its own memory and cannot directly access another processor's local memory.

Distributed systems: Systems with a high degree of autonomy.

Global scheduling: The assignment of tasks to processors (also called task placement and matching).

Heterogeneous systems: The property of having different underlying machine architectures or systems software.

Job: A group of tasks cooperating to solve a single problem.

Load balancing: A special form of load sharing in which the system attempts to keep all nodes equally busy.

Load sharing: The practice of moving some of the work from busy processors to idle processors. The system does not necessarily attempt to keep the load equal at all processors; instead, it tries to avoid the case where some processors are heavily loaded while others sit idle.

Local scheduling: The decision as to which task, of those assigned to a particular processor, will run next on that processor.

Loosely coupled hardware: A message-passing multiprocessor.

Mechanism: The ability to perform an action.

Parallel systems: Systems with a low degree of autonomy.

Policy: A set of rules that decides what action will be performed.

Shared memory: A system in which all processors have the same view of memory. If processors have local memories, then other processors may still access them directly.

Space sharing: A system in which several jobs are each assigned exclusive use of portions of a common resource. For example, if some of the processors in a parallel machine are dedicated to one job, while another set of processors is dedicated to a second job, the jobs are space sharing the CPUs.

Stability: The property of a system that the service rate is greater than or equal to the arrival rate. A stable scheduling algorithm will not make a stable system unstable.

Task: The unit of computation in a distributed system; an instance of a program under execution.

Task migration: The act of moving a task from one node to another within the system.

Tightly coupled hardware: A shared-memory multiprocessor.

Time sharing: A system in which jobs have the illusion of exclusive access to a resource, but in which the resource is actually switched among them.

For Further Information

Many of the seminal theoretical papers in the area are contained in *Scheduling and Load Balancing in Parallel and Distributed Systems*, edited by Shirazi, Hurson, and Kavi [Shirazi et al., 1995]. This volume contains many of the papers cited in this chapter, and is an excellent starting point for those interested in further reading in the area.

Advanced Concepts in Operating Systems by Singhal and Shivaratri [Singhal and Shivaratri, 1994] contains two chapters discussing scheduling for parallel and distributed systems. These two references contain pointers to much more information than could be presented here.

Descriptions of other distributed scheduling systems may be found in papers describing Stealth [Singhal and Shivaratri, 1994] [Ch. 11], Utopia [Zhou et al., 1993], as well as in [Theimer and Lantz, 1989, Litzkow, 1987, Stumm, 1988]. The Global Grid Forum (<http://www.gridforum.org>) is codifying best practices for all aspects of Grid systems. More information about scheduling in distributed operating systems such as Sprite, the V System, Locus, and MOSIX can also be found in [Singhal and Shivaratri, 1994].

89.1 Introduction

The model of a single file system shared by all users of a computer is not only convenient but expected by most computer users. It seems natural to extend this model across multiple computers so that all users on a collection of computers share the same file system, thus forming a *distributed file system*. Similarly, the model of a collection of threads of control sharing the same address space as they cooperate in a computation is attractive for exploiting concurrency. This single-address-space abstraction is certainly the natural model for use on a shared-memory multiprocessor. Its convenience for programming is so compelling that it is used increasingly to take advantage of parallelism on distributed systems, where it is called *distributed memory*.

Primarily because of the ubiquity of Sun's Network File System (NFS), programmers have become accustomed to distributed file systems; they realize how much more convenient such a system is than explicitly copying files across machines. Whereas distributed memory is not so commonplace (most existing implementations are research projects), it shows great promise for taking advantage of the collective power of networked computers for computationally intensive problems.

The traditional means for implementing parallel applications on distributed systems is to use explicit message passing or remote procedure calls. These certainly give programmers full control over the locations of data and processing but also force them to be concerned about such details. The promise of distributed memory is that some of these details can be handled by the underlying implementation. In particular, programmers need not be concerned about the transfer of data among computers. Instead, data appear as needed merely because the program has referenced it. As with traditional virtual memory, exceptionally poor performance can arise, but most programs exhibit reasonable locality of reference and thus work quite well.

In both distributed file and distributed memory systems, the usual implementation model is one of clients obtaining data from servers. Clients typically maintain a cache of data recently obtained from

servers: if data have been fetched previously, reads (in file systems) and loads (in memory systems) can often be satisfied directly from the cache without contacting the server. Writes (in file systems) and stores (in memory systems) can be applied to data in the cache and only later made visible to others by updating the server. For file systems, servers are typically distinct from clients and files are permanently assigned to servers, so that clients always contact the same server for the same file. However, an approach pioneered with distributed memory systems [Li and Hudak 1989] and recently adopted for distributed file systems [Anderson et al. 1995] distributes the server role among all of the clients: the home of a shared-memory segment is the client who last modified it.

Our primary concerns are performance, how (and whether) the clients' views of data are kept coherent, and how machine crashes and network outages are handled. Among the performance concerns are minimizing both network traffic and latency of responses to user requests. If the data necessary to handle a user request (such as a read operation on a file or a load from memory) are available locally, latency is minimal, but if not, it can be considerable. However, data can now be transferred over high-speed networks faster than from disks. Thus, it may be quicker to obtain data over the network from the primary storage of a server machine than from a local disk. In either case, since the impact of network traffic on overall performance is more dependent on the number of messages being transmitted than on their size, it is advantageous to transmit data in batches.

In the remainder of this chapter, we first discuss the underlying principles of distributed file and memory systems, including issues of coherency, performance, resilience, naming, replication, disconnected operation, and security. Next is a section on best practices in which we discuss two commercially distributed file systems — Network File System (NFS) and Distributed File System (DFS) — and two research distributed memory systems — IVY and Munin. Finally, we present a summary of the research issues in the field.

89.2 Underlying Principles

What distributed file systems and distributed memory systems have in common is an architectural model in which some number of computers have common access to data. The difference between the two lies primarily in their intended use. Distributed file systems provide data in the form of *files* whose lifetimes are usually far longer than the lifetimes of the processes accessing them. The usual emphasis in a distributed file system is on providing files for the private use of clients and providing shared files for the read-only use of clients. There might be some degree of support for read-write access to shared files, but such use is typically rare. In distributed memory systems the emphasis is on the read-write sharing of data organized into *segments*, and little attention is typically paid to data permanence; the lifetime of data is roughly equal to that of the processes sharing it. In distributed file systems a major concern is resiliency: coping with server and client crashes and network outages. This typically has not been a major concern of distributed memory systems, though there is no reason why it could not be. One usually thinks of the data provided by distributed memory systems as being mapped into the address spaces of the client processes, whereas the files provided by distributed file systems are thought of as being accessed by explicit input/output (I/O) calls (e.g., read and write), but a client operating system could provide a filelike interface to shared memory (though this would be unusual) and files could be mapped into a client's address space (a not uncommon technique).

What is usually desired of distributed file systems and distributed memory systems is that they be **access transparent**: that programs access data on remote computers in the same way as they would locally. Thus, programs use standard read- and write-type file-system calls or use standard load- and store-type operations on memory. This rules out approaches based on explicit file transfer, such as the Internet's file transfer protocol (FTP) and Unix's remote copy (rcp). The underlying implementation is responsible for whatever data movement may be required; the remote data appear to be local to the application program.

Another important property of files is *permanence*: they must be able to continue to exist even when they have no active users. Thus, files are stored on some form of nonvolatile storage, and this ties them to a particular site; files rarely move. Files require administration and maintenance: limitations on the use of available space may have to be enforced. In some circumstances groups of files may have to be moved to

different storage devices, perhaps attached to different computers. Files must be backed up, i.e., copied, say to tape, to guard against loss of data because of loss of media or other problems.

It may also be convenient to replicate files and make them available from multiple sources to prevent bottlenecks and protect against loss of access due to server failure. Thus, the location of a file might change over time. An important property of a distributed file system for making such changes of location tolerable is **location transparency**: how one refers to a file, i.e., its name, should not depend on its location.

In the typical distributed memory system, permanence is not an issue. In a number of systems there is no fixed distinction made between clients and servers; instead, a segment has a moveable home, typically on the last computer to have modified it.

In the next few pages we examine the issues that arise in the design of distributed file and memory systems. For both, the idealization against which our designs are compared is the **single-system model**: the behavior observed by parties executing on a distributed system should be identical to the behavior they would observe if all were on a single computer.* In practice, some aspects of this ideal are not achievable or not even desirable, but it is our basis for examining the various approaches.

In the next few pages we discuss the major issues in the design of both distributed file systems and distributed memory systems. We start by discussing coherency, first of data, then of file attributes, and then we look at performance. The two concerns are somewhat at odds, and so we examine the interplay. Next we look at resilience, which is also interrelated with the first two concerns. We then look at naming issues, replication, disconnected operation, and finally security issues.

89.2.1 Coherency of Data

A major concern in both distributed file systems and distributed memory systems is coping with concurrent access to files or memory and still providing adequate performance and resilience. Strict adherence to the single-system model can be expensive. However, we can often weaken this model to provide improved performance without making sacrifices in other areas.

One way of achieving the ideal of the single-system model is for a system to be **strictly coherent**: whenever a thread running on a node reads from a file or loads from memory, the value it retrieves is the value produced by the most recent write or store to that location. This, of course, is exactly what happens in the single-system model. What makes strict coherency nontrivial to achieve is, of course, the distributed nature of the underlying architecture: it takes time to make modifications to data visible to all nodes. When a write or store is executed, we say that the value produced becomes *visible* when it can be retrieved by reads or loads from this location by other processors. We distinguish between when an instruction that modifies memory or files is *issued* and when its effect becomes visible to others. Thus, with strict coherency, something must be done to ensure that the effect of a write is visible to the next read to the same location.

Strict coherency, however, turns out to be stronger than necessary. A somewhat weaker requirement still equivalent to the single-system model is **sequential coherency** [Lampert 1979]: the effect of any execution of threads on a collection of nodes is one that could have happened had all been executed on the same processor. The idea here is that a read does not need to return the results of the most recent write if it was possible for that write to have occurred after the read; if it was just an accident of time that the write preceded the read, then there is no reason to require the read to return the write's results. However, if it was no accident that the write preceded the read — if due to synchronization or other mechanisms the write was required to precede the read — then the read must return the write's results.

To see the distinction between strict coherency and sequential coherency, consider the time lines for three nodes in [Figure 89.1](#). Each makes the sequence of accesses (reads and writes) indicated by the subscripts;

*The word *computer* can be a bit ambiguous: it can mean, among other things, a standalone system or a single processor from a parallel computer. We often use the word *node* instead, which for our purposes is a system on which the single-system model is easily implemented (for example, a node might be a personal computer or a workstation; a multiprocessor is a node if it is a shared-memory multiprocessor). Thus, a distributed system consists of a number of nodes interconnected by some means for reasonably high-speed communication.

FIGURE 89.1 Concurrent access by three nodes.

FIGURE 89.2 A possible execution in the sequentially coherent model.

the location accessed is given in parentheses. In a strictly coherent model, $r_1(i)$ of node C must retrieve what was written by $w_1(i)$ of node A, $r_2(i)$ of node B must retrieve what was written by $w_2(i)$ of node C, $r_3(j)$ of node C must retrieve what was written by $w_2(j)$ of node A, and $r_4(j)$ of node C must retrieve what was written by $w_3(j)$ of node B.

In a sequentially coherent model, however, any interleaving of the accesses of nodes A, B, and C is possible, as long as the relative order of the accesses by each node is preserved. The possible interleaving shown in Figure 89.2 demonstrates how the accesses might be multiplexed if all were run on a single node. The solid arrows indicate where write accesses would take place, and the dashed arrows indicate which values are retrieved by read accesses. The use of this model could certainly result in a number of possible outcomes of the accesses; if determinism is desired, then explicit synchronization is necessary.

Sequential coherency is certainly a weaker condition than strict coherency: under what circumstances can this weakness be exploited to yield more efficient systems? The fact that loads need not necessarily retrieve the values produced by the most recent stores suggests a technique for improving performance: stores of each processor may be collected into batches and made visible all at once; loads simply retrieve the values produced by the most recent visible stores. We discuss subsequently how we can guarantee that this technique results in sequentially coherent execution.

Unfortunately, there are further complications. Files are typically organized in terms of *blocks*: space may be allocated on disk in blocks and, more importantly for this discussion, files are transferred in block-sized pieces. Similarly, memory is usually organized in terms of *pages*: data are transferred in page-size units. Assume that a file server blindly obeys the requests of its clients to update blocks of a file with blocks supplied by the client (this is, in fact, how most file servers operate). One process might modify one data structure within a file with the knowledge that no other process is accessing that data structure. But some other process might be modifying a different data structure in the same file that happens to share the file-system block occupied by the first data structure. If these processes reside on different nodes, and if both modify their data structures at roughly the same time, a *race* results when each node sends its updated file-system block to the server. The server copies both versions of the file-system block to its (permanent) copy of the file, one at a time, probably in the order received. But since each copy of the block contains only a portion of the total update, the permanent copy of the file on the server will contain the result of one of the two updates, but not both, since the copy of the block it writes second overwrites the changes that came with the first copy. This problem, which occurs in distributed memory systems as well, is known as **false sharing**.

Some sort of synchronization is necessary to deal with the false-sharing problem. This synchronization can be provided automatically by the underlying distributed memory or file system. If a write access to any location within a unit is taking place, no other write or read access is allowed to take place at the same time to a location within the same unit. This ensures not only sequential coherency but also strict coherency. Furthermore, it allows writes to be made visible in batches.

However, even if the correctness issues of false sharing are adequately dealt with, there remains a performance problem: no concurrency of reads and writes to the same unit by different nodes is permitted. In many cases, particularly for file systems, such loss of concurrency is a minor problem since concurrent read/write access is rare. If concurrent access is frequent, however, then this loss of concurrency is serious.

Performance improvements are possible, even with false sharing, if we do not require the distributed file or memory system to take sole responsibility for sequential coherency but require user programs to assist. Thus, we define the notion of **weak coherency**, meaning that sequential coherency can be attained if additional instructions, not needed on a single-processor system, are executed by the program. In sequentially coherent systems we must make certain that, whenever a load takes place, it retrieves a value it could have retrieved on a single-node system. The underlying system has no means of determining ahead of time when loads will be taking place and thus must be ready to cope with them at all times. However, a programmer or compiler has knowledge of a program that can be used to advantage. For example, if certain locations are *private*, i.e., are used by only one thread, there is no need to ensure that their values are up to date in all nodes' views. Locations that are shared by multiple threads might be accessed only when they are protected by some sort of synchronization primitive, e.g., a mutex or a semaphore. Since they are not accessed when not so protected and are accessed by only the thread that arranged for the protection when they are protected, we can incorporate into the synchronization primitives code to ensure coherency. In particular, when a thread performs a lock operation to gain mutually exclusive access to a shared data structure, it might issue a *flushr* instruction (defined subsequently) that ensures that subsequent loads can retrieve data recently made visible. As part of an unlock operation, it might issue a *flushw* instruction (also defined subsequently), which ensures that its changes become visible.

How can a distributed file or memory system not be sequentially coherent? Consider the example in Figure 89.3, which is in terms of a memory system, though it applies equally well to file systems. Here we have two processors, each executing two instructions. Assume that the initial values in locations *a* and *b* are both 0. In the sequential coherency model, there are exactly three possible outcomes of the execution of the processors' instructions:

1. Processor 1's load returns 0, processor 2's load returns 1. This happens when processor 1's load occurs before processor 2's store.
2. Processor 1's load returns 1, processor 2's returns 0. This happens when processor 2's load occurs before processor 1's store.
3. Both loads return 1. This happens when neither processor 1's load occurs before processor 2's store nor processor 2's load occurs before processor 1's store.

However, if caching has delayed the effects of stores, has caused loads to retrieve old data, or both, there is a fourth possibility:

4. Both loads return 0. This happens when processor 1's load occurs after processor 2's store and processor 2's load occurs after processor 1's store. Since the effect of the stores is delayed, neither processor's load retrieves the value being set by the other processor's store.

FIGURE 89.3 Potential violation of sequential coherency.

Caching is beneficial for performance, but if it can cause unanticipated results, it must be done with care. In our example we can eliminate the unanticipated results, yet still allow caching, by flushing the cache before each load. We now show that such flushing will always produce sequential coherency.

We first define exactly what we mean by *flush*. We assume that when writes and stores become visible, they do so for all nodes at once; this is true in most, if not all, distributed file and memory systems today and greatly simplifies our exposition. The value produced by a store instruction is not necessarily visible immediately after the instruction is issued. However, once a *flushw* is executed by a processor, the values produced by all stores issued by that processor prior to the issuance of the *flushw* become visible (if they are not already). A *flushw* is said to be *ordered* if it causes the values produced by stores to become visible in the same order in which the corresponding stores were issued. When processor A issues a load instruction to obtain a value from some specific location, the value obtained is the most recent visible value stored there before t time units in the past by some other processor or, if it occurred more recently, the most recent value stored there by processor A. The parameter t is unspecified; it may have an upper bound, but there is a fair amount of uncertainty about its value. However, if a *flushr* is executed immediately prior to the load, then t is zero. A *flush* is the combination of a *flushw* and a *flushr*. An *ordered flush* is the combination of an ordered *flushw* and a *flushr*.

Consider a distributed system X in which the order in which stored values are made visible is the order in which the stores were issued, and in which each load is preceded by an ordered flush. Is this system sequentially coherent? To show that it is, we must show, for each execution in this system, that there is an equivalent one in a system Y in which all processors execute the same instructions in the same order as they do in X , but in which stores become visible when they are issued.

Our first concern is to define what we mean by an execution in X . Since X is a distributed system, its executions consist of the executions of its component nodes. To simplify the presentation, we assume that each of these nodes consists of a single processor. An execution of a single processor is represented as the sequence of the instructions that were executed. Thus, if α_i is the execution sequence of processor i , then α , an execution of the distributed system, is the collection of all α_i for each processor i .

There is clearly a total order on the instructions in any execution sequence α_i . But because the processors of X execute in parallel, there is no total order on all of the instructions of the components of α ; however, a number of partial orders can be defined. In particular, a store instruction supplies the value for a load instruction if the value retrieved from a location by the load was placed there by the store. We say that the store was the *source* of the load.

Our goal is to show that, for any execution α on distributed system X , there is a valid, equivalent execution sequence β on the single-processor system Y consisting of some interleaving of the execution sequences α_i of the component processors of X . Note that the store instructions in α become visible in some particular order. (If the store instructions of two different processors become visible simultaneously, we assume that their effect is as if one became visible before the other; we use this effective order to define our order of becoming visible.) We construct a proposed sequence β of instructions for system Y as follows (again to simplify the presentation, we assume that each of the α_i starts with a store): The first instruction of β is the first visible store of α . Following this in β are all of the initial instructions of each α_i up to, but not including, either the first store or the first load to retrieve a value not produced by the first visible store, whichever comes first. Next in β comes the next visible store from α , followed by all of the subsequent instructions of each α_i starting with the first not previously selected and continuing up to, but not including, either the first store or the first load to retrieve a value not produced by an already selected visible store, whichever comes first. The remaining instructions of β are sequenced accordingly.

We claim that β is not only a valid instruction sequence for the single-processor system Y but also is equivalent to α . To show this, we show that each load in β retrieves the same value as the corresponding load in α .

We first show that if s is the source of l in α (i.e., if store instruction s produced the value fetched by l), then s appears in β before l . This is due to the construction of β : if the source of a load has not been selected for inclusion in β , then the load cannot have been selected either.

Next we show that if a load appears in β , then any conflicting store (i.e., a store that places a value into the location being accessed by the load) that becomes visible after the source of the load became visible must

appear after the load in β . To see this, again consider the construction of β . Suppose there is a load l in β , from processor i , for which a conflicting store appears between it and its source store. For this to happen, l could not have been selected for β as part of the instructions selected along with the source store. Thus, during the construction of β , there must have existed some positive number of stores and unsatisfied loads (i.e., loads whose source has not yet been selected for β) in the initial unselected portion of α_i appearing before l .

All of the stores in this portion must have been nonconflicting, because if they had been conflicting, since they occur in α_i and became visible after the source store, they would have overridden the value provided by the source store in α and prevented it from being the source store. If a conflicting store of some other processor had become visible before any of these nonconflicting stores of α_i and had thus been selected in β before l , then it too would have overridden the source store in α . This is because the flush executed before each load guarantees that any store instruction w in α_i appearing before l becomes visible before l is executed, and thus that if a conflicting store of another processor becomes visible before w , it will override l 's source before l is executed.

Consider now the loads in the initial unselected portion of α_i . If they accessed the same location as l , they must have the same source store as l , since a different source store would have become visible after the source store of l and thus would have overridden it in α . If any of these load instructions was accessing a different location, both they and l could not have been selected for β until after the sources of these loads became visible. If a conflicting store of l comes before any of these stores and after l 's source, then it over-rides this source in α . Thus, there cannot appear between a load in β and its source store a conflicting store.

Since we have shown that the source of a load appears before it in β and that no conflicting stores appear between the source and the load in β , we have what we were after: that loads in β produce the same values as loads in α . Because of this and the fact that the instructions of each α_i appear in the same relative order in β as they do in α_i , each execution in X has an equivalent execution in Y . Thus, X is sequentially coherent.

89.2.2 Coherency of File Attributes

An issue that affects file systems is maintaining *file attributes*: information about files, such as their sizes and the times of the most recent read and write accesses. This information is used often by clients and thus is often cached. Even if the underlying model is strictly coherent, the clients' views of the file system could be at odds with the single-system model if the attributes are not properly maintained.

For example, the following scenario has occurred (and has caused problems) in NFS: file X contains a sequence of records. A process P makes a private copy Y of X and records X 's attributes at the time of the copy. P then edits Y , deleting some of the records contained in it (there are no consistency issues, since Y is a private file). P then uses some sort of mechanism to gain mutually exclusive access to X and replaces the contents of X with the contents of Y if X has not been modified (as reflected in the time of last modification stored in its attributes) since the copy Y was produced. If X has been modified (e.g., a new record has been added), then, rather than replacing X , P reproduces the changes it made to Y in the current version of X . Now, suppose a new record is added to X just before P gains mutually exclusive access to X . If P 's copy of X 's attributes is not appropriately updated, then, regardless of the memory model, P might replace X 's contents with Y 's rather than merge its edits to Y with the modified X . The result is that the record added to X is lost.

89.2.3 Performance

The primary performance concerns for distributed file and memory systems are minimizing both network traffic and latency of responses to user requests. If the data necessary to handle a user request (such as a read operation on a file or a load from memory) are available locally, latency is minimal, but if not, latency can be considerable. Since the impact of network traffic on overall performance is more dependent on the number of messages being transmitted than on their size, it is advantageous to transmit data in batches.

To reduce latency and network loads, most systems use *caching*: portions of files or segments are automatically maintained on client nodes, either on disk or in primary memory. Assuming that local

access is quicker than remote access, this clearly helps reduce average latency, since many reads and writes (and loads and stores) can be handled directly from the cache. This also helps to reduce server and network loads since files and segments tend to be used repeatedly: once a file or segment has been transferred to a node, it is quite likely to be used many times, so that the number of transfers required over the network can be greatly reduced. In fact, many files, though they reside on server nodes, are accessed only on a single client node; thus, there is rarely a need for data transfer between server and client. Furthermore, network bandwidth can often be better utilized with caching, since large amounts of data can be transferred at once. However, data can now be transferred over high-speed networks faster than from disks. Thus, it may be quicker to obtain data over the network from the primary storage of a server machine than from a local disk.

To further improve latency, many systems, particularly file systems, use *prefetching*: a file or portion of a file is fetched before it is needed. Some operating systems provide asynchronous I/O facilities with which one can explicitly request data to be transferred without having to wait for it. One can use multithreaded programming techniques to get the same effect. These approaches require a very knowledgeable programmer and are often difficult to take advantage of. Some operating systems, such as Unix, attempt to predict what data are needed next and fetch it automatically before the program needs it. These techniques are effective only if files are being accessed sequentially (which is the only case for which the operating system can make predictions of data needs), but this happens frequently enough to be quite useful. Prefetching from the disk to primary storage is common in local file systems, and this notion is extended to prefetch from server to client in most distributed file systems.

One uses distributed memory systems to take advantage of parallelism. Thus, the most important measure of the performance of such systems is the speedup obtained when running a program on multiple nodes. This, of course, depends on the program being run, but we can compare actual performance with ideal performance: the time required if the nodes actually shared memory and all memory access times were those of local access.

89.2.4 Resilience

The next major concern is resilience. Failure is easy to cope with in the single-system model: either all components are running or all components are down — a crash crashes everything. Recovering from a crash entails restarting everything; merely resuming operations where things had left off is generally not possible. But this is one aspect of the model that we do not want to mimic in a distributed system: crashes of individual nodes should be handled gracefully by the other nodes. Functionality and data that are available only on the down nodes are lost for the duration of the downtime, but all other functionality and data should continue to be available. Moreover, operations emanating from client nodes that were in progress on a server node when it went down should be able to continue when the server comes back up, if they were not already completed on some other node.

Crash recovery involves first recognizing that there was a crash and then coping with it. Recognizing that there has been a crash is not simple, since a crashed node normally does not broadcast that it is about to crash before doing so. One node might suspect that another is down when nothing is received from the other node, despite expectations, after a reasonable period of time. But this unresponsiveness could be due to a communication failure having nothing to do with the node, or it could arise because the node is merely extremely busy, not down. Thus, the only sure way of determining that a node is down is for it to announce that it has been down as it restarts itself.

Coping with a server crash on a client might be as simple as waiting until the server restarts, then continuing normal operations, as if nothing had happened. Alternatively, the client operation might timeout, passing to the caller the decision on what to do. Yet another approach is to transfer requests from a down server to another server that provides equivalent files (i.e., replicas of the files provided by the down server).

A server's recovery from its own crash depends on how much state information was lost with the crash and hence must be recovered. In the simplest case, servers are *stateless*: there is no state information on the server, thus there is no state information that must be restored, and thus crash recovery involves simply restarting the server.

For servers that maintain state, the state information must be recovered. Such state information could be maintained on nonvolatile storage where it could survive a crash. This is generally not done: doing so would be expensive, and, moreover, losing state information in a crash can be advantageous. Suppose a client crashes while the server is down, thus invalidating its contribution to the server's state. If the server's state were maintained in nonvolatile storage, then, when it comes back to life, it must first determine that the client had crashed and then reset the client's contribution to the state. Since the server's recovery of state information depends on information supplied by clients when the server comes back to life, if the down client provides no information, there is no information that the server must reset.

For a client crash, the general assumption is that the operations in progress on the client cannot be resumed, and thus the client is simply restarted. The onus falls on the server to recognize a client crash and to react by restoring any client-specific state information to some initial value and recovering any resources that may have been allocated to the client. For stateless servers, nothing need be done, but for other types of servers a fair amount of work may be required.

89.2.5 Naming

Our next concern is the naming of files and how it relates to locating files. In the single-system model, we assume that a single tree-structured directory hierarchy (extended to a directed acyclic graph if links are allowed) is used for file naming. Files are identified by their pathnames in the directory hierarchy; this identification also serves as the means for locating files in secondary storage.

The entire name space can be viewed as a disjoint collection of subtrees joined together to form a tree: the root of one subtree is somehow connected to or superimposed on a directory of another. Each server provides some number of these subtrees to its clients. At issue are the mechanism for joining the subtrees into a single tree and the appearance of the tree to the clients. One approach is for each client to piece together the subtrees itself, independent of the other clients. This approach, which is used by NFS, allows each client node to tailor the combination of subtrees. Thus, though all client nodes might share access to all files, the pathnames of these files might differ across nodes (though, in practice, nodes are typically configured so this is not the case, i.e., any shared file has the same pathname on all nodes).

Another approach is that the connections between subtrees are built into the subtrees themselves. For example, in DFS, subtrees contain links to other subtrees; the subtrees are connected into a single tree whose appearance is identical to all clients.

It is also important that client nodes have private files, containing information to be used only on the node. This could be done by giving each client a subtree and position within the global name space, e.g., */NodeA/. . . /NodeB/. . .*. But what is usually done is to provide a private name space so that the same name can refer to different files on different nodes. For example, on Unix systems, whether using NFS or DFS (or both), */etc/passwd* refers to the password file on the node on which the pathname is used. This provides what we call **inverse location transparency**: programs referring to node-private files (e.g., */etc/passwd*) can use the same pathname regardless of the node on which they are running. The disadvantage is that one cannot easily refer to node-private files on other nodes, but this is rarely important.

89.2.6 Replication

One of the advantages of distribution is that multiple copies of files can be maintained on separate servers, i.e., files can be *replicated*. This can be taken advantage of both for performance and for reliability: the task of providing files to clients can be spread over several servers, thereby reducing the load on each of them. If one server goes down, the others can take over its load.

With location transparency we have the notion that the name of a file or group of files does not tie it to a particular site. Thus, if for administrative or other reasons the files must be moved, they need not be renamed. If the naming technique permits a group of equivalent files to be given a single name, then any of the group can be used to satisfy a read of the files associated with the name. This allows easy **failover** to an alternative server if one holding a copy of the file fails.

89.2.7 Disconnected Operation

Another concern is support for *disconnected operation*: Can a client continue to operate when disconnected from a file server for extended periods of time? For this to take place, those files needed by the client must be somehow cached on the client. In connected operation clients and servers cooperate to maintain the consistency of the various cached copies of files with the copies maintained on servers, but in disconnected operation, such consistency management is not possible. The same sort of consistency management performed in connected operation could be performed for the disconnected case during the possibly brief periods for which a node is connected to the server. The difference, of course, is the time scale involved. In a typical scenario a client node might load its cache from the server, disconnect from the network, and then operate on the cached files for hours or days before reconnecting with the server. Any attempt to provide single-system semantics will fail in this sort of environment.

89.2.8 Security

Our final concern is security. In the single-system model all files and accessors appear to be on the same node and thus access is controlled by a single operating system. There is no opportunity to circumvent security measures other than by successfully masquerading as another user (perhaps by guessing a password). For distributed file systems things are more difficult. File-system data and other information are transmitted across communication networks and are thus subject to being read and modified by malicious third parties. Thus, providing a single-node-system level of security requires measures far beyond those required on such a system.

Providing security across nodes can be expensive. Such expense is justifiable in many, but certainly not all, situations. One approach, as suggested in Hartman and Ousterhout [1995], is to have fairly relaxed security within local clusters of nodes (whose users presumably trust one another) and to apply more stringent security measures to accesses between such clusters.

89.3 Best Practices

In this section we look at the application of the principles discussed in the previous section by examining two commercially available distributed file systems — Sun's Network File System (NFS) and OSF DCE's Distributed File System (DFS) — and two distributed memory systems that are products of university research — IVY from Yale University and Munin from Rice University. NFS, which has been the standard for use in distributed Unix systems for the past decade, is a relatively simple system that has undergone much scrutiny as it has evolved and improved. DFS, which was developed by Transarc and is an outgrowth of their Andrew file system (AFS), is considerably more complex than is NFS and comes closer to achieving our single-system-model ideal in some respects, though not in others. IVY, the seminal research implementation of distributed memory, shows how a virtual memory implementation could be extended to support a strictly coherent distributed memory. Munin takes a somewhat different approach: its model is weakly coherent and sequential coherency is achieved by a variety of techniques, chosen depending on the types of shared data structures and programmer-supplied information on how such data structures are used.

89.3.1 NFS

NFS has four component protocols: a *mount protocol* for making collections of files stored on servers available to client nodes, a *file protocol* for accessing and manipulating files and directories, a *lock* and *status protocol* for locking files over the network and recovering lock state after failures, and an *automount protocol* to support replication and name-space management.

Servers divide their files into disjoint collections called *file systems*, each of which contains a rooted directory tree naming all its members. Servers, as specified in their local `/etc/exports` files, specify which file systems or subtrees within a file system are available to which clients. By cooperating with a server via

the mount protocol, a client can then *mount* a remote file system. This entails superimposing the root of the remote file system on top of a directory in the client's current naming tree. The root of the remote file system (the mounted file system) effectively replaces the mounted-on directory. Thus, the remote file system is attached to the client's naming tree at the mounted-on directory (and the previous contents of that directory are invisible as long as the remote file system remains mounted). The mount protocol additionally provides some minimal security by allowing administrators to specify for each file system on a server which client nodes are allowed to mount it.

Once a client has mounted a remote file system, its processes may access files in this system. This is where the file protocol is used: it provides a remote-procedure-call interface on the server for the client to use. A client process initiates activity on a file by opening it, an action that involves presenting a pathname to its local operating system, which follows the path, into remote file systems as necessary. If the path terminates in a remote file system, a *file handle* is returned to the client operating system identifying the remote file. The server, being stateless, keeps no record of the fact that the file is being used by the client. The file handle is used to identify the file to the server for all operations, including reading and writing.

The original NFS protocol took advantage of a cache of recently accessed file blocks maintained in the client's primary storage, known as the *buffer cache*, which allowed the prefetching of file-system blocks before they are needed (if the file is being accessed sequentially) and the write-behind of modified blocks. The buffer cache has been augmented in the most recent version of the protocol (version 3) with an on-disk cache, used primarily for files that rarely change. The buffer cache suffers from cache-coherency problems. NFS keeps such problems to a normally unnoticeable minimum, but occasionally false sharing and other problems can give the programmer unpleasant surprises.

The NFS approach to cache coherency is for the client to check with the server periodically to determine if items in its cache are stale and, if so, remove them. This is done by maintaining an *attributes cache* on each client that contains, for each file for which the client is caching blocks, the file's attributes, consisting of the file's size and access and modification times. When a file's attributes are fetched, they are tagged with the current time. Blocks of the file in the cache may be used on the client until the attributes expire, usually in a few seconds (the expiration time is a function of how recently the file was last modified; a file modified in the recent past is likely to be modified again soon). When an attempt is made to access blocks in the cache after the attributes have expired, a call is made to the server for the current attributes. If the file has been modified since the previous attributes were fetched, all blocks of the file are removed from the cache (modified blocks are sent back to the server to update the file). Thus, the cache is always close to a consistent state, but its consistency is never guaranteed.

Note that NFS is weakly coherent only if used via its mapped-file interface. On Unix systems, one can map an NFS-provided file into a client's address space. If one is careful to lay out data structures to prevent false-sharing problems, one can use *flushr*- and *flushw*-type instructions to achieve program-assisted sequential coherency. Though a *flushw*-type instruction exists for the file interface (i.e., accessing files via reads and writes), there is no *flushr* instruction.

An important aspect of performance is the minimization of messages transferred between client and server. NFS is normally layered on top of Sun RPC, which in turn is layered on the user datagram protocol (UDP) of the Internet suite. Sun RPC, particularly when layered on top of UDP, is quite simple: for each request, a response is expected. If the response is not received in a reasonable amount of time, the request is retransmitted, and again and again until a response is received. The usual case, of course, is that the request and response are each transmitted only once, and thus a minimum number of messages is transmitted.

There is a potential problem here. If a response is not received, then the request is retransmitted. If the reason that the response was not received is that the request was lost, then, assuming the retransmitted request arrives at the server, only one instance of the request is executed on the server. But suppose not the first request, but the first response was lost. When the retransmitted request arrives at the server, it is executed, with the result that two instances of the same request are executed on the server. If the request has a cumulative effect, such as transferring \$100 from one bank account to another, this double execution would be a serious bug. However, in NFS most requests are designed to be **idempotent** — the effect of executing such a request twice is exactly the same as executing it once. For example, a request to write to

a file specifies which file, the location in the file, and the data to be written. Executing the request twice causes the same data to be written to the same place twice — inefficient, but not harmful.

Recent improvements in the performance of transmission control protocol (TCP) implementations have caused some vendors to run NFS on TCP. Although this protocol guarantees reliability, idempotency is still an issue. If a server crashes while performing an operation, the client is uncertain whether the operation took place. Idempotency allows the client simply to repeat the operation once the server is running again, without fear of causing harm.

NFS is the prime example of the advantages of statelessness. Servers running NFS's file protocol need not retain any information about their clients or what their clients are doing: any information about clients maintained on a server is an optimization; it can be regenerated if necessary. Thus, no recovery actions are required of the file protocol on the server after the server has crashed.

As previously mentioned, an issue for the client side is determining *if* the server has crashed. With stateless servers, the client application (as opposed to client operating system) can be oblivious to whether a server has crashed; the operating system simply repeatedly retries file-protocol RPCs to the server until a response is received; the application perceives a slowdown but no loss of function or data. However, via the mount protocol, a client node can specify how a server's crash (or, more accurately, server unresponsiveness) is to be dealt with, by specifying how the remote file system is mounted. One option, known as the *hard mount*, is for the client to retry operations repeatedly, as just described, until they succeed. This has the advantage that, other than a delay in execution, the client process's semantics are unaffected. However, it has the disadvantage that it can cause a client process to block indefinitely, waiting for the result of the operation. Thus, another option, known as the *interruptible hard mount*, allows the remote operation to be aborted while in progress. This has the benefit of releasing a process (and perhaps an entire user session) from the clutches of a server that will be down for an indefinite period but certainly has a dramatic effect on the process's semantics. The final option, the *soft mount*, is that the operation returns an error code indicating that no response was obtained after a reasonable number of retries (note that the operation may or may not have successfully taken place on the server — all the client knows is that there has been no response). This is a useful alternative if the client application takes the trouble to notice such error codes and is prepared to deal with them, but otherwise could cause serious problems. The great advantage of the first two options is that from the client application's point of view, no special treatment is required for server failures — the system is **failure-transparent**.

Coping with a client crash is equally simple since servers are stateless. When a client crashes, whatever was running on it at the time of the crash is lost; when the client restarts, no information is available on what it was doing at the time of the crash. Thus, if the client had state on the server that must be cleaned up after the crash, it cannot direct the cleanup, since it has no knowledge of what this state is. Since servers are stateless, this is not a problem: clients simply restart and servers are oblivious to the fact that anything happened.

However, some sort of state information is required to support file locking: we must keep track of whether files are locked or not. NFS deals with this with a pair of protocols: one for maintaining locks (the *lock protocol*) and one for keeping track of whether clients have restarted (the *status protocol*). A file's server maintains the state information associated with locking. If a client crashes while holding a lock on a file, this lock must be removed. As noted earlier, the server cannot use the lack of communication from the client as an indication that the client has crashed; it requires definite notification, which is supplied when the client restarts (thus, files remain locked while the client is down). Manual intervention may be necessary if the client is down for an extended period of time.

A server crash is more difficult to deal with: the state information concerning locks is kept in volatile storage, which is lost after a crash. If it were kept in nonvolatile storage, then if both a client and the server crashed, there would be difficulties in determining that the client's locks must be removed; the server would realize that certain items are locked but would not realize that not only should they no longer be locked but also that the client is unaware that the items are locked. Thus, when a server crashes, all locks are removed by default. It is then up to the clients, if they remain up, to restore the lock information on the server. When a server restarts after a crash, it informs all its clients via the status protocol that it is now

back in operation. It also establishes a grace period during which clients must notify it of locks they had held before the crash, so as to reclaim them. During this period no new lock requests are honored. After the grace period, all state information is recovered (that not recovered, presumably due to down clients, is lost) and the server goes back to normal operation.

The final aspect of NFS has to do with the name space. There are two issues here. It is the responsibility of each node to set up its own name space by mounting into its hierarchy file systems provided by servers. The number of such file systems could be huge, even though, for any one particular node, many are rarely, if ever, accessed. Thus, rather than attempting to use the mount protocol to mount all conceivable file systems when a node is booted, the *automount protocol* is used to mount file systems when needed.

The other issue, also dealt with by the automount protocol, is to support the replication of read-only file systems. If a server providing an important file system, such as the binary images of system commands, crashes, it is important that there be some sort of failover facility so that an alternative server can provide the file system. To accomplish this transparently to the clients, both instances of the file system should appear to have the same name, i.e., the same pathname in a client's directory tree. When a client node mounts a remote file system using the automount protocol, it broadcasts a request asking for providers of the desired file system. There could be many potential providers; the first one whose response is received is chosen. Thus, if one provider is down, another can be used.

The only drawback of this approach occurs when the provider of the important file system crashes while it is mounted on a client's naming tree. There is no support for automatically unmounting the file system and looking for a new provider. Thus, though a new provider is available, it cannot be used. What is done is to unmount file systems automatically if they have not been used after a period of time, typically five minutes. An automount broadcast is then performed on the next access to the file system. This approach works well for file systems that are used sporadically but does not solve the problem for file systems in constant use.

89.3.2 Distributed File System

OSF DCE's DFS goes much farther in some areas than NFS toward achieving the single-system ideal, though not as far in others. Assuming all components (clients, servers, and network) stay up and running, its variance from the ideal is small. DFS achieves this even though it employs large client caches on local disks to hold all files (split into chunks) being used on each client. It maintains consistency via a token-passing algorithm, which produces much state information on servers that must be restored after a server crash and cleared after a client crash.

A DFS installation is an optional part of a DCE *cell*, which is a potentially large (thousand-node) collection of computers sharing a common security database. Each cell supporting DFS has a single DFS name space used by all nodes. As in NFS, the name space consists of a collection of *file sets* (a better term than the ambiguous file system used in NFS and other Unix file systems). The file sets are connected together into a single tree structure by storing mounting information not at each node but in the file sets themselves. This mount information is represented via a form of *symbolic link* that provides the name of the file set mounted at this directory. Unlike NFS, in which the root of the mounted file set replaces the mounted-on directory, here the root of the mounted file set becomes the child of the mounted-on directory. In fact, one mounted-on directory can contain links to any number of file sets.

DFS exploits these links to help provide for the replication of read-only file sets. One can create any number of read-only copies of a file set. Each file set has a short, descriptive name; a read-only copy has the suffix "readonly" at the end of its name. Encoded in the mounting information stored in a file-set link is an indication of whether it is a read-write mount point, so that the read-write version is required, or that it is a read-only mount point, so that any of the read-only replicas may be used.*

*There is also a regular mount point that is equivalent to a read-write mount point if it (the mount point) resides in a read-write file set, and to a read-only mount point if it resides in a read-only replica.

A special replicated database, the file-set location database (FLDB), provides a mapping from file-set names to the names of the servers that hold the various replicas of the file set. This database is used by client-side DFS code when following a path: when a file-set link is encountered, the client code looks up the file-set name stored in the link in FLDB (these lookups are cached so that name-to-file-set translation is not terribly expensive). Depending on the type of mount point, it selects either the server containing the read–write replica of the file set or any of the servers containing read-only replicas. If the client is using a read-only replica and the server becomes unresponsive (perhaps because it has crashed), the client operating system simply finds from FLDB another server containing a read-only replica and (quietly) switches to it; the client application is oblivious. Thus, when using read-only file sets, failover is automatic. No attempt is made to support read–write replication.

DFS maintains strict coherency. Its clients maintain caches on their local disks that store files in chunks of typically 64 kilobytes each. As in NFS, prefetching and write-behind are used to overlap I/O and computation. Servers maintain the consistency of the chunks from their files that appear on client caches by controlling which clients may read and modify the chunks. This is accomplished via a token-passing algorithm: for a client to perform an operation on some portion of a file in its cache, it must have, from the server, a token that grants it the necessary permission (note that this is not access permission in the sense of whether or not the client is authorized to access the file but merely indicates whether an access can now be done in a strictly coherent fashion).

Various forms of permissions are represented by tokens. There are tokens that allow a client node to read data from a portion of a file and tokens that allow a client node to modify data in a portion of a file. There are tokens for locking a file (or portions of a file), both for shared (read) locks and for exclusive (write) locks. Tokens are required for reading and setting file attributes (such as modification time, access time, and file size). To maintain strict coherency, if any client node is modifying a portion of a file, no other node may be reading or modifying that portion of the file. Of course, any number of nodes may be reading a portion of a file at once, as long as no node is modifying it. This is controlled through the distribution of tokens: to modify a portion of a file in its cache, a client node must obtain a write token from the file's server. To read the data in its cache, the node must have a read token. The server is responsible for making certain that if a write token for a particular portion of a file has been granted, then no read tokens for that portion are outstanding, and so forth. If, for example, a write token is outstanding and some node wishes to read the file, the server contacts the holder of the write token to revoke it and then gives the other node a read token.

Similarly, to modify a file's attributes, a client must have an appropriate token; the server will grant the token only if no tokens are outstanding for reading the attributes. A small problem here is that included with file attributes is the file access time, which should be updated every time the file is read. But doing so requires a *status write* token, which cannot be granted if there are *status read* or *status write* tokens outstanding. Thus, for single-system semantics, multiple nodes cannot be reading the same portion of a file at once, since doing so would require that they all have *status write* tokens. Because of this, DFS must deviate from single-system semantics and not maintain the access time of a file exactly as done on a single system. Instead, the update of the access time may be delayed, so that the file may have been accessed some time ago, but the access time does not yet reflect it.

Because DFS must maintain a lot of state information (e.g., what tokens are out), its crash recovery is much more complicated than NFS's. Three independent things can go wrong:

- *A client can crash:* Thus, the server will need to reclaim all of the tokens that were held by the client.
- *A server can crash:* Token information is not held in nonvolatile storage. It must somehow be re-created when the server comes back up.
- *The network can fail:* Though both client and server remain up, neither can communicate with the other.

Suppose that a server is unable to contact a client. If the client has possession of tokens and another client wishes to perform an operation that conflicts with the first client's tokens, then the server would like to revoke the tokens. Since the client is unresponsive, the server must do this unilaterally.

Conversely, suppose that a client is unable to contact a server. As long as the client has what it needs in its cache, then it really has no need to contact the server — it can get along quite well on its own. When the server comes back to life, it recovers its tokens using an approach similar to that used in NFS's lock protocol: the clients notify the servers of the tokens they possess.

Thus, we have two potentially conflicting points of view:

- The client should be able to use its cache even if the server is down or not accessible.
- The server should be able to revoke tokens from a client even if the client is down or not accessible.

If either the server or the client has crashed, then providing the other's point of view is not difficult. But if a network outage occurs and the server and client become separated from each other but both continue to run, then the two points of view conflict with each other.

DFS uses a compromise approach. If the client cannot contact the server, it continues to use its cache until its tokens expire; they are typically good for two hours, though they are normally refreshed every minute or so. However, say the server is actually up and running but is somehow disconnected from the client. If the server has no need to revoke tokens, then it does nothing. But if some other client that is communicating with the server attempts an operation that conflicts with the unresponsive client's tokens, then the server is forced to take action.

If the server has not heard from the client for a few minutes, it can revoke the client's tokens unilaterally. This means that when the client does resume communication with the server, it may discover that not only are some of its tokens no longer good, but some of its modifications to files may be rejected.

To protect client applications from such unexpected bad news, the client-side DFS code causes attempts to modify a file to fail if it has discovered that the server is not responding. A client program can take measures to deal with this problem by repeatedly retrying operations until the server comes back to life. This does not provide the transparency of the NFS hard-mount approach, but it does allow the client to use its cache to satisfy reads while the server is down.

89.3.3 IVY

IVY [Li and Hudak 1989] is one of the earliest distributed memory systems. A research project that included a study of various techniques for handling the visibility of writes while maintaining strict coherency, it helped to establish the viability of the concept of distributed memory by demonstrating impressive performance.

A primary concern was how to maintain strict coherency yet propagate the effects of writes efficiently. All of their solutions involve the notion of a node owning a shared page. Ownership is dynamic: to modify a page, a node must first own it. Other nodes can have copies of a page in their cache; when the owner modifies a page, it *invalidates* the copies in the other nodes' caches by sending them invalidation messages.

To modify a page, a node must first become its owner. This involves first determining the present owner, so that an ownership transfer can be arranged. Thus, some sort of mapping must be established associating page number with owning node. One technique is to have a central server handling the mapping chores: a node attempting to modify a page of which it is not the owner contacts the single mapping node to find the location of the owner, establishes a new mapping giving itself as the owner, and finally contacts the current owner to take over the page. The technique has the advantage of being simple but the disadvantage of creating a performance bottleneck and a single point of failure.

An alternative technique is to distribute the mapping functionality. The simplest implementation of this idea is to spread the mapping chores across all nodes but to have a fixed assignment of page number to node mapping the page to its owner. The developers' experiments showed that this technique was superior to the central mapping technique, but they found it difficult to obtain a fixed assignment that fit all applications well.

The final technique involves a dynamic approach to mapping page number to owner node: each node maintains a table mapping each page to its *probable* owner. Requests for change of ownership are sent to the probable owner who, if not the actual owner, forwards the request to the node it believes to be the

owner, and so forth until the actual owner is reached. In the worst case, $N - 1$ messages are required to locate a page's owner, assuming N nodes. The ownership information is updated whenever a node receives an invalidation request, relinquishes ownership, or suffers a write fault, so that the worst-case number of messages for locating a page's owner rarely occurs. Li and Hudak [1989] show that the maximum number of messages required to locate the owner of a single page k times is $O(N + k \log N)$; in practice, a page's owner can be found fairly quickly.

89.3.4 Munin

Munin [Carter et al. 1995], developed at Rice University and the University of Utah, is an example of the use of weak coherency and other techniques to improve the performance of a distributed memory system. Rather than use a single software approach to ensure sequential consistency, multiple approaches are used, depending on the access patterns to the shared data. The loss of concurrency due to false sharing is minimized by using a *write-shared protocol* that merges together modifications made to the same page by separate nodes. In addition, an *update-with-timeout* mechanism removes copies of shared data from caches of nodes that have not used them for a while — this reduces the number of nodes whose caches must be invalidated when there is an update.

Research by the developers suggests that support for five access patterns can significantly improve performance in a distributed memory system:

- *Conventional shared variables* are treated just like shared data in IVY: to modify such a variable, a node must be the sole owner of the page containing it. When modifications occur, invalidation messages are sent to nodes containing copies of the page.
- *Read-only data*, once initialized, are never modified. Thus, no overhead is required to maintain coherency.
- *Migratory data* are used by one node at a time. Thus, once a node that has not been accessing such a data item starts accessing it (via a read or a write), the entire item is transferred to the new node and the original copy in the old node is invalidated.
- *Write-shared data* is a collection of items, each being modified by a single node, that share a page. Without special treatment there would be a false-sharing problem, but, by using the *write-shared protocol*, full concurrency can be achieved: when a node propagates its changes to write-shared data, it transmits merely its changes to the page rather than the entire page. Receivers of these updates can then merge these changes with their own. Conflicting changes can be detected and flagged as run-time errors.
- *Synchronization variables* are specialized implementations of three common synchronization constructs: *locks* (otherwise known as *mutexes*), *barriers*, and *condition variables*. They allow the programmer to take advantage of weak coherency by modifying shared data only when they are protected by the synchronization variables. Sequential coherency is obtained by making modifications visible at appropriate moments (e.g., during an unlock operation).

The net effect of these features of Munin is to decrease significantly the number of messages from those required by strictly coherent distributed memory systems. The developers' measurements show their system to be within 5% of implementations of a number of applications done with explicit message passing and within roughly 30% for others. They argue that further enhancements will improve the latter results substantially.

89.4 Research Issues and Summary

The notion of distributed file systems is a straightforward extension of the notion of local file systems: functionality available on nonnetworked individual computers has been made available to networked computers collectively. But computing has changed a great deal since the days when the only file systems

were local file systems — it is no longer enough for data, organized into files, to be made available strictly to a collection of machines statically interconnected with cable. For the notion of a distributed file system to remain relevant, it must be useful in a world in which mobile computing, multimedia, and enterprise computing play key roles.

In mobile computing, client machines are often disconnected from servers. When they are connected, it might be via relatively low-speed links, such as direct and cellular telephone connections. Some commercial products, such as Lotus Notes[®], provide some support for data access by mobile users, but they operate in specialized domains (electronic mail, simple databases) and do not provide the general-purpose foundation for constructing applications that is the promise of distributed file systems. Research is under way in adapting distributed file systems to mobile use (e.g., Satyanarayanan et al. [1993] and Huston and Honeyman [1995]). One goal of such research projects is to extend to mobile computing the functionality currently available to clients statically connected to their servers via high-speed networks. The issues being grappled with include providing some degree of coherency (sequential coherency may prove completely infeasible in such environments), loading a client's cache with appropriate files for a lengthy disconnected session, and scheduling communications traffic so that information needed urgently is given top priority. Dealing with coherency may involve resolving the effects of conflicting changes to files by multiple clients. This may be automatic in some cases, but many currently require assistance from the user. Preloading the cache often requires user input. Scheduling communications traffic allows currently needed data to be fetched prior to write-backs of modified data (though this, of course, has an effect on coherency).

Distributed file systems supporting multimedia have stringent performance demands. Not only must data be transferred quickly, but the transmission rate must be reliable so that data arrive before they are needed. A system specialized as a video server developed at Microsoft [Rashid 1994] transmits movies chosen from a library to a large number of clients at an appropriate rate and allows VCR-like functions such as fast forward and reverse. The demands on this system could well prevent its functionality from being subsumed by a general-purpose distributed file system, but some of the techniques used could be of use in general-purpose systems for handling more moderate numbers of clients.

Many of the issues arising in large enterprise systems have to do with scaling, taken here as the number of clients that can use a distributed file system. One point of view is that the collected file systems of a large company (or the entire world, for that matter) should be transparently accessible by anyone from anywhere subject, of course, to security constraints. A relatively small-scale implementation of this view involves users of Transarc's AFS system (the latest incarnation of the forerunner of DFS). Users around the world see one another's files as fitting in a single-directory hierarchy. A program running on a workstation in Providence, RI, can access files in Sydney, Australia, using exactly the same steps as to access files on a local disk. This works because, though the participating sites are widespread, they are relatively few; each site maintains a list of all other sites. If the entire world is to be made available in this fashion, other means will be necessary for sites to locate one another.

With large numbers of clients potentially accessing individual files, improvements in caching and load balancing become essential. Whereas both NFS and DFS support the replication of read-only collections of files, the processes of determining how many replicas to make and where to place them are entirely manual. At the very least, monitoring tools must be available to let an administrator react quickly to changing access patterns, creating and placing replicas, and deleting unneeded ones. Ideally, this sort of load balancing would be automatic.

The promise of distributed memory systems is to provide an easy-to-use programming paradigm for highly parallel systems. For the promise to become reality, the amount of parallelism must approach levels of interest to those with significant computational demands. As the numbers of processors increase, it may become important to integrate some degree of fault tolerance into the model so that individual processor failures do not take down the entire system.

In architecture there are two separate trends, one toward the interconnection of a collection of workstations into a distributed memory system and the other toward a system consisting of a large number of processors (perhaps all in one box) designed from the beginning to be a distributed memory system. In

the former, the distributed memory is implemented entirely with software (other than hardware support for virtual memory); the latter typically uses hardware support.

Utilizing a collection of workstations as a parallel computer has been a goal of a number of researchers and many reasonably successful implementations exist (e.g., IVY and Munin). The attraction is that an organization might have a large number of workstations, many of which are unused over long stretches of time (overnight, for example). Among the longstanding issues only partly resolved in current systems are identifying available workstations and coping when workstations become unavailable (i.e., forcing off distributed memory users when the workstation is needed for other work). Adequate resolution of these issues could make this model of computation much more common.

In dedicated distributed memory systems in which processors are physically close to one another, interprocessor communication speeds can be quite high, rivaling processor-memory communication speeds. Such systems are beginning to appear on the market. Among the research issues still requiring attention are means for adequately distributing the parallel components of a computation, balancing the loads of the various processors, and devising and popularizing programming techniques for exploiting large-scale parallelism.

Defining Terms

Access transparency: A system property by which the complications involved in providing access to something (e.g., data) are not apparent to the accessor.

Failover: A system property by which, in the event of a failure of one component, the function provided by that component is taken over by another.

Failure transparency: A system property by which no special actions are required of clients to cope with failures of servers.

False sharing: What happens when two data structures share the same unit of storage, e.g., blocks in file systems in pages in memory systems.

Idempotency: The effect of performing an operation many times in succession (with no conflicting operation appearing between the repetitions) is the same as the effect of performing the operation once.

Inverse location transparency: A system property by which a given name refers to a different item on each node. Thus, a name can be used transparently by a program to refer to information specific to the node on which the program is running.

Location transparency: A system property by which how one refers to something depends on the location of neither the subject nor the object.

Sequential coherency: The property of a distributed file or memory system in which the effect of any execution is an effect that could have happened had all computation taken place on a single processor.

Single-system model: The computational model in which all computation takes place on a single processor.

Strict coherency: The property of a distributed file or memory system in which each read or load retrieves the value produced by the most recent write or store to that location.

Weak coherency: The property of a distributed file or memory system that does not necessarily provide sequential coherency by itself but that can provide sequential coherency if certain additional instructions are executed by any program running on the system.

Further Information

Good coverage of a number of the issues covered in this chapter can be found in *Distributed Systems*, edited by Sape Mullender, Addison–Wesley, 1993.

Both ACM's bi-yearly *Symposium on Operating Systems Principles* and the ACM journal *Transactions on Computer Systems* often contain a number of excellent papers on issues related to distributed file and memory systems. Copies of the proceedings and subscription information for the journal can be obtained from ACM, 1515 Broadway, 17th Floor, New York 10036, (212) 869-7440.

The USENIX journal *Computing Systems* also often contains excellent papers on issues related to distributed file and memory systems. Subscription information can be obtained from The MIT Press Journals, 55 Hayward Street, Cambridge, MA 02142, (617) 253-2866, journals-info@mit.edu.

X

Programming Languages

The area of Programming Languages includes programming paradigms, language implementation, and the underlying theory of language design. Today's prominent paradigms include imperative (with languages like COBOL, FORTRAN, and C), object-oriented (C++ and Java), functional (Lisp, Scheme, ML, and Haskell), logic (Prolog), and event-driven (Java and Tcl/Tk). Scripting languages (Perl and Javascript) are a variant of imperative programming for Web applications. Event-driven programming is useful in Web-based and embedded applications, and concurrent programming serves applications in parallel computing environments. This section also provides a balanced treatment of the underlying theories of language design and implementation such as type systems, semantics, memory management, and compilers.

90.5 Research Issues and Summary

90.1 Introduction

In the 1940s, John von Neumann pioneered the design of basic computer architecture by structuring computers into two major units: a central processing unit (CPU), responsible for computations, and a data storage unit, or memory. This architecture is demand driven, based on a command and instruction-oriented computing model. The basic unit cycle of execution, typically composed of a single instruction, consists of four steps:

1. Obtain the addresses of the result and operands.
2. Obtain the operand data from the operand location(s).
3. Compute the result data from the operand data.
4. Store the result data in the result location.

Note in this sequence how separation of the execution unit from the memory unit has structured the sequence. Data must be located and piped from memory, operated on, and transferred back to memory to be available for the next operation. All operations in a von Neumann machine operate this way, in a stepwise, structured manner. The von Neumann model has been the basis of nearly every computer built since the 1940s.

Imperative programming languages are modeled after the von Neumann model of machine execution and were invented to provide the abstractions of machine components and actions in order to make it easier to program computers. Abstractions such as variables (which model memory cells), assignment statements (which model data transfer), and other language statements are all abstractions of the basic von Neumann approach.

In this chapter we address the fundamental principles underlying imperative programming languages and examine the way the constructs of imperative languages are represented in several languages. We devote special attention to features of more modern imperative programming languages, among them support for abstract data types and newer control constructs such as iterators and exception handling. Examples in this chapter are given in a variety of imperative programming languages, including FORTRAN, Pascal, C, C++, MODULA-2, and Ada 83. In the Best Practices section we explore in more detail the languages FORTRAN IV (chosen for historical reasons), C and C++ (its imperative parts), and Ada 83.

90.2 Data Bindings: Variables, Type, Scope, and Lifetime

In this section we discuss some of the fundamental properties of imperative programming languages. In particular, we address issues related to binding time, the properties of variables, **types**, scope, and lifetime.

90.2.1 Binding Time

We will find it useful to classify many of the differences in programming languages based on the notion of binding time. A **binding** is the association of an attribute to a name. The time at which a binding takes place is an important consideration. There are many times when a binding can occur. Some of these follow:

- Language definition: when the language is designed. An example is the binding of the constant name `true` to the corresponding Boolean value.
- Language implementation: when a compiler or interpreter is written. An example is the binding of the representation of values of various types.
- Compile time: when a program is being translated into machine language. For example, the type of a variable in a statically typed language is bound at compile time. In statically typed languages, overloaded functions are bound at compile time.
- Load time: when the executable machine language image of the program is loaded into the memory for execution by the execution unit. The location of global variables is bound at load time.
- Procedure or function invocation time: the time a program is being executed. Actual parameters are bound to formal parameters and local variables are bound to locations at procedure invocation time.
- Run time: any time during the execution of a program. A new value can be bound to a variable at run time. In dynamically typed languages, overloaded functions are bound at run time.

As we examine fundamental issues in the definition of imperative programming languages, we will keep in mind the distinctions between languages based on differences in binding time.

90.2.2 Variables

Imperative languages support computation by executing commands whose purpose is to change the underlying state of the computer on which they are executed. The *state* of a computer encompasses the contents of memory and also includes both data which are about to be read from outside of the computer and data which have been output.

Variables are central to the definition of imperative languages as they are objects whose values are dependent on the contents of memory. A variable is characterized by its attributes, which generally include its name, location in memory, value, type, scope, and lifetime.

Depending on context, the meaning of a variable may be considered to be either its value or its location. For instance, in the assignment statement, $x := x + 1$, the meaning of the occurrence of the variable x to

the left of the assignment symbol is its location (sometimes called the l-value of x), whereas the meaning of the occurrence on the right side is its value, that is, the value stored at the location corresponding to x (sometimes called the r-value). The location of global variables is bound at load time, whereas the location of local variables and reference parameters is typically bound at procedure entry. The value of the variable can be changed at any point during execution of the program.

90.2.3 Types

Types in programming languages are abstractions which represent sets of values and the operations and relations which are applicable to them. Types can be used to hide the representation of the primitive values of a language, allow type checking at either compile time or run time, help disambiguate overloaded operators, and allow the specification of constraints on the accuracy of computations. Types also can play an important role in compiler optimization.

Types in a programming language include both simple and composite types. The use of *simple types* such as integer, real, Boolean, and character types allows the user to abstract away from the actual computer representation of these values, which may differ from computer to computer. The operations on simple types may or may not be supported directly by the underlying hardware. For instance, many early microprocessors supported only real or floating-point operations in software.

Some languages (e.g., those derived from Pascal) allow the programmer to define their own simple *enumerated* types by simply listing the values of the type. The ordering of elements in this enumeration is significant as these types typically support successor and predecessor functions as well as ordering relations. Later we will discuss mechanisms for supporting **abstract data types**, another way of constructing types which can be used as though they were primitive to a language.

Many languages support the creation of *subrange* types, which allows a programmer to define a new type as a copy of a type with a subset of its values. The new type comes equipped with the same operators as its parent type and is usually compatible with the original type.

Composite or structured data types can be created from simple types using *type constructors*. Typical composite types include arrays, records (or structures), variant records (or unions), sets, subranges, pointer types, and, in a few languages, function or procedure types. For instance, arrays are typically constructed from two types: a subrange type which provides the set of indices of the array, and another type representing the values stored in the array. Not all languages support all these type constructors. For instance, function and procedure types are provided by MODULA-2 but are not available in Ada 83. Many languages support strings as special types of composite types, for instance, as arrays of characters, but they may also be provided as builtin types.

Most imperative languages bind types to variables statically. These bindings are usually specified in declarations, but some languages, such as FORTRAN, allow implicit declaration of variables, with the type binding determined by the name of the identifier (e.g., in FORTRAN if the name starts with I through N then the variable is an integer, otherwise real).

An important issue in type-checking programming languages is type equivalence. When do two terms have equivalent types? The two extremes in the definitions of **type equivalence** are structural and name equivalence:

- Structural equivalence: Two types are said to be *structurally (or domain) equivalent* if they have the same structure. That is, they are built from the same type constructors and builtin types in the same way.
- Name equivalence: Two types are *name equivalent* if they have the same name.

The language C uses structural equivalence, whereas Ada 83 uses name equivalence. There are also a range of possibilities between these two extremes. For instance, Pascal and MODULA-2 use *declaration equivalence*: two types are declaration equivalent if they are name equivalent or they lead back to the same structure declaration by a series of redeclarations.

Inequivalent types may be compatible in certain situations. For instance, two types are assignment compatible if an expression of one type may be assigned to a variable of another. For instance, in Pascal a subrange of integer is assignment compatible with integer, even though the types are not equivalent.

An application of these ideas can be found in the rules for determining whether a particular actual parameter may be used in a procedure call for a particular formal parameter. In Pascal, if the formal parameter is a reference parameter then the actual parameter must be a variable of equivalent type. If the formal parameter is a value parameter then the actual parameter must be assignment compatible.

As mentioned earlier, some languages support the creation of subrange types. The new subrange type is usually assignment compatible with the original type. Because of this compatibility, the new type is called a **subtype** of the parent in Ada. Another mechanism available in Ada, called **derived typing**, defines a new type by constructing an exact copy of a type that already exists. However, the resulting new type is distinct and is not type equivalent or even assignment compatible with the existing type.

The type equivalence rules are the cause of one of the greatest limitations in the use of Pascal. If a formal parameter has an array type, then the actual parameter must have an equivalent type. In particular, the subscript ranges of the two arrays must be identical. Thus, it is impossible to write a procedure in Pascal which can be used to sort different-sized arrays of real numbers. (Actually, the current ANSI standard Pascal provides a special mechanism to allow exceptions to this rule.)

Ada escapes from this problem by designating some properties of types to be static, while others are dynamic. For example, in a type defined to be a subrange of integers, the underlying static type is integer while the subrange bounds are a dynamic property. Only the static properties of types are considered at compile time by the type checker, whereas restrictions due to dynamic properties are checked at run time.

Consider the following Ada declarations as an example of type bindings:

```
type COINS is (PENNY, NICKEL, DIME, QUARTER);
subtype SILVER is COINS range (NICKEL..QUARTER);
type CHANGE is new COINS;

C1, C2; COINS;
S: SILVER;
CH: CHANGE;
```

COINS is an enumerated type, defined by the programmer to allow assignments such as

```
C1 := DIME;
```

SILVER is a subrange of **COINS**, which includes only the values **NICKEL**, **DIME**, and **QUARTER**. **CHANGE** is a derived type taken from **COINS**.

Because Ada employs name equivalence, only **C1** and **C2** are equivalent, but **S** is assignment compatible with them. If Ada used structural equivalence, then variables **C1**, **C2**, and **CH** would be equivalent.

90.2.4 Scope

The scope of a binding is the area or section of a program in which that particular binding is effective. The method and extent of **scope rules** that define a binding scope will, to a large degree, affect the usefulness and applicability of a language. If, for instance, the rules allow the scope of a binding to be determined by the execution path of a program, the language might be more flexible, yet the code becomes harder to understand.

Scope rules are tied tightly to concepts of binding time. *Static scope rules* determine the scope of a binding at compile time and are based on the lexical structure of the program. *Dynamic scope rules* determine the scope of a binding at run time. Thus, an occurrence of a variable name in a procedure may refer to one variable the first time it is evaluated yet refer to an entirely different variable the next time, depending on the execution path at run time. Most imperative languages use static scope rules.

```

with TEXT_IO; use TEXT_IO;
procedure SCOPED is
  package INT_IO is new INTEGER_IO (integer); use INT_IO;
  I,J: integer;

  procedure P is begin put (J); new_line; end P;

begin
  J := 0;
  I := 10;
  declare -- Block 1
    J: integer;
  begin
    j := I; -- reference point A
    P;
  end;
  put (J); new_line;
  declare -- Block 2
    I: Integer
  begin
    I := 5
    J := I + 1; -- reference point B
    P;
  end;
  put (J); new_line;
end;

```

FIGURE 90.1 Scoping rules in Ada.

As an example of scope rules in Ada, consider the code in Figure 90.1. Static scope rules are determined by the program block structure, which does not change while the program runs. Therefore, the call to procedure **P** prints the variable **J** defined in the outer, main program, no matter where it is called from. Likewise, the assignment in block 1 at reference point A changes **J** from the block and not from the main program. Dynamic scope rules, on the other hand, typically follow dynamic call paths to determine variable bindings. If Ada used dynamic scope rules, the first call to **P** from block 1 would print the value 10 corresponding to the **J** from block 1, whereas the second call to **P** would print the value 3 corresponding to the **J** from the main program.

90.2.5 Execution Units: Expressions, Statements, Blocks, and Programs

An *expression* is a program phrase which returns a value. Expressions are built up from constants and variables using operators. As described earlier, variables may represent two values, depending on context: their location and the value stored at that location. Operators may be builtin, like the arithmetic and comparison operators, or may be user-defined functions.

Reflecting the sequential order of von Neumann computation, an imperative language specifies the order in which operations are evaluated. Typically, evaluation order is determined by precedence rules. A typical precedence rule set for arithmetic expressions might be the following:

1. Subexpressions inside parentheses are evaluated first (according to the precedence rules).
2. Instances of unary negation are evaluated next.
3. Then, multiplication (*****) and division (**/**) operators are evaluated in left to right order.
4. Finally, addition (**+**) and subtraction (**-**) are evaluated left to right.

Although procedure rules are commonly used by imperative languages, some languages use other conventions to avoid precedence rules. For example, PostScript uses postfix notation for expressions, while LISP uses prefix notation. APL evaluates all expressions from right to left without regard to precedence, using only parentheses to change the evaluation order.

The fundamental unit of execution in an imperative programming language is the *statement*. A statement is an abstraction of machine language instructions, grouped together to form a single logical activity.

The simplest and most fundamental statement in imperative programming languages is the assignment statement. This statement, typically written in the form $\mathbf{x} := \mathbf{e}$ or $\mathbf{x} = \mathbf{e}$ with \mathbf{x} a variable (or other expression representing a location) and \mathbf{e} an expression, is usually interpreted by evaluating \mathbf{e} and copying its value into the location represented by \mathbf{x} . This is known as the *copy semantics* for assignment.

Less common are languages which use the sharing interpretation of assignment. In these languages, variables generally represent references to objects which contain the actual values. The assignment $x := y$ would then be interpreted as binding the object referred to by y to x rather than its value. Since both variables refer to the same object, they share the same value. If the value of one is changed, the value of the other will also change. This is the *sharing semantics* for assignment.

Declarations and statements may be grouped together to form a *block*. Procedure and function bodies are represented as blocks, whereas **control structures** (discussed subsequently) can also be understood as acting on blocks of statements (generally without declarations). The most general form of a block contains a *declarative* section, which contains the declarations that define the bindings that are effective in the block, and an *executable* section, which contains the statements over which the binding is to hold, i.e., the scope of the declarations.

In so-called block-structured languages (including most languages descended from ALGOL 60, e.g., Pascal, Ada, and C), blocks may be nested. Within any block, therefore, there can be two kinds of bindings in force: *local bindings*, which are specified by the declarative sections associated with the block, and *nonlocal bindings* (also known as *global bindings*), which are bindings defined by declarative sections of blocks within which the specific block is nested.

Consider again the code from [Figure 90.1](#). The first two assignments of the main program assign \mathbf{J} from the main program the value 0 and \mathbf{I} from the main program the value 10. The next assignment assigns the value 10, derived from the global \mathbf{I} , to the variable \mathbf{J} from the first inner block. When the definition of the second inner block is encountered, the variable \mathbf{I} is found in the local scope, while \mathbf{J} is found in the *outer* scope, that of the main program. The value 6 will be printed for \mathbf{J} at the end of the main program.

90.3 Control Structures

By adopting the semantics of the basic execution cycle of a von Neumann architecture, an imperative language adopts a strict sequential ordering for its statements. By default, the next statement to execute is the next physical statement in the program. Control structures in imperative languages provide ways to alter this strict sequential ordering. The most common control structures are *conditional structures* and *iterative structures*. *Unconstrained control structures* are also allowed in most languages through the use of goto statements.

90.3.1 Conditional Structures

Conditional control structures (also known as *selection statement*) determine whether or not a block of statements is executed based on the result of one or several tests. These structures fall into one of two classes:

90.3.1.1 If Statements

All imperative languages include some form of if statement. This control structure provides a text and a single statement or statement block to be executed if the test evaluates to a true value. Optionally, the

programmer may provide another block of statements which can be executed only if the test evaluates to false. The following is a simple example from Ada:

```
if (x = 2) then
  y := 3;
else
  y := 6;
end if;
```

The variable **y** is set to either 3 or 6 depending on the value of **x**.

In most languages, if statements can be nested within other control structures, including other if statements. However, nested if statements can result in awkward, deeply nested code. Thus, many languages provide a special construct (e.g., **elsif** in Ada) to represent *else if* constructs without requiring further nesting. The two Ada examples given next are equivalent semantically, though the first, which uses **elsif**, is easier to read than the second, which uses nested conditionals:

```
if (x = 2) then      if (x = 2) then
  y := 3;            y := 3;
elsif (x = 3) then  else
  y := 15;          if (x = 3) then
elsif (x = 5) then  y := 15;
  y :=18;           else
else                if (x = 5) then
  y := 6;           y := 18;
end if;            else
                   y := 6;
                   end if;
                   end if;
end if;           end if;
```

90.3.1.2 Case Statements

This conditional combines case-by-case expression examination with a restricted multiway conditional. This conditional may be seen to be simply a syntactic convenience, but in many cases its implementation results in a much faster determination at run time of the actual block of code to be executed. Consider the following case statement from Ada:

```
case y is
  when 2 => y := 3;
  when 3 => y := 15;
  when 15 => y := 18;
  when others => y := 6;
end case;
```

An expression (**y** in this case) of an ordinal type occurs after the keyword **case**. Each **when** clause contains a guard, which is a list of one or more constants of the same type as the expression. Most languages require that there be no overlap between these guards. The expression after the keyword **case** is evaluated, and the resulting value is compared to the guards. The block of statements connected with the first matched alternative is executed. If the value does not correspond to any of the guards, the statements in the **others** clause is executed. Note that the semantics of this example is identical to that of the previous example.

The case statement may be implemented in the same way as a multiway if statement, but in most languages it will be implemented via table lookup, resulting in a constant time determination of which block of code is to be executed.

C's switch statement differs from the case previously described in that if the programmer does not explicitly exit at the end of a particular clause of the switch, program execution will continue with the code in the next clause.

90.3.2 Iterative Structures

One of the most powerful features of an imperative language is the specification of *iteration* or statement repetition. *Iterative structures* can be classified as either definite or indefinite, depending on whether the number of iterations to be executed is known before the execution of the iterative command begins:

- Indefinite iteration: The different forms of indefinite iteration control structures differ by where the test for termination is placed and whether the success of the test indicates the continuation or termination of the loop. For instance, in Pascal the **while-do** control structure places the test before the beginning of the loop body (a pretest), and a successful test determines that the execution of the loop shall continue (a continuation test). Pascal's **repeat-until** control structure, on the other hand, supports a posttest, which is a termination test. That is, the test is evaluated at the end of the loop and a success results in termination of the loop.

Some languages also provide control structures which allow termination anywhere in the loop. The following example is from Ada:

```
loop
  ...
  exit when test;
  ...
end loop
```

The **exit when test** statement is equivalent to **if test then exit**.

A few languages also provide a construct to allow the programmer to terminate the execution of the body of the loop and proceed to the next iteration (e.g., C's **continue** statement), whereas some provide a construct to allow the user to exit from many levels of nested loop statements (e.g., Ada's named **exit** statements).

- Definite iteration: The oldest form of iteration construct is the definite or fixed-count iteration form, whose origins date back to FORTRAN. This type of iteration is appropriate for situations where the number of iterations called for is known in advance. A variable, called the *iteration control variable* (ICV), is initialized with a value and then incremented or decremented by regular intervals for each iteration of the loop. A test is performed before each loop body execution to determine if the ICV has gone over a final, boundary value. Ada provides fixed-count iteration as a **for** loop; an example is shown next.

```
for i in 1..10 loop
  y := y + i;
  z := z * i;
end loop;
```

Here, **i** is initialized to 1, and incremented by 1 for each iteration of the loop, until it exceeds 10. Note that this type of loop is a pretest iterative structure and is essentially syntactic sugar for an equivalent **while** loop.

An ambiguity that may arise with a **for** loop is what value the iteration control variable has after termination of the loop. Most languages specify that the value is formally undetermined after termination of the loop, though in practice it usually contains either the upper limit of the ICV or the value assigned which first passes the boundary value. Ada eliminates this ambiguity by treating the introduction of the control variable as a variable declaration for a block containing only the **for** loop.

Some modern programming languages have introduced a more general form of for loop called an *iterator* construct. Iterators allow the programmer to control the scheme for providing the iteration control variable with successive values. The following example is from CLU [Liskov et al. 1977]. We first define the iterator:

```
string_chars = iter (s : string) yields (char);
  index: Int := 1;
  limit: Int := string$size (s);
  while index <= limit do
    yield (string$fetch(s, index));
    index := index + 1;
  end;
end string_chars;
```

which can be used in a **for** loop as follows:

```
for c: char in string_chars(s) do LoopBody end;
```

When the for loop controlled by an iterator is encountered, control is passed to the iterator, which runs until a **yield** statement is executed. The value associated with the **yield** statement is used as the initial value of the iterator control variable **c**, and the body of the loop is executed. Control is then passed back to the iterator, which resumes execution with the statement following the **yield**. Control is passed to the loop body each time a yield statement is executed and back to the iterator each time the loop body finishes execution. Thus, iterators behave as a restricted form of coroutine, passing control back and forth between the two blocks of code. The loop is terminated when the iterator runs to completion. In the preceding examples this will occur when **index > limit**.

90.3.3 Unconstrained Control Structures: Goto and Exceptions

Unconstrained control structures, generally known as goto constructs, cause control to be passed to the statement labeled by the **identifier** or line number given in the goto statement. Dijkstra [1968] first questioned the use of goto statements in his famous letter, “Goto statement considered harmful,” to the editor of the *Communications of ACM*. The controversy over the goto mostly centers on readability of code and handling of the arbitrary transfer of control into and out of otherwise structured sections of program code.

For example, if a goto statement passes control into the middle of a loop block, how is the loop to be initialized, especially if it is a fixed-count loop? Even worse, what happens when a goto statement causes control to enter or exit in the middle of a procedure or function? The problems with readability arise because a program with many goto statements can be very hard to understand if the dynamic (run time) flow of control of the program differs significantly from the static (textual) layout of the program. Programs with undisciplined use of gotos have earned the name of *spaghetti code* for their similarity in structure to a plate of spaghetti.

Although some argue for the continued importance of goto statements, most languages either greatly restrict their use (e.g., do not allow gotos into other blocks) or eliminate them altogether. In order to handle situations where gotos might be called for, other, more restrictive language constructs have been introduced to make the resulting code more easily readable. These include the **continue** and **exit** statements (particularly labeled **exit** statements) referred to earlier.

Another construct which has been introduced in some languages in order to replace some uses of the goto statement is the *exception*. An exception is a condition or event that requires immediate action on the part of the program. An exception is *raised* or *signaled* implicitly by an event such as arithmetic overflow or an index out of range error, or it can be explicitly raised by the programmer.

The raising of an exception results in a search for an exception *handler*, a block of code defined to handle the exceptional condition and (hopefully) allow normal processing to resume. The search for an

appropriate handler generally starts with the routine which is executing when the exception is raised. If no appropriate handler is found there, the search continues with the routine which called the one which contained the exception. The search continues through the chain of routine calls until an appropriate handler is found, or the end of call chain is passed without finding a handler.

If no handler is found the program terminates, but if a handler is found the code associated with the handler is executed. Different languages support different models for resuming execution of the program. The termination model of exception handling results in termination of the routine containing the handler, with execution resuming with the caller of that routine. The continuation model typically resumes execution at the point in the routine containing the handler which occurs immediately after the statement whose execution caused the exception.

The following is an example of the use of exceptions in Ada (which uses the termination model):

```
procedure pop(s: stack) is
begin
  if empty(s) then raise emptyStack
  else ...
end;

procedure balance (parens: string) return boolean is
  pStack: stack
begin
  ...
  if ... then pop(s) ...
exception
  when emptyStack => return false
end
```

Many variations on exceptions are found in existing languages. However, the main characteristics of exception mechanisms are the same. When an exception is raised, execution of a statement is abandoned and control is passed to the nearest handler. (Here “nearest” refers to the dynamic execution path of the program, not the static structure.) After the code associated with the handler is executed, normal execution of the program resumes.

The use of exceptions has been criticized by some as introducing the same problems as goto statements. However, it appears that disciplined use of exceptions for truly exceptional conditions (e.g., error handling) can result in much clearer code than other ways of handling these problems.

We complete our discussion of control structures by noting that, although many control structures exist, only a very few are actually necessary. At the one extreme, simple conditionals and a goto statement are sufficient to replace any control structure. On the other hand, it has been shown [Boehm and Jacopini 1966] that a two-way conditional and a while loop are sufficient to replace any control structure. This result has led some to point out that a language has no need for a goto statement; indeed, there are languages that do not have one.

90.3.4 Procedural Abstraction

Support for abstraction is very useful in programming languages, allowing the programmer to hide details and definitions of objects while focusing on functionality and ease of use. **Procedural abstraction** [Liskov and Guttag 1986] involves separating out the details of an execution unit into a procedure and referencing this abstraction in a program statement or expression. The result is a program that is easier to understand, write, and maintain.

The role of procedural abstraction is best understood by considering the relationships between the four levels of execution units described earlier: expressions, statements, blocks, and programs. A statement can contain several expressions; a block contains several statements; a program may contain several blocks. Following this model, a procedural abstraction replaces one execution unit with another

one that is simpler. In practice, it typically replaces a block of statements with a single statement or expression.

The *definition* of a procedure binds the abstraction to a name and to an executable block of statements called the *body*. These bindings are compile-time, declarative bindings. In Ada, such a binding is made by specifying code such as the following:

```
procedure area (height, width: real; result: out real) is
  begin
    result := height * width;
  end;
```

The *invocation* of a procedure creates an activation of that procedure at run time. The *activation record* for a procedure contains data bound to a particular invocation of a procedure. It includes slots for parameters, local variables, other information necessary to access nonlocal variables, and data to enable the return of control to the caller. In languages supporting recursive procedures, more than one activation record can exist at the same time for a given procedure. In those languages, the lifetime of the activation record is the duration of the procedure activation.

Although scoping rules provide access to nonlocal variables, it is generally preferable to access nonlocal information via **parameter** passing. Parameter-passing mechanisms can be classified by the direction in which the information flows: *in parameters*, where the caller passes data to the procedure, but the procedure does not pass data back; *out parameters*, where the procedure returns data values to the caller, but no data are passed in; and *in out parameters*, where data flow in both directions.

Formal parameters are specified in the declaration of a procedure. The *actual parameters* to be used in the procedure activation are specified in the procedural invocation. The procedure passing mechanism creates an association between corresponding formal and actual parameters. The precise information flow which occurs during procedure invocation depends on the parameter passing mechanism.

The association or mapping of formal to actual parameters can be done in one of three ways. The most common method is *positional parameter association*, where the actual parameters in the invocation are matched, one by one in a left-to-right fashion, to the formal parameters in the procedural definition. *Named parameter association* also can be used, where a name accompanies each actual parameter and determines to which formal parameter it is associated. Using this method, any ordering can be used to specify parameter values. Finally, *default parameter association* can be used, where some actual parameter values are given and some are not. In this case, the unmatched formal parameters are simply given a default value, which is generally specified in the formal parameter declaration.

Note that in a procedural invocation, the actual parameter for an in parameter may be any expression of the appropriate type, since data do not flow back, but the actual parameter for either an out or an in out parameter must be a variable, because the data that are returned from a procedural invocation must have somewhere to go.

Parameter passing is usually implemented as being one of copy, reference, and name. There are two copy parameter passing mechanisms. The first, labeled *call-by-value*, copies a value from the actual to the formal parameter before the execution of the procedure's code. This is appropriate for in parameters. A second mode, called *call-by-result*, copies a value from the formal parameter to the actual parameter after the termination of the procedure. This is appropriate for out parameters. It is also possible to combine these two mechanisms, obtaining *call-by-value-result*, providing a mechanism which is appropriate for in out parameters.

The *call-by-reference* passes the address of the actual parameter in place of its value. In this way, the transfer of values is not by copying but occurs by virtue of the formal parameter and the actual parameter referencing the same location in memory. Call-by-reference makes the sharing of values between the formal and actual a two-way, immediate transfer, because the formal parameter becomes an alias for the actual parameter.

Call-by-name was introduced in ALGOL 60 and is the most complex of the parameter passing mechanisms described here. Although it has some theoretical advantages, it is both harder to implement and

generally more difficult for programmers to understand. In call-by-name, the actual parameter is re-evaluated every time the formal parameter is referenced. If any of the constituents of the actual parameter expression has changed in value since the last reference to the formal parameter, a different value may be returned at successive accesses of the formal parameter. This mechanism also allows information to flow back to the main program with an assignment to a formal parameter. Although call-by-name is no longer used in most imperative languages, a variant is used in functional languages which employ lazy evaluation (see [Chapter 92](#)).

Several issues crop up when we consider parameters and their use. The first is a problem called *aliasing*, where the same memory location is referenced with two or more names. Consider the following Ada code:

```
procedure MAIN is
  a: integer;
  procedure p(x, y: in out integer) is
    begin
      a := 2;
      x := y + a;
    end;
begin
  a := 10;
  p(a, a);
  ...
end;
```

During the call of **p(a, a)** the actual parameter **a** is bound to both of the formal parameters **x** and **y**. Because **x** and **y** are in out parameters, the value for **a** will change after the procedure returns. It is not clear, however, which value **a** will have after the procedure call. If the parameter passing mechanism is call-by-value-result then the semantics of this program depend on the order in which values are copied back to the caller. If they are copied into the parameters from left to right, the value of **a** will be 10 after the call. The results with call-by-reference will be unambiguous (though perhaps surprising to the programmer), with the value of **a** being 4 after the call. In Ada, a parameter specified to be passed as in out may be passed using either call by value-result or call by reference. The preceding code provides an example where, because of aliasing, these parameter passing mechanisms give different answers. Ada terms such programs to be erroneous and considers them not to be legal, even though the compiler may not be able to detect such programs.

Most imperative programming languages support the use of procedures as parameters (Ada is one of the few exceptions). In this case the parameter declaration must include a specification of the number and types of parameters of the procedure parameter. MODULA-2, for example, supports procedure types which may be used to specify procedural parameters. There are few implementation problems in supporting procedure parameters, though the implementation must ensure that nonlocal variables are accessed properly in the procedure passed as a parameter.

There are two kinds of procedural abstractions. One kind, usually known simply as a *procedure*, is an abstraction of a program statement. Its invocation is like a statement, and control passes to the next statement after the invocation. The other type is called a *value returning procedure* or *function*. Functions are abstractions for an operand in an expression. They return a value when invoked, and, upon return, evaluation of the expression containing the call continues.

Many programming languages restrict the values which may be returned by functions. In most cases, this is simply a convenience for the compiler implementor. However, although common in functional languages, most imperative languages which support nested procedures or functions do not allow functions to return other functions or procedures. The reason has to do with the stack-based implementation of block-structured languages. If allowed, it might be possible to return a nested procedure or function which depends on a nonlocal variable which is no longer available when the procedure is actually invoked.

To avoid confusion, most languages allow a name to be bound to only one procedural abstraction within a particular scope. Some languages, however, permit the *overloading* of names. Overloading permits several procedures to have the same name as long as they can be distinguished in some manner. Distinguishing characteristics may include the number and types of parameters or the data type of the return value for a function. In some circumstances, overloading can increase program readability, whereas in others it can make it difficult to understand which operation is actually being invoked.

Program mechanisms to support concurrent execution of program units are discussed in [Chapter 98](#). However, we mention briefly *coroutines* [Marlin 1980], which can be used to support pseudoparallel execution on a single processor. The normal behavior for procedural invocation is to create the procedural instance and its activation record (runtime environment) upon the call and to destroy the instance and the activation record when the procedure returns. With coroutines, procedural instances are first created and then invoked. Return from a coroutine to the calling unit only suspends its execution; it does not destroy the instance. A resume command from the caller results in the coroutine resuming execution at the statement after the last return.

Coroutines provide an environment much like that of parallel programming; each coroutine unit can be viewed as a process running on a single processor machine, with control passing between processes. Despite their interesting nature (and clear advantages in writing operating systems), most programming languages do not support coroutines. MODULA-2 is an example of a language which supports coroutines. As mentioned earlier, iterators can be seen as a restricted case of coroutines.

90.3.5 Data Abstraction

Earlier in this chapter, we introduced the idea of data types as specifying a set of values and operations on them. Here we extend that notion of values and operations to abstract data types and their definitional structures in imperative languages.

The primitive data types of a language are specified by both a set of values and a collection of operations which may be applied to them. Clearly, the set of integers would be useless without the simultaneous provision of operation on those integers. It is characteristic of primitive data types that the programmer is not allowed access to their representations.

Many modern programming languages provide a mechanism for a programmer to specify a new type which behaves as though it were a primitive type. An abstract data type (ADT) is a collection of data objects and operations on those data objects whose representation is hidden in such a way that the new data objects may be manipulated only using the operations provided in the ADT. ADTs abstract away the implementation of a complex data structure in much the same way primitive data types abstract away the details of the underlying hardware implementation.

The *specification* of an ADT presents interface details relevant to the users of the ADT, whereas the *implementation* contains the remaining implementation details that should not be exported to users of the ADT. *Encapsulation* involves the bundling that together of all definitions in the specification of the ADT in one place. Because the specification does not depend on any implementation details, the implementation of the ADT may be included in the same program unit with the specification or it may be contained in a separately compiled unit. This encapsulation of the ADT typically supports information hiding so that the user of the ADT (1) need not know the hidden information in order to use the ADT, and (2) is forbidden from using the hidden information so that the implementation can be changed without impact on correctness to users of the ADT (at least if the specifications of the operations are still satisfied in the new implementation). Of course, one would expect a change in implementation to affect the efficiency of programs using the ADT. A further advantage of information hiding is that, by forbidding direct access to the implementation, it is also possible to protect the integrity of the data structure.

CLU was among the earliest languages providing explicit language support for ADTs through its clusters. Ada also provides facilities to support ADTs via packages. Let us consider an example from MODULA-2, a successor language to Pascal designed by Niklaus Wirth. The stack ADT provides a stack type as well as

operations `init`, `push`, `pop`, `top`, and `empty`. A MODULA-2 specification for a stack of integers resembles the following:

```
DEFINITION MODULE StackADT;
  TYPE stack;
  PROCEDURE init (VAR s: stack);
  PROCEDURE push (VAR s: stack; elt: INTEGER);
  PROCEDURE pop (VAR s: stack);
  PROCEDURE top (s: stack): INTEGER;
  PROCEDURE empty (s: stack): BOOLEAN
END StackADT.
```

Note the declaration includes the type name and procedural *headers* only. The type **stack** included in the preceding specification is called an *opaque* type in MODULA-2, because users cannot determine the actual implementation of the type from the specification. This ADT specification uses information hiding to get rid of irrelevant detail. Now, this specification can be placed in a separate file and made available to programmers. By including the following declaration:

```
FROM StackADT IMPORT stack, init, push, pop, top, empty;
```

at the beginning of a module, a programmer could use each of these names as though the complete specification was included in the module. Thus, the user can write

```
var s1, s2: Stack;
begin
  push(s1, 15);
  push(s2, 20);
  if not empty(s1) then pop(s1) ...
```

is such a module.

In MODULA-2 the complete definitions of the type **stack** and its associated operations are provided in an implementation module, which typically is stored in a separate file.

```
IMPLEMENTATION MODULE StackADT;
TYPE stack = POINTER TO stackRecord;
   stackRecord = RECORD
       top: 0..100;
       values: ARRAY[1..100] OF INTEGER;
   END;
PROCEDURE init(VAR s: stack);
  BEGIN
    ALLOCATE(s, SIZE(stackRecord));
    S^.top := 0
  END
PROCEDURE push (VAR s: stack; elt: INTEGER);
  BEGIN
    S^.top := S^.top + 1;
    S^.value[S^.top] := elt
  END;
PROCEDURE pop(VAR s: stack); ...
PROCEDURE top(s: stack): INTEGER; ...
PROCEDURE empty(s: stack) BOOLEAN; ...
END StackADT.
```

Notice that the type name **stackRecord** is not exported.

The specification module must be compiled before any module that imports the ADT and before its implementation module, but importing modules and the implementation module of the ADT can be compiled in any order. As previously suggested, the implementation is irrelevant to writing and compiling a program using the ADT, though, of course, the implementation must be compiled and present when the final program is linked and loaded in preparation for execution.

There is one important implementation issue which arises with the use the language mechanisms supporting ADTs. When compiling a module which includes variables of an opaque type imported from an ADT (e.g., **stack**), the compiler must determine how much space to reserve for these variables. Either the language must provide a linguistic mechanism to provide the importing module with enough information to compute the size required for values of each type or there must be a default size which is appropriate for every type defined in an ADT. CLU and MODULA-2 use the latter strategy. Types declared as CLU clusters are represented implicitly as pointers, whereas in MODULA-2 opaque types must be represented explicitly using pointer types as in the **Stack ADT** example just given. In either case, the compiler need reserve for a variable of these types only an amount of space sufficient to hold a pointer. The memory needed to hold the actual data pointed to is allocated from the heap at run time. As discussed later, Ada uses a language mechanism to provide size information for each type to importing units.

The definition of ADTs can be *parameterized* in several languages, including CLU, Ada, and C++. Consider the definition of the **stack** ADT. Although the preceding example was specifically given for an integer data type, the implementations of the data type and its operations do not depend essentially on the fact that the stack holds integers. It would be more desirable to provide a parameterized definition of **stack** ADT which can be instantiated to create a stack of any type *T*.

Allocating space for these parameterized data types raises the same problems as previously discussed for regular ADTs. C++ and Ada resolve these difficulties by requiring parameterized ADTs to be instantiated at compile time, whereas CLU again resolves the difficulty by implementing types as implicit references.

90.4 Best Practices

In this section, we will examine three quite different imperative languages to evaluate how the features of imperative languages have been implemented in each. The example languages are FORTRAN (FORTRAN IV for illustrative purposes), Ada 83, and C++. We chose FORTRAN to give a historical perspective on early imperative languages. Ada 83 is chosen as one of the most important modern imperative languages which supports ADTs. C++ might be considered a controversial choice for the third example language, as it is a hybrid language that supports both ADT-style and object-oriented features. Nevertheless, the more modern feature contained in the C++ language design makes it a better choice than its predecessor, C (though many of the points that will be made about C++ also apply to C). In this discussion we ignore most of the object-oriented features of C++, as they are covered in more detail in [Chapter 96](#).

90.4.1 Data Bindings: Variables, Types, Scope, and Lifetime

Like most imperative languages, all three of our languages use static binding and static scope rules. FORTRAN is unique, however, because it supports the *implicit declaration* of variables. An identifier whose name begins with any of the letters *I* through *L* is implicitly declared to be of type integer, whereas any other identifier is implicitly declared to be of type real. These implicit declarations can be overridden by explicit declaration. Therefore, in the fragment:

```
INTEGER A
I = 0
A = I
B = C + 2.3
```

A and **I** are integer variables, while **B** and **C** are of type real. Most other statically typed languages (including Ada and C++) require *explicit declaration* of each identifier before use. Aside from providing better documentation, these declarations lessen the danger of errors due to misspellings of variable names.

FORTRAN has a relatively rich collection of numerical types, including integer, *double precision* (real), and *complex*. *Logical* (Boolean) is another builtin type, but FORTRAN IV provided no direct support for characters. However, characters could be stored in integer variables. (The *character* data type was added by FORTRAN 77). FORTRAN IV supported arrays of up to three dimensions but did not support records. Strings were represented as arrays of integers. FORTRAN IV did not provide any facilities to define new named types.

Later languages provided much richer facilities for defining data types. Pascal, C, MODULA-2, Ada, and C++ all provided a full range of primitive types as well as constructors for arrays, records (structures in C and C++), variant records (unions in C and C++), and pointers (access types in Ada). All provided facilities for naming new types and for constructing types hierarchically (constructing nested types). Variant records or unions opened up holes in the static type systems of most of these languages, but Ada (and CLU before it) provided restrictions on the access to variants and builtin run time checks in order to prevent type insecurities.

The scope rules for each language, though static in nature, differ significantly. In FORTRAN, the rules are the simplest. The unit of scope for an identifier is either the main program or the procedural unit in which it is declared. Declarations of procedures (subroutines) and functions are straightforward as well in FORTRAN, with no nesting and all parameters passed by reference. Whereas FORTRAN does not support access to nonlocal variables through scoping rules, it allows the programmer to explicitly declare that certain variables are to be more globally available. When two subprograms need to share certain variables, they are listed in a *common* statement which is included in each subprogram. If different combinations of subprograms need to share different collections of variables, several distinct common blocks can be set up, with each subprogram specifying which blocks it wishes access to.

Ada (like Pascal) supports *nested declarations* of procedures and functions. As a result, block structure becomes extremely important to scope determination.

Whereas C and C++ do not provide for nested procedures and functions, they do share with Ada the ability to include declaration statements in local blocks of code. In C++, blocks are syntactically enclosed in bracket {...} symbols, and any declarations that occur between the symbols hold for the duration of the block. Consider the following code:

```
for (i = 0; i<20; i++) {
    int i = 1, j;
    j = 0;
    while (i < 25) {
        j += i*2;
        i ++;
    }
}
```

One might think that when the inner loop is done, the outer loop also will be done, because **i** has the value 26. But since the inner block of statements redeclared **i**, the scope rules state that the new, inner **i** was manipulated, leaving the outer **i** untouched and free to correctly manipulate the for loop.

In FORTRAN IV the lifetime of all variables is the lifetime of the program. As a result, all memory in a program could be statically allocated, including activation records. Because each subprogram has only one activation record, FORTRAN could not support recursion.

Pascal, Ada, C, and C++ all support recursive functions and procedures. In order to support these, implementations generally rely on stack-allocated activation records. Thus, the lifetime of a local variable in a procedure *p* extends from the call of *p* to the return to its caller. Each of these languages also supports pointer or access types, generally representing data accessed from the heap (though C and C++ also allow

pointers to stack-allocated memory). The lifetime of these variables is generally from the time that the programmer executes a creation instruction until a corresponding destruction statement is executed.

90.4.2 Execution Units

FORTRAN and Ada make a strong distinction between expressions and statements, with expressions simply returning a value, but with statements forming the basic unit for program execution. In C and C++, however, these two units of execution are merged, with statements treated as expressions. The statement $\mathbf{x} = 5$ assigns the value 5 to the variable x . But, in C++, the $=$ sign is also an operator, and this assignment statement is actually an expression that returns the value being assigned. Thus, the statement $\mathbf{y} = \mathbf{x} = 5$ assigns the value 5 to *both* x and y , because the value 5 is assigned to x and the expression $x = 5$ returns 5, which is assigned to y . Although interesting, it can also be very confusing. Because many expressions will have side effects, the order of evaluation will affect the value returned from an expression. Consider the code

```
if ( (y = ++x) == (x + 6) ) { ... }
```

This code actually has two statements embedded in it; first, $\mathbf{++x}$ increments \mathbf{x} , then this value is assigned to \mathbf{y} , then the value assigned is tested against the value of $\mathbf{x} + 6$. If the compiler decides to change the order in which the subexpressions are evaluated (a not unheard of occurrence in C++ compilers), it may change whether the guard on the if statement is true or false.

Allowing statements to be part of expressions also means that typographical errors are more likely to give rise to syntactically correct (but logically incorrect) statements. For instance, if one of the $=$ signs in

```
if (x == 6) { ... }
```

is omitted, then it will assign of value 6 to x and the conditional will always evaluate to true as all non-0 integers in C and C++ are treated as representing true.

90.4.3 Control Structures

Because FORTRAN was one of the earliest high-level languages, it is not surprising that its control structures are much closer to the underlying machine language instructions. Aside from the do loop (which was similar to the for loop in Pascal and Ada), most other control structures were based on the use of goto statements. Thus, the if statement of FORTRAN IV evaluated an integer expression and, depending on whether the result was negative, zero, or positive, resulted in a jump to one of three statement labels included with the statement. Aside from the usual goto statement, FORTRAN IV also included assigned and computed gotos, which provided some of the flexibility of case statements. FORTRAN 77 and the more recent FORTRAN 90 provide more modern control structures such as the if and while statements of other languages.

The control constructs in Ada are similar to those of Pascal, including if, case, while, and for loops, as well as indefinite loops, which are terminated with exit statements. Several of these were described earlier in the general discussion of control structures.

C and C++ include if statements and a switch construct which is similar to the case statement. The while loop is similar to that in Pascal and Ada, but for the loops in C and C++ are more general than those in most other languages. For loops have the form:

```
for (E1; E2; E3) S;
```

where E_1 is initialization code, E_2 is a test for termination, E_3 contains code to update variables for the next iteration of the loop, and S represents the code to be executed each time through the loop. The test for termination is executed before the update code. Thus, a statement of the form

```
for (i = 1; i < 10, i++) S;
```

will result in S being executed once for each value of i from 1 to 10. (The expression $i++$ is an expression which increments the value of i .) However, much more flexible statements are also possible

```
for (i = 1; not done and i < 1024; i = 2 * i) S;
```

This statement repeatedly executes S while i ranges through the powers of 2 from 1 to 1024. If done is ever true, it will terminate early.

90.4.4 Procedural Abstraction

Each of Ada, FORTRAN, C, and C++ provides procedural abstraction. Ada and FORTRAN distinguish between functions and procedures, whereas C and C++ do not since procedures are just functions which return an element of type void. FORTRAN IV also supported single-line statement functions, which could be defined local to a program or subprogram. As noted earlier, Ada, C, and C++ all support recursive functions and procedures, whereas FORTRAN does not.

The languages differ in minor ways in how they return values from functions. FORTRAN, like Pascal, treats the name of the function as a pseudovisible which can be assigned to. An explicit return statement returns control to the calling program unit. When the function returns, the last value stored in the function name is returned as the value of the function. Ada, C, and C++ use return statements of the form `return exp` to return control to the calling program unit. The value of the expression associated with the return statement is the value returned from the function.

Most programming languages provide system-defined overloaded functions, such as arithmetic operators (+, -, *, etc.) and comparison functions (e.g., =, <, etc.). Ada and C++ are relatively unusual, though, in allowing user-defined overloading. In both, the compiler must be able to disambiguate at compile time whichever of the versions of the overloaded operator are called for at each of its occurrences. C++ determines which version is called for by looking at the number and types of the actual parameters. Ada goes further and can also use the return type to determine which version works in the particular context in which it is found. Thus, in Ada one may overload the + operator to take two integer parameters and return a user-defined rational type, even though there already exists a built-in version of + which takes two integer parameters and returns an integer. If + occurs in a context in which only an integer result would make sense, the builtin version would be selected. If + occurs in a context in which only a rational value would make sense the user-defined version would be selected. If the system cannot tell which should be used, then an error will occur at compile time.

Unlike FORTRAN, Pascal, and C, both Ada and C++ provide language support for exceptions. Ada and C++ both use the termination model for program resumption after handling the exception.

90.4.5 Data Abstraction and Separate Compilation

FORTRAN provides support for separate compilation of subroutines and functions but provides no type checking across compilation unit boundaries. Thus, the main program may call a function F with two real parameters, but the definition of F in a separately compiled unit may have only one formal parameter, and it might be an integer. Because FORTRAN does not support the definition of new named types, it provides no support for abstract data types.

C and C++ provide slightly better support for separate compilation by allowing the programmer to put external function and procedure declarations in a header file, which may be included into compilation units which use them. The header files are treated as though they were textually part of the compilation unit into which they are included. C provides no support for abstract data types, though C++ does provide strong support through its class facilities. C++ classes give the programmer control over which aspects of a data type the user will be allowed to see and use. Because C++ is described in some depth in [Chapter 96](#), we omit a detailed description here.

Standard Pascal provides no support for separate compilation, though virtually all Pascal implementations provide support for separately compiled units. These units typically include both interface and

implementation sections. The interface of a unit may be explicitly imported into another compilation unit with a *uses* statement. This provides for separate, but not independent, compilation without requiring the programmer to create individual header files by hand. These units generally do not provide support for information hiding.

Ada provides both separate compilation and strong support for abstract data types. Like MODULA-2's modules described earlier, Ada packages come in two separately compiled units, the specification and body. Only items listed in the nonprivate part of the package specification are accessible at compile time to units which import the package. The following is an Ada package specification for stacks:

```
package StackADT is
  type stack is private;
  procedure push(s: in out stack; elt: in integer);
  procedure pop(s: in out stack);
  procedure top(s: in stack) return integer;
  procedure empty(s: in stack) return boolean;
private
  type stack is record
    top: integer := 0;
    values: array (1..100) of integer
  end record
end StackADT;
```

The private section of a package specification is necessary to provide a description of private types. This is necessary so that importing programs know how much space to provide for a variable of that type. This is not as clean as the MODULA-2 solution, since any change of representation of the type will require the recompilation of the specification and hence of any program which imports the package. For this particular representation of stack, no initialization routine is necessary because top is initialized to 0 in the declaration of the type.

If the implementation of the private variable is a pointer, then only partial type information need be provided. That is, if we replace the private part of the preceding example by

```
private
  type stackRecord;
  type stack is access StackRecord;
end StackADT;
```

then this would provide sufficient information for importing programs to determine the memory needs for a variable of this type (i.e., the amount of space necessary to hold a pointer).

An implementation of the original package specification is given next:

```
package body StackADT is
  procedure push (s: in out stack; elt: in integer) is
  begin
    s.top := s.top + 1;
    s.value[s.top] := elt
  end push;
  procedure pop(s: in out stack); ...
  function top(s: in stack): integer; ...
  function empty(s: in stack) boolean; ...
end StackADT;
```

The **StackADT** package specification can be imported into an Ada program unit by including with **StackADT** at the beginning of the unit. Components can be referred to as record components,

e.g., **StackADT.stack** and **StackADT.push**. The package name prefix can be omitted if use **StackADT** is also included at the beginning of the unit.

Both Ada and C++ provide mechanisms for supporting parameterized packages (or classes in the case of C++). The C++ template mechanism is quite primitive, with template instantiations being treated as being similar to compile-time macroexpansions. The template is never type checked, only its instantiations. Ada also requires its generic packages to be instantiated at compile time, but the generics are type checked before, rather than after, instantiation. Thus, a generic package can be compiled and later used in another until which does not have access to the implementation.

The following is an example of the header of a generic **BinarySearchTree** package:

```
generic
  type Element is private;
  with function LessThan (x, y: Element) return boolean;
package BinarySearchTree is
  type BSTree is private;
  ...
end BinarySearchTree;
```

This can be used in another unit by instantiating it with a type and appropriate function, for example,

```
package PeopleDict is new BinarySearchTree (People, PeopleComp)
```

where **PeopleComp** is a function taking pairs of type **People** and returning a Boolean. **PeopleDict** can then be used like any other package. The ability to require generic package instantiations to include necessary functions and values as well as types ensures that they will not be instantiated with types which do not support the appropriate operations.

90.5 Research Issues and Summary

Research issues in imperative languages in recent years have tended to focus on many of the new constructs presented in this chapter. These include support for exceptions, iterators, abstract data types, and parameterized or generic types. It is fair to say that most current research in programming languages is devoted to implementation and environment issues or to other programming paradigms. There are not many new concepts currently being introduced into imperative programming languages. Many languages which formerly were purely imperative have recently been extended to include object-oriented concepts (e.g., Object Pascal, Objective C, C++, Ada 95). Another series of extensions has provided features for concurrent and distributed programming. Discussions of these two different kinds of extensions can be found in [Chapters 96](#) and [98](#) of this Handbook.

From our earlier discussion, it is clear that support for abstraction plays an important role in imperative language design and use. Variables abstract away details of memory usage; data types (and in particular abstract data types) abstract from the representation of values to provide support for operations that are independent from the actual implementation; execution units abstract away details of machine instruction execution and expression computation while providing clean interfaces for sharing information between caller and callee.

A second major focus in the development of modern imperative programming languages has been the enrichment of type systems, especially static type systems. Abstract data types can be understood as the enrichment of type systems with so-called existential types, in which the existence of a type is revealed by being instantiated with any type (or in Ada and CLU's case any type which comes supplied with the appropriate operations). These more flexible type systems allow for the construction of safe statically typed programming languages which are more expressive than their predecessors. There is hope that we

are moving forward to a time when most programmers will see such secure languages as assisting them in their goal of creating correct and efficient software, rather than getting in the way. (See [Chapter 104](#) for a further discussion of type systems.)

We have surveyed the class of programming languages modeled after the sequential organization of the von Neumann architecture. The imperative programming language paradigm is characterized by its sequential, stepwise statement execution.

As discussed in the [Section 90.4](#) the imperative programming constructs are implemented in a variety of ways in different languages. There are many languages to choose from; choosing the right language for the applications at hand is an important first step to software implementation.

It could be argued that the object-oriented paradigm is simply a minor variation on the imperative paradigm in which remote procedure and function calls replace the more familiar imperative calls. However, the object-oriented paradigm requires an entirely different way of thinking about the organization of a program, with the traditional conception of a program as a series of operations being applied to values replaced in the object-oriented view by an organization of more distributed responsibility. In this view, values (typically referred to as objects) are responsible for knowing how to perform their own operations, and the programmer is responsible for bringing together a group of objects with appropriate capabilities and organizing a program which relies on these distributed capabilities to accomplish a task. Subtyping and inheritance provide important organizing tools and promote code reuse in ways unavailable in traditional imperative languages.

Most programmers today are initially taught to program in imperative languages. Thus, these languages reflect the way that most programmers currently think about algorithm construction and program execution. Whether this will continue in the face of the challenge of the object-oriented paradigm will be interesting to see.

Defining Terms

Abstract data type: A collection of data type and value definitions and operations on those definitions which behaves as a primitive data type. The specifications of these types, values, and operations are generally collected in one place, with the implementations hidden from the user.

Binding: A connection between an abstraction used in the language and a data object as it exists in the computer hardware. The usage, establishment, and number of these bindings characterize the various imperative languages and affect their ease of use and performance.

Control structures: Structures or statements that alter the strict sequential ordering in an imperative program, presenting alternatives to sequential control. Control structures can be conditional, iterative, or unconstrained.

Derived type: A new data type constructed by copying a type that already exists. The resulting new type is distinct and not identified as being copied from the existing type, though operations on the old type are automatically inherited in the new type.

Identifier: The name bound to an abstraction.

Parameters: Data objects passed between the caller and the called procedural abstraction.

Procedural abstraction: Separating out the details of an execution unit in such a way that it may be invoked in a program statement or expression.

Scope rules: Rules in a language that define the area or section of a program in which a particular binding is effective.

Subtype: A new data type defined as a copy of another defined type, typically with a restricted subset of its values. It may generally be used in the same contexts as its parent type.

Type: A collection of values with an associated collection of primitive operations on those values.

Type equivalence: Rules that govern when variables or values from two different data types may be used together.

Variable: An abstraction used in imperative languages for a memory location or cell.

91.1 Introduction

During the 1990s, **object-oriented programming** (OOP) established itself as the dominant programming paradigm. Although it was first viewed as a revolutionary new programming paradigm, such a characterization is only partly accurate.

OOP is, to be sure, a paradigm in the current sense of that term. It embodies a way of organizing and representing knowledge, “a way of viewing the world” [Budd 2001], that encompasses a wide range of programming activities, including program analysis, design, and implementation. The paradigm derives its power from its view of computation as the simulation of real-world entities. That is, according to Dan Ingalls, “Instead of a bit grinding processor . . . plundering data structures, we have a universe of well-behaved objects that courteously ask each other to carry out their various desires” [Ingalls 1981].

Central to this view of computation is the notion of self-contained little systems that work together. OOP tools and languages facilitate the description of **objects** as self-contained systems that maintain their own internal state (data), perform actions (**methods**) in their own interest, and interact with other objects (by sending **messages** to one another). Objects can be low-level programming tools, such as lists, stacks, and trees, akin to traditional abstract data types (ADTs). They can also be higher-level abstractions that reflect what a program is intended to model: an automated teller machine (ATM), a deck of playing cards, an elevator, or a collection of graphical objects on a screen.

The primary power of OOP derives from the fact that, once defined, objects enjoy a type-like status. (As we will explain later, objects are defined via **classes**, which are very much like types). That is:

- Objects can be used without the user’s knowing the details of their implementation and can be properly protected from their consumers.

- Objects can be used according to a standard notation, using names, symbols, and operators in conventional ways.

- Objects can be combined with other objects and types in expressive and efficient ways (composition and hierarchy) to define new, more complex types.

Whereas structured programming languages such as C and PASCAL allowed a programmer to define new types, these were primarily a notational convenience. In such languages, user-defined type names served as shorthand to improve readability and as aids to compilers for recognizing type equivalences. These types, though, did not enjoy the status or flexibility of the built-in types. That is, one could not overload operators to apply to these new types and, more importantly, one could not easily hide the implementation details of a new type from its consumers.

The seeds for the object-oriented paradigm can be found in the languages that developed in the 1970s and 1980s to provide more direct support for building user-defined ADTs. ADA-83, for example, allows one to build clearly specified, modular software components that effectively hide their implementation details. ADA-83 uses the package construct to describe type specifications and subprograms that can belong to a user-defined ADT. Languages that provide this level of support for ADTs are now called object-based.

In many ways, the evolution of the OOP paradigm extends that of the structured paradigm which preceded it. We saw the structured paradigm, as manifested in a succession of increasingly high-level programming languages, progress from straight-line code laced with unconditional transfers of control, to block-oriented code that exploited control structures, to finer-grained code built from simple subprograms, to top-down, structured code that relied on parameterized and separately developed libraries of code which distinguished a subprogram's interface from its implementation. The object-based paradigm followed, to enable the capture of ADTs. Finally, OOP combines procedural and data abstraction into the notion of a class that can be part of a class hierarchy.

Hindsight being what it is, we can now see how the seeds of OOP have been nurtured by developments in many subfields of computer science over the past three decades: the basic idea of computation as simulation was first popularized in the programming language SIMULA 67, which also introduced the concepts of class, object, and message. Hardware architectures were developed in the 1970s using an object-based approach to describe the components of the machine and their interactions at a higher, more natural level. This development was further motivated by operating systems and applications that depended increasingly on graphical interfaces, which lend themselves directly to object-oriented descriptions. In the entity-relationship database model, in which a collection of information is described in terms of entities, attributes, and relations among entities, we see yet another manifestation of objects (at least the information content aspect of them). Even in knowledge representation schemes that supported work in artificial intelligence (frames, scripts, and semantic networks), we can see clearly this object orientation. Most clearly, the first purely object-oriented language, Smalltalk, has been around since the early 1970s.

Still, all of the premonitions of OOP did not coalesce into a recognizable influence on programming language and practice until they were motivated to do so by our collective practical experience in software engineering. As we became increasingly adept at exploiting the procedural paradigm and its languages, we recognized more directly their shortcomings. The more we pushed that paradigm, the more difficult it was to support data abstraction to that same degree that algorithm abstraction could be supported. Further, methods of encapsulation were relatively primitive, thus making it difficult to develop safe, reusable code. Finally, software analysis and design techniques that relied on procedural abstraction as the basis for performing decomposition of complex systems were proving increasingly awkward to apply to domains that were increasingly dependent on data, as opposed to algorithms.

In summary, structured methods flourished in the era of application domains that were either algorithm-centric or information-centric. These same methods prove less useful in an increasingly complex application world, where functionality and information structure must be considered in context. The concept of an object is a simple and elegant combination of all informational and algorithmic aspects of an application entity.

Today, all of these technologies have matured and all of the motivations have been established to the extent that OOP is a viable, recognizable, and popular approach to software development. Programming languages and commercial development environments abound. Smalltalk, as an example of a pure object-oriented programming language, is still commercially available; however, Java and C# have gained significant popularity. A variety of hybrid OOP languages (like C++, ANSI COBOL, and Visual Basic,

which extended existing languages to incorporate essential OOP features) dominates the programming language marketplace.

Because OOP is rightly referred to as a paradigm, it has spawned the development of many software analysis and design techniques that support the identification and description of objects in a problem specification. As with all paradigms, OOP languages and techniques are best suited to problems that match the paradigm's view of the world. The use and popularity of OOP rises with the increased demand for complex, interface-intensive systems, those that can be modeled in real-world terms.

Finally, if OOP raises the level of abstraction to bridge the gap between programmer and machine, it may be that novice programmers would stand to benefit the most from its use. Indeed, Smalltalk was developed based on research detailing how young children describe and interact with the world in solving problems. OOP is now influencing significantly how we teach and learn programming. There is a growing recognition that object orientation makes learning to program easier for the novice. Universities are now teaching object orientation as part of the computer science (CS) introduction. Java is now widely used in CS curricula.

However, it is also recognized that experienced programmers and software engineers must be retrained significantly: not because object orientation is hard, but because of their experience in traditional, function-centered (or information-centered) problem solving. Experienced programmers must, as Bertrand Meyer puts it, reacquire an object-oriented frame of mind.

Proponents of OOP claim that the paradigm represents the state of the art in terms of bridging the language gap between programmer and machine. It offers the prospect for achieving many of the software quality goals to which all programmers aspire: easily designed, safe, efficient, uniform software.

91.2 Underlying Principles

OOP takes a quite natural, but also quite different, view of programming. In a process-state view of computing (which reflects both the machine's fetch-execute cycle and its data processing nature), one thinks about programs as lists of instructions executed sequentially, and serving to manipulate and change the state of memory is the fundamental strategy of imperative languages. In contrast, OOP sees a software system as set of collaboration objects. Old-style programming involves thinking in terms of algorithms and data structures separately. OOP languages, on the other hand, permit the programmer to take a broader view and think of a program as a collection of cooperating objects, each of which encapsulates both structure and function.

Each object has three aspects: what it is, what it does, and what it is called. We illustrate these aspects by considering a geometric object, a circle. Most programming languages do not have circles as a built-in data type, so if we want to write a program that manipulates circles, we must write our own description of circle objects into a program. The descriptive information associated with an object, called its state, includes its properties and the values of these properties. For most objects, the state properties do not change, although the state values may very well be modified during the object's lifetime. For instance, a circle has a radius and a center, and at a given time, these might have the values 4.67 and (0, 0). A circle object will always have a radius and a center, although their values will change if the circle's size or location changes.

The collection of actions an object may perform on itself is called its behavior. In our example, we may want to use a circle as part of a program that draws on a computer screen, and so we would need to be able to set the center and radius of the object and instruct the circle to draw itself on the screen. Notice that we said a circle would draw itself on the screen. This is an important feature of the object-oriented approach. In a language with an algorithmic approach, one could describe circles by radius and center, as we have, but the description of the actions to perform on a circle would not be as tightly associated with the state data as it is here. That is, the drawing command would not be part of the circle object itself. Encapsulating data and actions together in an object helps us design and understand a program because, for instance, all circle-related data and actions are collected in one place. If we had to modify a circle object's definition, we would know exactly where the modifications would go. Furthermore, we would know that we would not have to modify any other part of the program.

Finally, each object has an identity, which serves to distinguish it from all others. One can refer to an object uniquely via its identity. In most programming languages, we identify an object by giving it a name, so we might call our circle `theCircle` — `theCircle` is our reference to the object.

It is entirely reasonable to assume that a program that would use one circle object might use several. All of these circle objects would be similar, in that they would have the same collection of member data and functions. It would clearly be a wasteful duplication of effort to describe each separately, since they would differ only in their data values and names. Object-oriented languages allow one to describe a template, if you will, for an entire set of objects. Such a template is called a class.

A class is used to generate a set of objects sharing common properties. Continuing our example, we could describe a class, `Circles`, by describing the state properties (but generally not the state values) and behaviors of all objects that belong to that class. Then, we could describe as many circle objects as we needed merely by declaring that they are instances of the `Circles` class, that is, they are `Circle` objects. An object can never exist in isolation; every object must be an instance of some class. This means that if we are going to use an object in a program, we must first provide the class to which the object belongs.

One can think of a class as a means for implementing an abstract data type. That is, to describe a class we identify the properties that any instance of the class (a particular object) must have. These properties consist of state information (referred to as member, or state, data) and a collection of behaviors (member functions, or methods) that such objects are capable of performing. Methods typically involve accessing, setting, or otherwise manipulating the object's member data.

Methods are invoked by an object in response to a message (i.e., a request of the object to perform one of its methods). Message passing as a means for invoking methods differs subtly from subprogram invocation in most other programming paradigms. In OOP, there is a formal distinction between the subprogram call (the sending of a message) and the method of invocation (the receiving of the message). It is the responsibility of the receiver of a message to interpret the message, that is, to determine which of its methods to perform in response. Think of OOP as programming by sending messages to objects.

Taken together, these two mechanisms support the description of full-fledged ADTs in a more general and extensible way than was provided by the first object-based languages. In particular, classes provide an abstraction mechanism that can be used to model a wide range of information structures and information processing agents. Using classes as the primary descriptive vehicle also characterizes an OOP approach to program design that has proved extremely effective for many real-world applications.

Not only are classes a rich descriptive tool; they are safe, in the software engineering sense of that term. That is, classes effectively encapsulate the abstractions they model by controlling (either implicitly or explicitly, depending on the language being used) access to an object's members. Some of an object's members will be public in nature (visible and accessible to other objects), and some will be private to the object itself (visible and accessible only to other members). Many OOP languages also support a formal distinction between a class's interface and its implementation.

Classes are also an efficient means of representation by virtue of the fact that they can be related to one another both compositionally (an object of one class can serve as a member of an object of another class) and hierarchically (to express *is-a* relationships). This latter feature is unique to OOP, and it affords a means for describing directly any information that is hierarchical in nature.

In cases where classes are arranged in a hierarchy, a **subclass** is said to **inherit** from its superclasses. That is, instances of the subclass contain (either directly as copies or indirectly via the superclass) both the data and methods described by the superclass. These same general properties are associated with all subclasses of the particular superclass. Each subclass extends the descriptions of its superclasses by adding specialized member data and methods that differentiate it from the superclass and from other subclasses.

Going back to our geometric example, we do not have to restrict our objects to circles; we could equally well have objects that are rectangles, triangles, and so on. We could augment our program by including declarations and definitions for the classes `Rectangles` and `Triangles`, just as we did when we defined the `Circles` class. In doing so, we notice that all of these are what we might call geometric objects.

Object-oriented languages allow a class like `Rectangles` to inherit the methods and data from a parent class, such as `GeometricObjects`. For example, because every object in our hierarchy has an extent

(a bounding rectangle inside which the object fits as closely as possible), we could declare the data `bounds_top`, `bounds_left`, `bounds_bottom`, `bounds_right`, and the method `ReportBounds` within a superclass named `GeometricObjects`. These would apply to all the derived classes `Rectangles`, `Triangles`, and `Circles`. Doing this, we would not need to re-declare these data items in any of these subclasses. They would be inherited from the base class `GeometricObjects`. Indeed, it is sometimes useful to define a superclass, such as `GeometricObjects`, knowing full well that we will never be interested in generating direct instances of it. That is, the only instances of `GeometricObjects` that we will use in our programming are those that are also instances of its subclasses: `Circles`, `Triangles`, or `Rectangles`. In such cases, superclasses are referred to as **abstract classes**.

Inheritance is not only distinctive of OOP languages; it is also the means by which the paradigm addresses many software engineering concerns. For example, inheritance is an efficient, non-redundant notation for representing information that is hierarchical in nature. It is natural in the sense that it reflects how we humans tend to describe such information (which explains in part why OOP has spawned so many related program design techniques). The efficiency of the notation derives from the ability to reuse code that was used in defining a superclass when defining a subclass. This, in turn, allows the inherited members of classes that are derived from one another to project consistent interfaces to their consumers. That is, member data and methods can be referred to by the same names in both the super- and subclasses.

There are times, though, when a base class action or state might not be appropriate for use by a derived class. All of the classes in our hierarchy would have `Draw` methods, but drawing a rectangle might involve different strategies than drawing a circle. OOP languages allow a derived class to redefine, or **override**, a method inherited from a base class. If, for example, we have an object called `theShape` and send it a message to draw itself, how is the computer to know which `Draw` action to use? Whereas procedural languages and object-based ones would resolve this ambiguity statically (i.e., based on the declared type of `theShape`), an OOP language solves this problem at run time, by looking up the class to which `theShape` belongs and finding a reference to an appropriate `Draw` method.

This ability to use the same name for actions on objects of different classes is an example of a kind of **polymorphism** (called inclusion polymorphism) that is common to all OOP languages. In the OOP sense of the term, polymorphism describes the fact that a superclass includes all **instances** of its subclasses. Thus, the notion of a geometric object contains all circle, rectangle, and triangle objects. As a result, an entity can take on different types of information during the execution of a program. For example, a geometric object can be a circle, a rectangle, or a triangle at any point during our program.

The concept of **interface** is related to the polymorphic use of the class concept. An interface is a listing of methods where, for each method, one only lists its name and any potential parameters. OO languages allow classes to **implement** an interface; that is, the classes provide explicit bodies for all methods listed in the interface.

Other forms of polymorphism often supported in OO languages include

Overloading — Two or more functions or operators can share the same name, so the `+` operator is allowed to apply to both integers and real numbers.

Parametric polymorphism — A parameter is used to establish choices: for example, generic packages — or C++ class templates — use a parameter to allow another level of abstraction.

Coercion polymorphism — C type casting is an example.

The following characteristics are the essence of OOP:

Objects — As a means for encapsulation of state and behavior

Classes — As templates for generating objects

Message passing — As the mechanism by which computation takes place

Dynamic method invocation — As the means by which methods are bound and interpreted

Inheritance — As a technique for modifying classes and creating subclasses

Inclusion polymorphism — As a means for allowing expressions of one type to be used in place of expressions of a supertype

Each contributes significantly to the overall utility of the paradigm, and each allows the paradigm to address one of the many software engineering concerns that motivated it. Whereas different programming languages implement them in various combinations and to varying degrees, any language that implements them all is considered object oriented.

91.3 Best Practices

To illustrate these characteristics of object-oriented programming, let us construct a very simple application to deal with queues of packets as they might appear in a network simulation. Packets in our program maintain their names and priorities, and allow their observation and comparison. Different kinds of packets are modeled as subclasses: one for packets that carry protocol information (Ack) and one for packets that carry data (Data). The subclasses specialize how packets are observed. The second set of classes models the queue concept. Class FifoQueue represents the algorithmic and data abstraction of a standard first-in-first-out queue. Internally, it employs a doubly linked list — anchored by a *head* and *tail member field* — to maintain the packets currently queued. The member functions *enter* and *leave* implement the standard protocol of such a queue. The FifoQueue class ignores the packet's priority information but also serves as a superclass for two additional subclasses, PriQueue and QueuePri, which use the packet's comparison abilities to handle packets of different degrees of importance.

We will develop the example in terms of Smalltalk, C++, Java, and C#, four of the major object-oriented programming languages in use today. Our intention here is to provide quick overviews of these languages and to illustrate the different notations and styles for implementing the object-oriented paradigm.

91.3.1 Smalltalk

Smalltalk is an integrated programming environment and language [Goldberg and Robson 1981]. It led the OOP evolution by incorporating the ideas of personal computer, interactive computing, graphical user interface (GUI), and OOP. The underlying design principle was to raise the level of abstraction substantially, so that program elements could communicate at a level closer to that of human problem solvers.

The language is purely object oriented. Every entity in a program is an object — everything from windows and projects to integers. Smalltalk defines only a limited syntax for declaring variables, assigning objects to variables, and sending messages to objects. Control structures are accomplished by message passing, where methods in standard classes define their behavior.

Smalltalk was originally developed as a research tool, and it is thoroughly integrated with its complex and powerful graphical programming environment. It spurred the subsequent development of all current commercial OOP languages and has seen some commercial acceptance, especially in the financial services industry. A variety of implementations are available.

Let us develop a Smalltalk program for our network/packet/queue example. We start by describing the class Packet:

```
Object subclass: #Packet
  instanceVariableNames: 'name priority '
  classVariableNames: ''
  poolDictionaries: ''
  category: 'MyFifoQueue-Examples'
```

A packet is defined as a subclass of Object. Smalltalk enforces a single class hierarchy, that is, all classes need a superclass. Object is the anchor of the existing Smalltalk class hierarchy. The # character before Packet is needed as part of Smalltalk syntax (i.e., it defines a symbol). The Packet class defines two instance variables (member fields): *name* and *priority*. Smalltalk does not type its member fields; in effect, they can refer to an instance of any object within Smalltalk.

Class variables are fields that do not carry unique values per object, such as **instance variables**, but rather one value per class. For our Packet class, we do not need to define any class variables; *pool dictionaries* are another way to refer to variables, and *category* defines that this new class belongs to a set of classes called MyFifoQueue-Examples. Categories are used in the Smalltalk programming environment to find classes quickly.

The packet class needs member functions—*instance methods* in Smalltalk terminology. The first instance method, *list*, is defined as follows:

```
!Packet methodsFor: 'printing'!  
list  
    Transcript show: name, ' packet: '.
```

The first line constructs the relationship of this method to the packet class (the exclamation marks differentiate it from regular Smalltalk syntax). The method is part of the *printing* protocol (Smalltalk categorizes related methods into protocols). The method has the name *list*; no arguments are listed. The body of the method consists of a single statement: it instructs to send message *show:* to object Transcript. Transcript is a preexisting Smalltalk object that records text and displays it to the user.

In Smalltalk syntax, a method name that ends with a colon (:) signifies that a parameter is expected. Here, a string constructed from the *name* of the packet and the text *packet* is sent along with the message as a parameter. The comma (,) is used to concatenate the two parts of the string. And finally, a Smalltalk statement is delimited by a period (.).

Next, we define two methods that allow us to compare packets: *less than or equal to*, written as <=, and *greater than*, written as >.

```
!Packet methodsFor: 'access'!  
<= aPacket  
    ^ (priority <= aPacket priority).  
> aPacket  
    ^ (priority > aPacket priority).  
priority  
    ^ priority.
```

Here, <= is defined with a single parameter, that is, *aPacket*. Again, Smalltalk does not type method parameters: any object can be sent along as parameter. The body of the first method lists a single *return* statement (^ is used to denote return). Returned is the expression that is listed in parentheses: a comparison of the instance variable *priority* to the priority of the *aPacket* parameter. Smalltalk hides all instance fields inside an object. Therefore, one packet object has no access to the *priority* of another packet. It is therefore necessary to define an instance method *priority*, which is used by both the <= and > methods. The *priority* method just returns the *priority* instance variable.

Finally, the *initialize* method allows one to set a packet's instance variables. It uses two parameters: one for *name* and one for *priority*. Smalltalk uses a special style for methods with multiple parameters: they are embedded into the method name. The complete name of this method is *initialize:priority:*, where after each colon, Smalltalk expects a parameter:

```
!Packet methodsFor: 'initializing'!  
initialize: aName priority: pri  
    name := aName.  
    priority := pri.
```

Methods can be defined at the instance and at the class level. *Instance methods* are those that are invoked when an object receives a message. Class methods are typically used to create new instances of a class. For example, a new packet object would be created with

```
Packet new.
```

The *new* method is not defined for class Packet; rather, it is inherited from its superclass Object. Here, *new* creates and returns a new instance of class Packet. It can be initialized with our *initialize:priority:* method, as in

```
Packet new initialize: 'one' priority: 10.
```

Because all packets should be initialized when created, we can define a new class method for Packet that enables the creation and initialization of Packet objects in a single method:

```
!Packet class methodsFor: 'initializing'!  
new: aName priority: pri  
  ^ (Packet new initialize: name priority: pri).
```

The name of this method is *new:priority:*. It does not override the *new* method that Packet inherits from its superclass; rather, it uses it internally. The body of the method is a single line that proceeds in three steps:

1. It sends the message *new* to the Packet class, which creates a new instance and returns it.
2. The new instance then receives an *initialize:priority:* message to initialize the new packet.
3. The method then returns the new and initialized object.

Subclass Data is based on the Packet class. It adds two more instance variables, *body* and *length*:

```
Packet subclass: #Data  
  instanceVariableNames: 'body length '  
  classVariableNames: ''  
  poolDictionaries: ''  
  category: 'MyFifoQueue-Examples'
```

Because data packets have additional instance variables, it makes sense to define an *initialize* method different from the one that is inherited from the Packet class. It takes three parameters: one each for the instance variables name, priority, and body (the full name of this method is now *initialize:body:priority:*):

```
!Data methodsFor: 'initializing'!  
initialize: aName body: aBody priority: pri  
  body := aBody.  
  length := body size.  
  self initialize: aName priority: pri.
```

The *body* instance variable is set from the parameter. The length is calculated by sending a *size* message to the *body* parameter. Note that although parameters are not typed, there is an assumption that it belongs to a class that defines the *size* method.

The third line in the body shows how one method delegates to another. Because *name* and *priority* still need to be set, which we already spelled out in the *initialize:priority:* method in the Packet superclass, we send message *initialize: aName priority: pri* to object self. Self refers to the Data object itself that is currently executing the method. It will now execute the method inherited from its superclass. And finally, the *list* method

```
!Data methodsFor: 'printing'!  
list  
  super list.  
Transcript show: body.
```

uses the keyword *super*, which is similar to *self*; it allows one to send a message to the current object. However, the corresponding method that is executed is not found in the class of the current object, but

rather in its superclass, that is, the Packet class. In effect, the *list* method defined here extends the list behavior of the superclass.

The class methods for Data allow for the creation of Data objects with or without an explicit priority:

```
!Data class methodsFor: 'initializing'!  
new: aBody  
  ^ super new initialize: 'Data' body: aBody priority:5.  
new: aBody priority: pri  
  ^ super new initialize: 'Data' body: aBody priority: pri.
```

The *super* keyword is needed here. Otherwise, if we sent a new message to the Data class, we would have an infinite loop because we are currently defining the *new* class method for Data. *Super* will ensure that the *new* method defined in the superclass is executed.

Subclass Ack is also based on Packet. It defines no further instance variables, but it redefines the *list* method:

```
Packet subclass: #Ack  
  instanceVariableNames: ''  
  classVariableNames: ''  
  poolDictionaries: ''  
  category: 'MyFifoQueue-Examples'  
!Ack methodsFor: 'printing'!  
list  
  Transcript show: 'acknowledged'.
```

The class method for Ack ensures that Ack objects are created with priority 10:

```
!Ack class methodsFor: 'initializing'!  
new  
  ^ (super new initialize: 'Ack' priority: 10).
```

Here, the *new* method overrides the *new* method inherited from its superclass. It also uses the *super* keyword to invoke the *new* method defined by its superclass.

The Packet class hierarchy is now complete. Before we construct our Queue class, we need one more helper class: Node, which will be used to implement a doubly linked list. The Node class defines three instance variables: *value* to hold a packet object, *next* to refer to the next node in the list, and *previous* to refer to the previous node in the doubly linked list. The instance methods allow for the manipulation of all instance variables.

```
Object subclass: #Node  
  instanceVariableNames: 'value next previous'  
  classVariableNames: ''  
  poolDictionaries: ''  
  category: 'MyFifoQueue-Examples'  
!Node methodsFor: 'access'!  
next  
  ^ next.  
next: aNode  
  next := aNode.  
previous  
  ^ previous.  
previous: aNode  
  previous := aNode.  
value
```

```

^ value.
value: aValue
  value := aValue.
!Node methodsFor: 'initializing'!
initialize: aValue
  value := aValue.
!Node class methodsFor: 'initializing'!
new: aValue
  ^ super new initialize: aValue.

```

Now, we can construct the class `FifoQueue`, which defines two instance variables: *head* to refer to the beginning of the list of nodes, and *tail* to hold on to the end of the list.

```

Object subclass: #FifoQueue
  instanceVariableNames: 'head tail'
  classVariableNames: ''
  poolDictionaries: ''
  category: 'MyFifoQueue-Examples'

```

The first instance method enters a packet object into the queue. It uses a local variable *tmp* for a newly created node object, which is then inserted at the *tail* of the linked list.

```

enter: aPacket
  | tmp |
  tmp := Node new: aPacket.
  tmp previous: tail.
  tail := tmp.
  (head notNil)
    ifTrue: [ tmp previous next: tail ]
    ifFalse: [ head := tmp ].

```

Local variables in methods are listed between vertical bars (`|`). Here, *tmp* is created as a new instance of class `Node` by sending message *new:* to the `Node` class. The *tmp* object receives the message *previous:* to attach it to the rest of the linked list content (*tail*).

The last statement in the method body is an example of an *if-then-else* construct. First, *head* receives message *notNil*, which returns Boolean objects *true* or *false*, depending on whether *head* refers to a `Node` object or is undefined. The returned Boolean object then receives the *ifTrue:ifFalse:* message. The parameters to *ifTrue:ifFalse:* are delimited by brackets, which denote blocks of Smalltalk statements. The execution logic is as follows: if (*head notNil*) returns Boolean object *true*, then the parameter after *ifTrue* is executed. If the returned object is *false*, then the parameter after *ifFalse* is executed. In effect, we have a regular *if-then-else* construct modeled in a completely object-orientated fashion as a set of communicating objects.

The second instance method, *leave*, removes a packet object from the queue. It uses a local variable *it* to store that packet object, which is maintained as the value of the *head* node of the list. The instance method finally returns packet *it*, after it has reconnected the list.

```

leave
  | it |
  it := head value.
  (head = tail) ifTrue: [ head := tail := nil ]
  ifFalse: [ head next notNil ifTrue: [
    head := head next.
    head previous: nil.
  ]
  ].
  ^ it.

```

The third instance method, *list*, allows us to observe the current status of the queue and its contents. It assumes that each object in the list understands a *list* message. In our example, we will store packet objects in the queue, and all packet classes define a *list* method. This illustrates one of the major features of object-oriented programming languages in general and Smalltalk in particular: flexibility. At this point, we need not worry about which types of packets will actually be stored in a queue: Packet objects, Data objects, or Ack objects are welcome. Moreover, we might even have more packet subclasses in future versions of our software. The *list* method also illustrates a major feature of Smalltalk, that is, uncertainty. If we enter objects into the queue that do not understand the list message, then this code will fail when the queue is asked to *list*. Smalltalk represents a very flexible approach to software modeling. As we will see later, other object-oriented programming languages, notably Java, add considerably more safety and predictability.

```
list
| tmp |
tmp := head.
[tmp notNil] whileTrue: [
    tmp value list.
    tmp := tmp next.
].
```

The body of the list method uses a *while* loop: [*tmp notNil*] is a block that is executed for each iteration of the loop. If it results in *true*, then the body of the loop (listed after the *whileTrue:* marker) is executed. If it is *false*, then the loop terminates.

Now that we have described four classes, it is possible to exercise them. Let us create a queue object and some packets (two Data objects and two Ack objects), enter them into the queue, and observe the current queue content by sending the appropriate messages:

```
| q w1 c1 w2 c2 |
q := FifoQueue new.
w1 := Data new: 'first packet'.
c1 := Ack new.
w2 := Data new: 'second packet' priority: 6.
c2 := Ack new.
q enter: w1.
q enter: c1.
q enter: w2.
q enter: c2.
q list.
```

The output from *q list* is

```
Data packet: first packet
acknowledged
Data packet: second packet
acknowledged
```

Then, we ask the queue to remove the packets and list them as we go,

```
q leave list.
q leave list.
q leave list.
q leave list.
```

Not surprisingly, the packet objects are stored by the queue object in the order in which they were entered, and then they are released in exactly the same order. This is what we would expect of a first-in-first-out queue abstraction.

To extend our example, we can now extend our queue abstraction by taking the importance (i.e., priority) of packets into account. Class `PriQueue` is defined as a subclass of `Queue`. It inherits all instance variables and methods, and specializes the `enter` method:

```
FifoQueue subclass: #PriQueue
    instanceVariableNames: ''
    classVariableNames: ''
    poolDictionaries: ''
    category: 'MyFifoQueue-Examples'.

!PriQueue methodsFor: 'access'!
enter: aPacket
    | tmp p |
    tmp := Node new: aPacket.
    tail isNil ifTrue: [
        tail := tmp.
        head := tmp.
    ] ifFalse: [
        p := tail.
        [(p notNil) and: (aPacket > (p value))] whileTrue: [
            p := p previous
        ].
        p isNil ifTrue: [
            tmp next: head.
            head previous: tmp.
            head := tmp.
        ] ifFalse: [
            tmp previous: p.
            tmp next: p next.
            (p = tail) ifTrue: [
                tail := tmp.
            ] ifFalse: [
                p next previous: tmp.
            ].
            p next: tmp.
        ]
    ]
].
```

The implementation of `enter` for priority queues is significantly more complex. It traverses the existing list for each packet that is to be entered to determine its relative importance. The `enter` method uses the `>` instance method defined for packet objects. Again, it is important that all objects stored in a `PriQueue` understand such a message. The `PriQueue` class specializes the `enter` instance method of class `Queue`. Another way of providing a queue with priority handling would be to specialize the `leave` instance method rather than `enter`. Class `QueuePri`, described next, does that.

```
FifoQueue subclass: #QueuePri
    instanceVariableNames: ''
    classVariableNames: ''
    poolDictionaries: ''
    category: 'MyFifoQueue-Examples'

!QueuePri methodsFor: 'access'!
leave
```

```

| it p |
it := head.
head = tail ifTrue: [
    head := tail := nil.
] ifFalse: [
    p := head.
    [p notNil] whileTrue: [
        (p value) > (it value) ifTrue: [ it := p].
        p := p next.
    ].
    it = tail ifTrue: [
        tail := it previous.
        tail next: nil.
    ] ifFalse: [
        it = head ifTrue: [
            head := it next.
            it next previous: nil.
        ] ifFalse: [
            it previous next: it next.
            it next previous: it previous.
        ]
    ]
].
^ it value.

```

The strategy for implementing a priority queue is straightforward. Whenever a packet is to be removed from the queue, we traverse the linked list and determine which of the packets has the highest priority. The good news is that Queue, PriQueue, and QueuePri objects can now be used interchangeably, depending on what kind of queuing strategy is desired. All three classes provide the same protocol; that is, their objects understand the same set of messages.

In summary, Smalltalk is much more than just a programming language. It is also a very elaborate programming environment that includes a large library of ready-to-use classes and allows for the interactive and incremental development of Smalltalk programs. The Smalltalk language is a truly object-oriented programming language. It hides all informational detail of objects and makes all instance methods freely available. Smalltalk allows only one form of inheritance, as seen in the example, where a class is defined as a subclass of a single superclass. Other programming languages allow multiple inheritance, where a subclass may have more than one superclass.

Smalltalk is very flexible. All message requests are resolved when an object receives a message. Other programming languages enforce this OOP principle to varying degrees, thus allowing for trade-offs between flexibility and safety. The creation of objects is defined by programmers. The deletion of objects, however, is left unspecified. Smalltalk automatically detects if objects are obsolete and reclaims them. This capability of object-oriented run-time support systems is called *garbage collection*.

91.3.2 C++

Our next OOP language is C++. C++ is the evolutionary enhancement to the C language, originally developed at Bell Laboratories, to support OOP features. It is most accurately described as a hybrid language (i.e., one that extends a traditional procedural language and remains compatible with that language, to include a variety of OOP features). Basically, this is C with classes, inheritance, and polymorphism. As Bjarne Stroustrup [Stroustrup 1994], the designer of the language, likes to point out, C++ is not an object-oriented programming language, but a language with which one can write an object-oriented program.

In C++, a class specification is separated into two files: a header file that contains a class declaration (listing the class name, fields, and methods) and a body file that contains all method bodies. C++ uses the C preprocessor to unite the two files upon compilation. It also enables that client code need only to include the header file to be able to use a class.

As our first example, we list the header for class `Packet`. The keyword *public* indicates that the instance methods, now called member functions in C++ terminology, are publicly visible. The instance variables (or, as referred to in C++, member fields) are *private*. That is, they are not visible outside of this class.

```
class Packet {
    int priority;
    char *name;
public:
    Packet(char *n, int p) {
        name=n;
        priority=p;
    }
    virtual void list();
    int operator>(Packet &);
    int operator<=(Packet &);
};
```

The class header declares the member fields and member functions, along with their accessibility. *Priority* is defined as an integer number (*int*); *name* is a string (*char **). The comparisons are defined as operator functions — the ampersand (&) denotes call by reference. The header shows one other important member function: it has the same name as the class and is referred to as the **constructor**. The constructor serves to initialize a new instance of the class when it is created. Here, a new packet needs a name and a priority.

The keyword *virtual* in the declaration of member function *list* enables **dynamic binding** in C++. It is needed to allow inclusion polymorphism to work. Without it, C++ will use static binding, as in conventional programming languages.

The class body elaborates the bodies of the member functions:

```
int Packet::operator>(Packet & other) {
    return priority > other.priority;
}
int Packet::operator<=(Packet & other) {
    return priority <= other.priority;
}
void Packet::list() {
    cout << name << " packet: ";
}
```

where *cout* is the predefined output object in C++. It receives message << and prints its parameters.

C++ differs from Smalltalk in its support of encapsulation. Here, *private* does not mean that only a single object has access to its private data, but rather that it is private to the class. All other instances of class `Packet` have access to each others' *priority* and *name* fields. The member functions that implement the comparison capabilities take advantage of this fact.

Subclass `Ack` is very simple:

```
class Ack: public Packet {
public:
    Ack():Packet("Ack, '10){}
    void list() {
        cout << "acknowledged\n";
```

```

}
};

```

Its constructor uses a special syntax to invoke the constructor of its superclass `Packet`. This class header also shows that a member function can (if it is short enough) be fully defined right away.

Similarly, for class `Data`

```

class Data: public Packet {
    char *body;
    int length;
public:
    Data(char *b, int p = 5):Packet("Data, ' ' p) {
        length = strlen(b) + 1;
        body = new char [length];
        strcpy(body, b);
    }
    void list();
};
void Data::list() {
    Packet::list();
    cout << body << endl;
}

```

The constructor for class `Data` is defined with two parameters: one to initialize the *body* field and one for the *priority*, which will default to 5 if no value is provided in the call. The member function *list* refers to `Packet::list()`, which is the *list* function defined in the `Packet` class. Again, Smalltalk uses a simpler and cleaner approach by using the keyword *super* to refer to a method defined in a superclass. The word *endl* ensures that the output ends with a new line.

The next class, `FifoQueue`, contains and hides the definition of class `Node` (C++ would also support parameterized generic classes). The member fields *head* and *tail* are specified as *protected*. C++ allows one to control explicitly how subclasses have access to inherited members. Protected members are accessible in subclasses, whereas private members are not.

```

class FifoQueue {
protected:
    struct Node {
        Packet & value;
        Node *next, *previous;
        Node(Packet &p):value(p), next(nil), previous(nil){};
    } *head, *tail;
public:
    FifoQueue():head(nil), tail(nil){};
    virtual void enter(Packet &);
    virtual Packet & leave();
    void list();
};

```

Here, the constructor `Node` uses a shortcut to initialize the *value*, *next*, and *previous* member fields. Therefore, the body of the constructor can remain empty.

The body of class `FifoQueue` details the member functions *enter*, *leave*, and *list*:

```

void FifoQueue::enter(Packet &it) {
    Node *tmp = new Node(it);
    tmp->previous = tail;
}

```

```

tail = tmp;
if (head)
    tmp->previous->next = tail;
else
    head = tmp;
}
Packet & FifoQueue::leave() {
    Packet &it = head->value;
    if (head == tail)
        head = tail = nil;
    else if (head->next) {
        head = head->next;
        head->previous = nil;
    }
    return it;
}
void FifoQueue::list() {
    for (Node* tmp = head; tmp; tmp=tmp->next)
        tmp->value.list();
}

```

We can now exercise our objects. This program produces the same output as our previous example written in Smalltalk:

```

main(){
    FifoQueue q;
    Data w1("first packet");
    Ack c1, c2;
    Data w2("second packet, '6);
    q.enter(w1);
    q.enter(c1);
    q.enter(w2);
    q.enter(c2);
    q.list();
    q.leave().list();
    q.leave().list();
    q.leave().list();
    q.leave().list();
}

```

Again, we can use FifoQueue as the base class for subclass PriQueue to refine the *enter* member function:

```

class PriQueue: public FifoQueue {
public:
    void enter(Packet &) {
        //logic as before
    }
};

```

And, of course, a similar class QueuePri is also possible, as follows:

```

class QueuePri: public FifoQueue {
public:
    Packet & leave() {

```

```
    //logic as before
}
};
```

In summary, C++ provides detailed support for specifying the degree of access to its members. C++ goes beyond what we have illustrated here. It allows one to specify the type of inheritance that is used: public, protected, or private. All our examples use public inheritance, which propagates the accessibility of members to the subclass. Protected and private inheritance allow one to hide the fact that a class is based on a superclass. C++ supports both single and multiple inheritance. It requires that dynamic binding (i.e., the object-oriented behavior of an object to search for a suitable method for a message at run-time) be explicitly requested per member function. C++ uses the keyword *virtual* to request dynamic binding; otherwise, it defaults to static binding. C++ leaves memory management to the programmer, as garbage collection is not supported.

91.3.3 Java

Our next “best practice” programming language, Java, is perhaps the most compelling entry into the landscape of object-oriented programming languages. Java was developed at Sun Microsystems [Sun Microsystems]. Although its popularity stems from its ability to create highly interactive World Wide Web content, we discuss it here because it is a truly object-oriented programming language.

From an object-oriented perspective, Java can be seen as a distillation of many of the good features from Smalltalk and C++. From C++ it inherits its style of syntax, but with great simplifications: Java does not support pointers, and it has only single inheritance, no arbitrary typecasts, no class templates, no implicit type conversions defined by constructors, and no destructors. Method overloading is supported, but not operator overloading. Emphasis is placed on the readability and understandability of the source code.

From Smalltalk it inherits its execution model: all objects carry a unique identifier (reference), and all methods are dynamically bound (or *virtual*, in C++ terms). It is compiled into byte codes that are interpreted within the target environment, and all class information is available at run time, which provides additional type-checking capability and robustness. Java also provides automatic garbage collection, which simplifies a programmer’s task significantly and tends to reduce many errors related to memory management. And of course, Java comes with a large class library that contains support for GUIs, networking, Web software development, and more.

Consider this Java version of our Packet class:

```
public class Packet {
    int priority;
    String name;
    public Packet(String n, int p) {
        name = n;
        priority = p;
    }
    public void list() {
        System.out.print(name + " packet: ");
    }
    boolean more(Packet other) {
        return priority > other.priority;
    }
    boolean less(Packet other) {
        return priority <= other.priority;
    }
}
```

The resemblance to C++ is clear: most of the basic syntax, including declarations and control structures, use the C++ style. Missing are pointers and arrays based on pointers. Java supports actual arrays, but for character strings it has a built-in String class. All object handling is done by reference. Access specifiers (like private or public) are listed per field or function. Java comes with a significant set of predefined classes to allow input and output and, of course, to allow one to build *applets*, Java programs that can run within a Web browser that supports a Java interpreter.

Java insists on a closed-class hierarchy: all classes must have a superclass. If a superclass is not specified in the class declaration, then it defaults to class Object. In effect, all Java objects can be thought of as instances of that class (much as in Smalltalk). This enables broad run-time support, such as automatic garbage collection.

As in C++, Java member fields are explicitly typed. For example, *priority* is of atomic type *int*. Class Ack is defined as a subclass to Packet. The *extends* clause defines the inheritance relationship among classes. Java supports only single inheritance among classes.

```
public class Ack extends Packet {
    public Ack() {
        super("Ack, "10");
    }
    public void list() {
        System.out.println(" acknowledged");
    }
}
```

Class Data is just slightly more complicated. It inherits from class Packet using the explicit *extends* keyword. Like Smalltalk, Java uses the keyword *super* to refer to an instance method defined in the superclass.

```
public class Data extends Packet {
    String body;
    int length;
    public Data(String b) {
        super("Data, " 5);
        length = b.length();
        body = new String(b);
    }
    public Data(String b, int p) {
        super("Data, " p);
        length = b.length();
        body = new String(b);
    }
    public void list() {
        super.list();
        System.out.println(body);
    }
}
```

Again, before we can define the FifoQueue class, we need the Node class. Class Node is defined here as a simple class with an instance variable *value* of class Packet. This limits our queues to contain only Packets. Notable here are the types associated with fields *next* and *previous*. Both are defined as being of type *Node*. This does not mean that a Node object will contain other Node objects. They will, however, contain the object identifiers of other Node objects. Thinking of object identifiers as pointers to objects yields the conventional linked list metaphor. Moreover, a true object-oriented programming language does not need pointers at all. Since all objects carry their unique identity, that can be used instead. That is why Java and Smalltalk need not support pointers.

```

class Node {
    Packet value;
    Node next, previous;
    Node(Packet p) {
        value = p;
        next = null;
        previous = null;
    }
}

```

Class `FifoQueue` makes use of these classes to implement our first-in-first-out queue abstraction. The data features `head` and `tail` are defined as *protected*, that is, these fields will be accessible in subclasses. The `list`, `enter`, and `leave` methods are defined as *public*.

```

public class FifoQueue {
    protected Node head, tail;
    public FifoQueue() {
        head = tail = null;
    }
    public void enter(Packet it) {

        Node tmp = new Node(it);
        tmp.previous = tail;
        tail = tmp;
        if (head != null)
            tmp.previous.next = tail;
        else
            head = tmp;
    }
    public Packet remove() {
        Packet it = head.value;
        if (head == tail)
            head = tail = null;
        else if (head.next != null) {
            head = head.next;
            head.previous = null;
        }
        return it;
    }
    public void list() {
        for (Node tmp = head; tmp != null; tmp=tmp.next)
            tmp.value.list();
    }
}

```

As in the Smalltalk version of the example, we can assemble a few objects and send messages. In method `enter`, local object `tmp` is created as an instance of class `Node` using the C++ style *new* operator. Method `list` uses a *for* loop construct: before the loop starts, `tmp` is initialized to the value of `head`; the loop will continue to execute its body while `tmp` is not undefined (i.e., is not equal to `null`).

The next class doubles as the *main* program. Java does not allow the definition of stand-alone functions. The class has a single static method called `main`, which creates a few objects and starts execution. All objects must be explicitly created using the *new* operator. No object is allocated by default. The rest of the program

reflects the same logic as illustrated in the Smalltalk and C++ examples. We enter four objects into the queue, remove them, and observe the queue and its contents.

```
class Main {
    public static void main(String args[]) {
        System.out.println("Starting Main ... ");
        FifoQueue q = new FifoQueue();
        Data w1 = new Data("first packet");
        Ack c1 = new Ack(), c2 = new Ack();
        Data w2 = new Data("second packet, "6");
        q.enter(w1);
        q.enter(c1);
        q.enter(w2);
        q.enter(c2);
        System.out.println("The queue:");
        q.list();
        System.out.println("Order of leaving:");
        q.remove().list();
        q.remove().list();
        q.remove().list();
        q.remove().list();
    }
}
```

Classes PriQueue and QueuePri can be defined as follows. Both classes inherit from FifoQueue, one redefining method *enter* and the other *leave*.

```
public class PriQueue extends FifoQueue {
    public void enter(Packet it) {
        //logic as in Smalltalk example
    }
}
public class QueuePri extends FifoQueue {
    public Packet remove() {
        //logic as in Smalltalk example
    }
}
```

In summary, Java is a complete and truly object-oriented programming language. It supports a very open and flexible style of encapsulation. In addition to the three access rights of C++ — public, protected and private — Java defines a fourth: package. All fields and methods are of access right *package* unless explicitly stated otherwise. All classes in Java belong to packages, and all package-defined fields and methods are accessible from within any class within the package. Java also uses packages to organize its source and compiled code.

Java does not support multiple inheritance, where a class can have more than one superclass. Java supports the notion of interface, a specification of the public methods that an object can respond to. The interface does not include any member fields or method bodies. Multiple inheritance is supported for interfaces. Classes can be declared to implement interfaces. Interfaces allow the programmer to establish declared relationships between modules, which in turn can change their underlying implementation as the class changes.

Java also provides garbage collection as a means to reclaim obsolete objects. Java does not have a delete operator. Objects cannot be deleted explicitly.

91.3.4 C#

C# (pronounced *C sharp*) is the latest entry into the landscape of object-oriented programming languages. C# was developed at Microsoft [Microsoft 2003]. From an object-oriented perspective, C# can be seen as a distillation of many of the good features of Java and C, plus influences from Delphi [Cantu 2001], the object-oriented programming environment for ObjectPascal.

Like Java, C# is compiled into byte codes from a common language run-time (CLR) specification. All class information is available at run time, which provides additional type-checking capability and robustness. C# also provides automatic garbage collection, which simplifies a programmer's task significantly and tends to reduce many errors related to memory management. And, of course, C# comes with a large class library, called *common language infrastructure* (CLI), which contains support for common data structures, GUIs, database access, networking, etc.

Consider this C# version of our Packet class:

```
public class Packet {
    int priority;
    protected string name;
    public Packet(string n, int p){
        name = n;
        priority = p;
    }
    virtual public void print(){
        Console.Write("{0} packet: ", name);
    }
    public static bool operator>(Packet p1, Packet p2) {
        return p1.priority > p2.priority;
    }
    public static bool operator<(Packet p1, Packet p2) {
        return p1.priority < p2.priority;
    }
}
```

The resemblance to Java is clear. The basic syntax, including declarations and control structures, use the C++ style. All object handling is done by reference. Access specifiers (like *protected* or *public*) are listed per field or function. As in C++, dynamic binding must be requested using the *virtual* keyword. C# comes with a significant set of predefined classes to allow input and output. The example lists the Console class, which defines the *Write* method. C# insists on a closed-class hierarchy: all classes must have a superclass. If a superclass is not specified in the class declaration, then it defaults to class *Object*.

A C# subclass specification resembles C++ more closely than Java. In the following example, class *Ack* is defined as a subclass of *Packet*. The colon is used to designate the superclass. The constructor uses the *base* reference to denote the invocation of the superclass constructor. The *list* method is explicit about redefining the superclass's virtual *list* method by using the keyword *override*. If the superclass did not have a *list* method, the compiler would flag an error.

```
public class Ack: Packet {
    public Ack():base("Ack", "10"){
    override public void list(){
        Console.WriteLine(" acknowledged");
    }
}
```

Class Data is just slightly more complicated. It inherits from class Packet and redefines the *list* method. The keyword *base* is used to refer to methods defined in the superclass.

```
public class Data: Packet {
    String body;
    int length;
    public Data(String b):base("Data,"5){
        length = b.Length;
        body = String.Copy(b);
    }
    public Data(String b, int p):base("Data,"p){
        length = b.Length;
        body = String.Copy(b);
    }
    override public void list(){
        base.list();
        Console.WriteLine(body);
    }
}
```

Again, before we can define the FifoQueue class, we need the Node class. Class Node is defined here as a simple class with an instance variable *value* of class Packet. This limits our queues to contain only Packet objects. Like Java and Smalltalk, C# does not need pointers.

```
class Node {
    public Packet value;
    public Node next, previous;
    public Node(Packet p) {
        value = p;
        next = null;
        previous = null;
    }
}
```

Class FifoQueue makes use of these classes to implement our first-in-first-out queue abstraction. The code closely resembles Java. Note, however, that the methods *enter* and *leave* are not defined as *virtual*. Therefore, dynamic binding will not be available: subclasses will not be able to override the methods. C# uses the keyword *new* for methods in subclasses that just want to specialize methods of superclasses. More detail is forthcoming.

```
public class FifoQueue {
    protected Node head, tail;
    public FifoQueue() {
        head = tail = null;
    }
    public void enter(Packet it) {
        Node tmp = new Node(it);
        tmp.previous = tail;
        tail = tmp;
        if (head != null)
            tmp.previous.next = tail;
        else
            head = tmp;
    }
}
```

```

    public Packet remove() {
        Packet it = head.value;
        if (head == tail)
            head = tail = null;
        else if (head.next != null) {
            head = head.next;
            head.previous = null;
        }
        return it;
    }
    public void list() {
        for (Node tmp = head; tmp != null; tmp=tmp.next)
            tmp.value.list();
    }
}

```

As in the Java version of the example, our main program is a class with a static method *main*, where we assemble a few objects and send messages to test our Packet and FifoQueue classes:

```

class main {
    public static void Main(String[] args) {
        Console.WriteLine("Starting Main... ");
        FifoQueue q = new FifoQueue();
        Data w1 = new Data("first packet");
        Ack c1 = new Ack(), c2 = new Ack();
        Data w2 = new Data("second packet, "6");
        q.enter(w1);
        q.enter(c1);
        q.enter(w2);
        q.enter(c2);
        Console.WriteLine("The queue:");
        q.list();
        Console.WriteLine("Order of leaving:");
        q.remove().list();
        q.remove().list();
        q.remove().list();
        q.remove().list();
    }
}

```

Classes PriQueue and QueuePri can be defined as follows. Both classes inherit from FifoQueue, one redefining method *enter* and the other *leave*. Because the superclass did not define either method as virtual, C# does not allow the keyword *override* here. Instead, we use the keyword *new*. The difference is the fact that dynamic binding is not enabled for the *enter* and *leave* method. That is, given a variable of type FifoQueue that holds a reference to a PriQueue, it would respond to an incoming message *enter* with the method defined in the FifoQueue class.

```

public class PriQueue: FifoQueue {
    new public void enter(Packet it) {
        //logic as before
    }
}

```

```

public class QueuePri: FifoQueue {
    new public Packet remove() {
        //logic as before
    }
}

```

In summary, C# is a complete and truly object-oriented programming language. C# also provides garbage collection as a means to reclaim obsolete objects. C# also supports the notion of interface, a specification of the public methods that an object can respond to. The interface does not include any member fields or method bodies. Multiple inheritance is supported for interfaces. Classes can be declared to implement interfaces. Interfaces allow the programmer to establish declared relationships between modules, which in turn can change their underlying implementation as the class changes.

C# supports some additional novel features: it allows programs to treat values of atomic types, such as *int* or *char*, as objects, with a process called boxing. Boxing automatically converts an atomic value that is being stored in the execution stack to wrapper objects that are allocated on the heap and referenced from the stack. The reverse process, unboxing, is also done automatically. The advantage of this boxing feature is that values of atomic types can be passed by reference to methods. C# also supports C-like *structs*, which allow one to build object-like value sets that are allocated on the stack rather than the heap. Other performance-enhancing features of C# include the capability to declare unsafe code, where C-like syntax, with direct pointer addressing and arithmetic, is allowed.

91.4 Language Implementation Issues

In evolutionary terms, object-oriented programming languages can be described as either pure or hybrid. The hybrid approach adds object-oriented features on top of a procedural core: C++ and ObjectPascal are representatives of this approach. The pure approach, Smalltalk and Java, limits the language features to those that are strictly object oriented. C# presents a compromise in that it enforces its object-oriented principles but allows unsafe code, as long as it is clearly labeled.

In theoretical terms, the primary distinction between these kinds of languages lies in their interpretation of the concept of type. Because of their origins, hybrid languages rely on a traditional approach to typing. That is, the type of something resides with its container. Thus, when we declare an integer variable *i* in C++, for example, as *int i*, variable *i* is of basic type *integer*. In Smalltalk, variables do not carry the type of what they contain. That is, variables are untyped: they can contain any object. Rather, the command *Integer new* returns an integer object. The type in this case is seen to reside with the object, and if we store a reference to it in a variable, the variable could be said to be of type *Integer*.

In implementation terms, representing values of basic types as objects carries penalties in amount of storage and performance: if an integer value is stored as an object, it will occupy about double the amount of storage, let us say 4 bytes for its value and 4 bytes for the object reference. To access the value as an object, we first must dereference the object reference, then retrieve the value from the object. Java stores all values of basic types as simple values and does not treat them as objects. The programmer must explicitly create a wrapper object to treat the value as an object. C# does this implicitly through its boxing and unboxing mechanisms.

Another aspect of whether type resides with a variable or with an object is that, in Smalltalk for example, the implementation must simply ensure that every object knows its class (and, of course, somehow its superclasses). This can be implemented either by encoding into classes knowledge of (pointers to) their superclasses, or by allowing classes to contain directly all information that they inherit.

Hybrid languages must provide support for both notions of type: variables and objects can have type. In C++, object type information is added either via a *vtable* per object (which contains pointers to all functions that apply to the object) or, in newer implementations, by using run-time type information (RTTI) extensions.

A second critical distinction between OOP languages is in how they handle the binding of messages to methods. In languages such as Smalltalk that perform this binding dynamically (at run time), an object

receives a message and the search for an appropriate method begins at the class of the object. The search continues through superclasses until the message can be processed. Although this approach affords the programmer tremendous flexibility, it has clear practical downsides. A more efficient approach is to leave the binding choice to the system (i.e., the compiler and linker). That is, the system tries to determine at compile time which method should be invoked for each message sent. In cases where inclusion polymorphism is used (and it may be unclear which class to refer to), binding can be performed at run time using techniques varying from simple case statements to a more complex system of virtual method tables. In any case, it is still up to the compiler to detect and indicate the need for run-time binding.

Another important issue to consider in the context of language implementation is the approach one adopts to memory management. OO languages are relatively uniform in their approaches to memory allocation (object creation). Creating objects and all that that entails (determining how much memory to allocate, the types of member fields, etc.) is performed by the system. Initialization, on the other hand, is left to the programmer. Many languages provide direct support for initializing objects: we have constructors in C++, Java, and C# and initialize methods in Smalltalk. There are two common approaches to deleting objects from memory (deallocation). In the programmer-controlled approach, one uses a *delete* operator. The system-enabled approach to deleting objects uses the concept of garbage collection [Jones and Lins 1996]. All objects that are unknown to other objects are garbage. The system needs a way to detect that fact: reference counters, memory mirroring, mark and sweep, etc., are examples of algorithms that enable it. In principle, the system sweeps all objects constantly to determine which are reclaimable. Practically speaking, this is quite compute-intensive. To lighten the impact on system performance, garbage collection is typically done either during times of idling or when some threshold of memory usage is reached. Just before objects are removed from memory, the destructor is invoked: it describes what cleanup steps must be done. The problem here is that the programmer now needs to know all possible circumstances in which objects of the class will (ever) be used. In practice, this has been shown to be a problematic approach. Memory leaks — memory that is occupied by deleted objects — can occur easily in large bodies of C++ code.

91.5 Research Issues

Object-oriented programming languages have matured dramatically and have gained a significant degree of acceptance over their almost 40 years of history. Perhaps the most dramatic test of the paradigm will be in how it responds to demands imposed on it by the coming advances in computing hardware, architectures, and operating systems. Currently, the execution model for the OOP paradigm is strictly sequential and synchronous. Computation starts at one object, which sends a message to the next, and so on. Language constructs, such as threads in Java, and architectures, such as the common object request broker architecture (CORBA), attempt to go beyond these constraints, pushing OOP into the worlds of distributed and parallel computing.

Although viewed mostly as a programming language with a sequential execution model, Java actually allows the construction of parallel programs. Java supports threads. In addition to the conventional single thread of execution, it allows the creation, starting, and management of multiple threads. The Java run-time system then schedules the threads with the underlying operating system. If the underlying hardware has multiple processors, then it truly will execute in parallel. CORBA [Object Management Group 2003] enables communication among distributed objects, where these objects do not need to be from a single programming language. C++ objects can communicate with Smalltalk objects. The basic idea is to set up an object request broker that relays messages from a sender to a receiver object. Implementations of CORBA and similar architectures are widely available.

In summary, many of the original motivations for the OOP paradigm have been justified by our practical experience with it. OOP has been seen to

- Embody useful analysis and design techniques

- Revise the traditional software life cycle toward analysis and design, instead of coding, testing, and debugging

Encourage software reuse through the development of useful code libraries of related classes
Improve the workability of a system so that it is easier to debug, modify, and extend
Appeal to human instincts in problem solving and description — in particular, to problems that model real-world phenomena

Defining Terms

Abstract class: A class that has no direct instances but is used as a base class from which subclasses are derived. These subclasses will add to its structure and behavior, typically by providing implementations for the methods described in the abstract class.

Class: A description of the data and behavior common to a collection of objects. Objects are instances of classes.

Constructor: An operation associated with a class that creates and/or initializes new instances of the class.

Dynamic binding: Binding performed at run time. In OOP, this typically refers to the resolution of a particular name within the scope of a class, so that the method to be invoked in response to a message can be determined by the class to which it belongs at run time.

Inheritance: A relationship among classes, wherein one class shares the structure or behavior defined in an *is-a* hierarchy. Subclasses are said to inherit both the data and methods from one or more generalized superclasses. The subclass typically specializes its superclasses by adding to its state data and by redefining its behavior.

Instance: A specific example that conforms to a description of a class. An instance of a class is an object.

Interface: A named listing of method headers to be implemented by a class.

Member field: The data items that are associated with (and are local to) each instance of a class.

Message: A means for invoking a subprogram or behavior associated with an object.

Method: A procedure or function that is defined as part of a class and is invoked in a message-passing style. Every instance of a class exhibits the behavior described by the methods of the class.

Object: An object is an instance of a class described by its state, behavior, and identity.

Object-oriented programming (OOP): A method of implementation in which a program is described as a sequence of messages to cooperating collections of objects, each of which represents an instance of some class. Classes can be related through inheritance, and objects can exhibit polymorphic behavior.

Override: The action that occurs when a method in a subclass with the same name as a method in a superclass takes precedence over the method in the superclass.

Polymorphism (or *many shapes*): That feature of a variable that can take on values of several different types or a feature of a function that can be executed using arguments of a variety of types.

Subclass: A class that inherits variables and methods from another class (called the superclass).

Virtual function: Most generally, a method of a class that may be overridden by a subclass to the class. In languages in which dynamic binding is not the default, this may also mean that a function is subject to dynamic binding.

92.1 Introduction

Functional languages are a class of languages based on the **lambda calculus**, a very simple but powerful model of computation. Proponents claim that the use of a functional language supports faster production of software, shorter programs, and more readable and verifiable code than the use of conventional so-called imperative programming languages. Furthermore, in the research community functional languages have been used as the basis of study on advanced type systems, parallel computing, program optimization, and programming language semantics.

Within the class of functional languages there is substantial variety. In this chapter, we describe three popular languages that are representative of the class: SCHEME, a dialect of LISP; Standard ML; and HASKELL. Although these languages differ in significant ways, they all exhibit the necessary properties in order to be considered functional.

A program written in a functional language consists of function definitions and function applications. As in mathematics, a function is an entity that maps each input to a single output. This is in stark contrast to imperative languages such as C and FORTRAN in which a function is simply a collection of statements which may modify variables, allowing the same input to be mapped to different outputs over the course of the computation.

Consider the factorial function. It is described formally by

$$n! = \begin{cases} 1 & \text{if } n = 0 \\ n(n-1)! & \text{otherwise} \end{cases}$$

In a functional language, in this case Standard ML, the executable definition of factorial is usually written as

```
fun factorial(0) = 1
  | factorial(n) = n * factorial(n-1)
```

and follows directly from the formal definition. In contrast, the factorial function is typically written in an imperative language, in this case American National Standards Institute (ANSI) C, as

```
int factorial(int n)
{ int prod = 1;
  for (int i = 1; i <=n; i++)
    prod = prod * i;
  return(prod);
}
```

where the programmer specifies that a variable holds the running product and is modified in each iteration of the loop. Although a version similar to the first program could be written in most imperative languages, the syntax and traditional programming style of these languages encourage the writing of the second.

Because functional languages, and the programs written in them, are intended to have nice mathematical properties — such as the properties that functions written in functional languages are functions in the true mathematical sense — there is no explicit notion of memory and the modification of memory. As in mathematics, a variable in a functional program simply represents a value, it is not a cell in memory that can be modified. There is no need for an assignment operator, and thus functional languages do not provide one (at least **pure functional languages** do not, see [Section 92.4](#)). In Standard ML, for example, the operator = does not express assignment but rather an equation. Consider the following statement in C:

```
x = x + 1;
```

It is obvious to a C programmer that this statement specifies the modification of an existing variable **x**. Notice, though, that in mathematics this is an equation that has no solution. There is no **x** that satisfies the equation. The functional programming community has long argued that by departing from a mathematical interpretation of programs, the use of imperative languages leads to complex, poorly understood programs.

By preventing the modification of existing variables, functional languages exhibit what is known as **referential transparency**, which essentially means that in a functional program, equal expressions can be interchanged. Consider, for example, the following expression (in Standard ML):

```
let
  val x = f(a)
in
  ... x + x ...
end
```

This introduces a new variable \mathbf{x} whose value is the result of the function call $\mathbf{f}(\mathbf{a})$, and then evaluates an expression containing the sum $\mathbf{x} + \mathbf{x}$. Because \mathbf{x} cannot be modified, a reader of the program can be sure that each occurrence of \mathbf{x} has the value of $\mathbf{f}(\mathbf{a})$, and thus the sum would have the same result as if the programmer had written $\mathbf{f}(\mathbf{a}) + \mathbf{f}(\mathbf{a})$.

In an imperative program, it is difficult for the reader to be sure that the value of \mathbf{x} had not changed, either by a direct assignment to \mathbf{x} or indirectly via call to some procedure that modifies the value of \mathbf{x} . Expressions containing these modifications, either direct or indirect, are known as **side effects** because, aside from returning a value, these expressions have the side effect of changing a variable's value. Functional programmers argue that it is side effects (and the corresponding loss of referential transparency) that lead to incomprehensible large programs.

An additional property that functional languages exhibit is the ability to treat functions as data. That is, functions can be passed as parameters to other functions, returned as the result of function calls, and stored in data structures. Thus, functions are said to be **first-class objects** since their use is no more restricted than other kinds of data. This is attractive for philosophical reasons, since functions are mathematical entities just like integers and Booleans, and for practical reasons, it increases the flexibility of code.

For instance, all functional languages provide a construct for specifying a function value without having to declare the function's name, equivalent to lambda abstractions in the lambda calculus. In Standard ML, such an expression is of the form

```
fn(x) => e
```

and denotes a function whose formal parameter is x and whose body is the expression e . This function value can be used in larger expressions, function calls, etc.

Consider again the factorial function. It might be argued that the formal definition of factorial just given was tailored to suit the recursive nature of the definition of factorial in the functional language, and that a more reasonable and common definition of factorial is

$$n! = \prod_{i=1}^n i$$

The product operator \prod is a very useful operator for defining a wide range of functions and has the general form

$$\prod_{i=m}^n f(i)$$

for some initial value m , some final value n , and some function f . In a functional language, \prod would be written as a **higher order function**, namely, a function that takes a function as a parameter or returns a function as its result. In particular, \prod takes three parameters, \mathbf{m} , \mathbf{n} , and \mathbf{f} and could be written in Standard ML as

```
fun prod(m,n,f) = if m = n then f(m) else f(m) * prod(m+1,n,f)
```

Thus, factorial can simply be defined as

```
fun fac(n) = prod(1,n, fn i => i)
```

and the exponentiation function computing x^n can be defined as

```
fun power(x,n) = prod(1,n,fn(i) => x)
```

92.2 History of Functional Languages

All functional languages trace their roots to the lambda calculus, developed by the logician Alonzo Church [1941], in the 1930s. This simple model, which describes computation as a series of syntactic conversions between expressions, was developed in order to gain a deeper understanding into computation and what it

means for functions to be computable, rather than as a programming language (since it obviously predates computers).

The first programming language that at least resembled the lambda calculus was LISP, developed by John McCarthy in the late 1950s [McCarthy et al. 1962]. It differs from the lambda calculus in several important ways: It was dynamically scoped (although McCarthy attributes this to a bug in the initial implementation), and provided an assignment operator. McCarthy states that although the lambda calculus served as an influence on the syntax of LISP, it was not the primary factor in the design of LISP's semantic features [McCarthy 1978]. LISP, however, has had a tremendous influence on modern functional languages. In 1975, Steele and Sussman designed SCHEME [Sussman and Steele 1975], a dialect of LISP that fixed some of the problems of earlier LISPs, such as dynamic scoping, and now its pure subset serves as the most LISP-like of all functional languages.

Another early language to have a great impact on the design of modern functional languages, especially ML and HASKELL, was ISWIM, developed by Landin [1966]. It was an explicit attempt to create a language whose semantics mirrored those of the lambda calculus, provided more convenient syntax and programming features, and was able to be implemented efficiently. Prior to the development of ISWIM, Landin [1964] had developed an abstract machine model, called the SECD machine, which specified how the conversion rules of the lambda calculus could be efficiently executed. Thus, the behavior of ISWIM operators could be described by their effect on the SECD machine.

The visibility of functional languages received a large boost in 1978, when John Backus, the designer of FORTRAN and the recipient of the 1978 A.M. Turing Award (computer science's highest award), chose to describe a new functional language, FP [Backus 1978], in his invited talk upon receiving the award. FP was a language of less expressive power than other functional languages of its time, since it did not provide user-defined higher order functions but rather supplied a fixed number of higher order *combining forms* used to create complex functions out of simple ones, and was heavily influenced by the APL programming language. Despite its limitations, and despite being of little interest today, FP was very influential in attracting researchers to the field of functional programming due Backus's stature, background, and convincing arguments in its favor.

During the 1970s and 1980s, functional languages, both strict and nonstrict, proliferated. Receiving a fair amount of attention and popularity were languages such as ML, SASL, HOPE, Lazy ML, and MIRANDA. Because of this proliferation, there was a movement to create standardized functional languages. The results of these standardization movements were a standardized definition of SCHEME [Rees et al. 1992]; Standard ML [Milner et al. 1990, Milner and Tofte 1991], now the standard strict functional language; and HASKELL [Hudak et al. 1992], now the standard nonstrict functional language. It is these languages that we have chosen to describe in this chapter.

92.3 The Lambda Calculus: Foundation of All Functional Languages

No description of functional languages is complete without the introduction of the lambda calculus, a simple but powerful model of computation. The reader is referred elsewhere in this handbook and to Barendregt [1984] for a detailed description of the lambda calculus. The important points to note about the lambda calculus are the following:

1. All functional languages are simply syntactically sugared versions of the lambda calculus, in some cases typed versions of the lambda calculus. Thus, any property that holds for the lambda calculus, such as its computational power, also holds for functional languages.
2. The lambda calculus is Turing complete: Every computable function can be expressed in the lambda calculus, and thus it is at least as powerful as any other computational model (such as Universal Turing Machines, for example).
3. One of two common evaluation orders in the lambda calculus, applicative order and normal order, have been adopted by almost all functional languages. Those functional languages which use

applicative-order evaluation, in which the arguments in a function call are evaluated before the body of the function (as is the case with all imperative languages), are called **strict functional languages**. Those functional languages which use **normal-order evaluation**, in which the arguments in a function call are only evaluated if and when needed in the body of the function, are called **nonstrict functional languages**.

4. The first Church–Rosser theorem about the lambda calculus states that no matter which evaluation order is chosen, the result of functional program will be the same as long as the program terminates. Not all evaluation orders are equally likely to terminate, however, and the second Church–Rosser theorem states that the evaluation order that is most likely to lead to termination is normal-order evaluation.

The three languages described here, SCHEME, Standard ML, and HASKELL, are all based on the lambda calculus. They differ primarily in three ways: their syntax, their type systems, and whether they are strict or nonstrict.

92.4 Pure Versus Impure Functional Languages

Of the three functional languages described in this chapter, only one, HASKELL, is purely functional. That is, only HASKELL does not provide any mechanism for performing side effects. Both SCHEME and ML provide mechanisms for performing assignment to variables, although ML's mechanism is far more limited. However, SCHEME and ML deserve to be included in this chapter because good practice dictates that programs written in these languages are generally purely functional and side effects are used only where the programmer considers them absolutely necessary. At the end of the sections on SCHEME and ML, some of their impure features will be described.

A side-effect mechanism that is quite difficult to omit from a language is input/output (I/O). From an external viewpoint, such as the view of the operating system handling I/O requests from a functional program, input and output operations change the state of the input and output buffers (for the terminal, printer, etc.). However, to see why conventional I/O routines, such as read and print, do not support referential transparency within the program, consider

```
let x = read()
in x + x
end
```

where **read()** reads data from the standard input and returns the value read. If referential transparency were preserved, this code could be replaced by

```
read() + read()
```

which is clearly not the case.

SCHEME and ML adopt relatively conventional I/O routines, sacrificing referential transparency in expressions involving I/O. HASKELL, however, uses a more novel approach to support I/O in a referentially transparent manner.

92.5 SCHEME: A Functional Dialect of LISP

SCHEME is a dialect of LISP which differs from the more traditional LISPs (including Common LISP) primarily in that it is *statically scoped*. It is also a smaller, simpler language than most other LISPs. SCHEME, as defined in the IEEE Standard, is not a purely functional language. It supports the **set!** operator, similar to **SETQ** in traditional LISPs, which performs assignment on variables. However, SCHEME programmers tend to write in a functional style, and at least one SCHEME compiler (see Kranz et al. [1986]) performs optimizations specifically targeted at programs written in a functional style.

In this chapter, we will focus on *pure* SCHEME, a subset of SCHEME that is purely functional. Pure SCHEME differs from SCHEME only in that it omits the few side-effect operators that SCHEME provides. By doing so, the mathematical properties of pure SCHEME mirror those of the lambda calculus.

Like all LISPs, SCHEME adopts a prefix notion for all syntactic entities, thus looks strikingly different from conventional languages and other functional languages. The beauty of LISP and SCHEME syntax is that there are very few syntactic rules, thus learning the syntax of the language is trivial. Furthermore, the appearance of SCHEME data structures and SCHEME programs is quite similar, leading to the ability to manipulate programs as data, as is the case with interpreters, compilers, program verifiers, and program transformers.

Also like all LISPs, but unlike the other functional languages described in this chapter, SCHEME has **latent types**, which means that types are associated with values, not variables. Type checking occurs at run time, not compile time (which is why SCHEME is often called a *dynamically typed* language) and a type error is signaled only when a primitive operator (such as $+$, $-$, etc.) has been applied to a value of an inappropriate type. There are no type declarations, and the types of user-defined functions and variables are not specified. Variables can be bound to values of different types over the course of the computation.

92.5.1 SCHEME Data Types

There are two kinds of types in SCHEME (as in LISP), atomic types known as *atoms*, and *pairs*. The atomic types include numbers (floating point numbers and arbitrarily large integers), Booleans (written **#t** and **#f**), character strings, and a type that is peculiar to LISP dialects, namely, symbols. Symbols are objects that have only one property, their name. Two symbols are equivalent if and only if they have the same name. SCHEME symbols are different from those of traditional LISPs, since LISP symbols often have many properties associated with them.

The other kind of type, a pair, is a two-element record. This record is generally referred to as a *cons cell*. Each element can be of any type and is generally implemented as seen in Figure 92.1a. The first element is known as the *car* and the second is known as the *cdr*. There is a constant **()**, called the *empty list*. Any collection of pairs of the form pictured in Figure 92.1b where the *cdr* of each cons cell is either **()** or points to another cons cell, is called a *list*. The list is the primary aggregate data structure in SCHEME (and all

FIGURE 92.1 List structures.

functional languages). It is a very flexible data structure, since each element of a list can itself be a list. The list pictured in Figure 92.1b would be printed as

```
(3 4 5 6)
```

and the list in Figure 92.1c would be printed as

```
(( (1 2) 3) (4 (5 6)))
```

92.5.2 SCHEME Syntax

In SCHEME, every language construct is an expression that returns a value. An expression is either an *atomic expression* or a *combination*. An atomic expression can either be a numeric literal, a string literal, or an identifier (representing both symbols and variables).

A combination is an expression consisting of an open parenthesis followed by some subexpressions and then a close parenthesis. These represent a range of expressions, including function calls, definitions, conditionals, etc.

A function call is of the form

$$(e_0 e_1 \dots e_n)$$

where each e_i is an expression. The expression e_0 should evaluate to a function, which is then applied to the values of the expressions $e_1 \dots e_n$. A call to a function with no arguments is simply written as (e_0) . The function call syntax is used for all user-defined functions as well as all predefined functions, including the arithmetic operators.

There are two forms of conditional expressions. The simplest is the **if**, of the form

```
(if e0 e1 e2)
```

If e_0 evaluates to any value other than **#f**, then the value of e_1 is computed and returned as the result of the entire expression. Otherwise, the value of e_2 is computed and returned.

A more general conditional, the **cond** expression, has the form

```
(cond (c0 e0)
      (c1 e1)
      ...
      (cn en))
```

The expressions c_0, c_1, \dots, c_n are evaluated in order until the first c_i , for some i , evaluates to a value other than **#f**. The value of e_i is then computed and returned. The expression c_n may be replaced by the keyword **else**, in which case the value of e_n is returned if none of c_0, \dots, c_{n-1} evaluates to a value other than **#f**.

In the construct

```
(quote exp)
```

exp is treated as data — either a symbol, number, or list — instead of an expression to be evaluated. Thus,

```
(quote a)
```

returns the symbol **a**, not the value of the variable **a**. The result of the expression

```
(quote (f a b c))
```

is the list containing the symbols **f**, **a**, **b**, and **c**. It is not a call to function **f** with arguments **a**, **b**, and **c**. Because *quote* is used so extensively in SCHEME and LISP, a syntactic shorthand is provided. The construct *'exp* is simply shorthand for **(quote exp)**. Thus, *'a* is equivalent to **(quote a)** and *'(a b c)* is equivalent to **(quote (a b c))**. A nested list is easily specified, for example, *'(a b (c d))*.

SCHEME's **lambda** expression is an expression whose value is a function. It is of the form

```
(lambda (x1 ... xn) e)
```

and evaluates to a function whose formal parameters are $x_1 \dots x_n$ and whose body is the expression e . A lambda expression without parameters would be of the form (**lambda** () e).

A definition of the form

```
(define x e)
```

introduces a new variable x and binds it to the result of evaluating the expression e . The variable x is visible during the evaluation of e , thus allowing for recursive function definitions such as

```
(define fac (lambda (x) (if (= x 0) 1 (* x (fac (- x 1))))))
```

In most implementations, **define** is only allowed at the top level, i.e., not nested inside any other expression. In these cases, the variable introduced is global.

As a syntactic convenience, functions can also be defined using the form

```
(define (f x1 ... xn) e)
```

which is equivalent to (**define** f (**lambda** ($x_1 \dots x_n$) e)). Thus, the factorial function given previously is generally written

```
(define (fac x) (if (= x 0) 1 (* x (fac (- x 1)))))
```

The **let** construct, of the form

```
(let ((x1 e1)
      (x2 e2)
      ...
      (xn en))
  e)
```

is used to introduce the variables $x_1 \dots x_n$ and bind them to the values of the expressions $e_1 \dots e_n$, respectively. The value of e is then computed and returned as the value of the entire **let** expression. The scope of the new variables $x_1 \dots x_n$ is just the body of e . Thus, these variables cannot be referenced in expressions $e_1 \dots e_n$. This means that none of $x_1 \dots x_n$ can be defined recursively.

The **letrec** construct can be used to introduce recursively defined local variables. It has the same form as the **let** construct, except that the keyword **letrec** is used instead of **let**. In this case, the expressions $e_1 \dots e_n$ are defined in an environment in which each of $x_1 \dots x_n$ are visible and thus can be referenced. Here is an example of a use of **letrec**,

```
(letrec ((f (lambda (x) (if (= x 0) 1 (g (- x 1)))))
         (g (lambda (y) (if (= y 0) 1 (f (- y 1)))))
         (+ (f 3) (g 5)))
```

where **f** and **g** are mutually recursive functions.

92.5.3 Predefined Functions

SCHEME provides a large number of predefined functions. The usual collection of arithmetic and logical operators, **+**, **-**, **=**, **! =**, **>**, **<**, etc., are provided and can be applied to any numeric values. Examples of their use include (**+** 3 4), (**>** 6.2 5.1), and (**! =** 4 5).

A function commonly used to create lists is **list**. It takes an arbitrary number of arguments and creates a list containing their values. Thus, for example,

```
(list 'a (+ 2 5) b (list 6 2))
```

would return the list (**a 7 v 6 2**), where v is the value of the variable **b**.

The most heavily used list construction function is **cons**. It takes two arguments and, as its name implies, creates a cons cell whose **car** is the value of the first parameter and whose **cdr** is the value of the second. For example, here is a function that takes parameters **N** and **M** and constructs the list of integers between **N** and **M**, inclusive.

```
(define (listof N M)
  (cond ((> N M) '())
        (else (cons N (listof (+ N 1) M))))
  )
```

To access the **car** and **cdr** fields of a cons cell, SCHEME provides the functions **car** and **cdr**, respectively. For example, (**car** '(3 4 5 6)) returns **3** and (**cdr** '(3 4 5 6)) returns the list (**4 5**). If the first element of a list l_1 is itself a list l_2 , then **car** applied to l_1 returns l_2 , as one would expect. For example,

```
(car '((1 2) (3 4) 5))
```

returns the list (1 2) and

```
(cdr '((1 2) (3 4) 5))
```

returns ((3 4) 5).

The predicate **null?** is used to test for an empty list. Here (**null? x**) returns **#t** if the value of **x** is the empty list and returns **#f** otherwise. Here is an example of the use of **car**, **cdr**, and **null?**: Given a list of numbers, the function **sumof** returns the sum of the elements of the list.

```
(define (sumof l)
  (cond ((null? l) 0)
        (else (+ (car l) (sumof (cdr l)))))
  )
```

Also, **cons** is useful for constructing lists one element at a time. Another useful predefined function is **append**. It takes as parameters two lists l_1 and l_2 and returns a list containing the elements of l_1 followed by the elements of l_2 . For example,

```
(append '(1 2 3 4) '((a b) c d))
```

returns the list (**1 2 3 4 (a b) c d**). Although **append** is always provided by SCHEME implementations, it is not *primitive* in the sense that it can easily be written in SCHEME.

```
(define (append x y)
  (cond ((null? x) y)
        (else (cons (car x) (append (cdr x) y)))))
```

Another predefined function that can easily be written in SCHEME is **reverse**. This function takes a list l and returns a new list with the same elements as l , but in reverse order. For example,

```
(reverse '(1 2 (3 4) 5))
```

returns the list **(5 (3 4) 2 1)**. Notice that nested lists, such as the third element of the previous input list, are not recursively reversed. The reverse function can be defined in SCHEME as

```
(define (reverse l)
  (cond ((null? l) '())
        (else (append (reverse (cdr l)) (list (car l))))))
```

Unfortunately, the cost of this function is proportional to the square of the length of the input list. This can be seen by noting that **append** is linear in the size of its argument and is called each time that **reverse** is called recursively. The depth of the recursion in **reverse** is proportional to the length of its argument. A more efficient **reverse**, whose cost is linear in the length of its argument, is

```
(define (reverse l)
  (rev l '()))

(define (rev l accum)
  (cond ((null? l) accum)
        (else (rev (cdr l) (cons (car l) accum)))))
```

One can think of **rev** as successively taking the elements of **l** and putting them at the front of the list **accum**. Thus, when **l** is empty **accum** will contain the elements of **l** in reverse order.

The function **map** is a commonly used predefined function. It takes two parameters, a function *f* and a list *l*, and returns a list resulting from applying *f* to each element of *l*. For example,

```
(map (lambda (x) (* x 2)) '(3 4 5 6))
```

returns the list **(6 8 10 12)**. It can be written in SCHEME as

```
(define (map f l)
  (cond ((null? l) '())
        (else (cons (f (car l)) (map f (cdr l))))))
```

92.5.4 Impure Features in SCHEME: Assignment and I/O

The most heavily used impure SCHEME construct is **set!**. It is SCHEME's variant of **SETQ** in LISP and is used to modify the value of an existing variable. That is, **(set! x exp)** evaluates *exp* and assigns the result to the variable *x*. Other side-effect operators include **(set-car! l exp)** and **(set-cdr! l exp)**, which assign the value of *exp* to the car and cdr fields of the list *l*, respectively.

There are a number of I/O routines provided in SCHEME, including those for opening and reading or writing to files. The simplest routines, however, are **(read)** which reads a scheme object (either an atom or a list) from the standard input and returns the object as the result of the call and **(write exp)** which writes the value of *exp* to the standard output. Here **(newline)** starts a new line on the standard output.

92.6 Standard ML: A Strict Polymorphic Functional Language

Standard ML is a popular functional language that uses applicative-order evaluation and has a flexible but static type system. It has a more conventional syntax than SCHEME and provides a pattern-matching facility for programming in an equational style. It also has an exception facility and a sophisticated module system supporting the development of large programs. Several robust implementations of Standard ML implementations exist and are used primarily at universities and research laboratories around the world.

Since the dynamic behavior specified by expressions in ML is based on the lambda calculus, and is thus similar to SCHEME, we will concentrate on ML's syntax and its type system.

92.6.1 Predefined Types in ML

ML provides the usual primitive types, **int**, **real**, **bool**, and **string**. Its aggregate types include lists, tuples, and records. A list is homogeneous, meaning that, unlike SCHEME, all elements of the list must be of the same type. The type for a list of integers is written **int list**, the type for a list of Booleans is written **bool list**, and so on. Literals for lists start and end with square brackets and the elements are separated by commas. Examples of list literals include **[1, 2, 3]**, **[true, false, true]**, and **[[1, 2, 3], [4, 5, 6]]**. The types of these lists are **int list**, **bool list**, and **int list list**, respectively. The literal **[]** denotes the empty list.

A tuple is an ordered collection of elements. Tuples are heterogeneous, their elements can be of different types. A tuple type is written as the element types separated by *****. Thus, **(int * bool * real)** is a tuple type whose first element is an integer, second element is a Boolean, and third element is a real. Tuple literals are written in the same way as list literals, except that parentheses are used instead of square brackets. For example, **(true, 3, [4.2])** denotes a tuple whose type is **bool * int * real list**. The elements of a tuple are accessed either by position or, more commonly, using patterns as described later in this section.

Records are similar to tuples except that, like in most languages, their elements are named. The type written **{a: int, b: real, c: string}** is a record type with field names **a**, **b**, and **c**, whose types are **int**, **real**, and **string**, respectively.

Being a functional language, ML provides higher order functions. These functions have types like any other object. The type of a function that takes a parameter of type *a* and returns a parameter of type *b* is written *a -> b*. Examples of function types are **int -> bool**, **real -> int -> bool**, and **int * real -> bool list**. The **->** is right associative, so the second example is equivalent to **real -> (int -> bool)**. This is a type describing functions that take a **real** as a parameter and return a function taking an **int** as a parameter and returning a **bool**.

Here, **->**, *****, and **list** are known as *type constructors* because they are not types themselves, but rather construct new types (such as **int list** or **bool -> real**) when combined with existing types (such as **int**, **bool**, and **real**).

92.6.2 Expressions in ML

Arithmetic and logical expressions are written using the familiar infix notation. Examples include **a+b**, **4>b**, and **c andalso (d = 5)**. The conditional expression is written

```
if condition then exp else exp
```

and function application is written simply as the juxtaposition of the function and the argument. For example,

```
f x
```

is the application of the function **f** to **x**. Often, ML programmers will put the argument in parentheses as was done in the factorial example in [Section 92.1](#). Simply placing parentheses around an expression has no effect on the value of the expression. Function application is left associative, thus

```
g 4 5
```

is equivalent to

```
(g 4) 5
```

List construction and selection are similar to that of SCHEME. The **::** operator is identical to SCHEME's **cons**, so that **x :: xs** returns a list whose first element is **x** and whose subsequent elements are those of the list **xs**. For example, the value of the expression

```
3 :: [4, 5, 6]
```

is the list **[3, 4, 5, 6]**.

The **@** operator is identical to SCHEME's **append** function. For example, the value of

```
[3,4,5] @ [6,7,8]
```

is the list **[3,4,5,6,7,8]**.

The ML functions **hd** and **tl** are identical to SCHEME's **car** and **cdr**, respectively. For example, the value of **hd [3,4,5,6]** is **3** and the value of **tl [3,4,5,6]** is **[4,5,6]**.

Function expressions, corresponding to **lambda** expressions in SCHEME, are written in the form

```
fn arg => body
```

Examples are

```
fn x => x + 1
fn a => fn b => a + (b * 2)
```

where **=>** is right associative, and so the second example is equivalent to

```
fn a => (fn b => a + (b * 2)) .
```

92.6.3 Declarations in ML

Variables and functions are declared using the **let** construct, much like SCHEME's **let**. It has the form

```
let declaration1
    declaration2
    ...
    declarationn
in
    exp
end
```

where each *declaration_i* defines a new variable or function, and *exp* is the body of the **let**.

A variable declaration has the form

```
val x = e
```

in which case the expression *e* is evaluated and the variable *x* is given the resulting value. A function declaration has the form

$$\text{fun } f x_1 \dots x_n = e$$

where $x_1 \dots x_n$ are the formal parameters and *e* is the body of the function.

Here is an example of a let expression:

```
let val x = 6
    val g = fn z => z + 2
    fun fac n = if n = 0 then 1 else n * fac (n-1)
in
    fac (g x)
end
```

Notice that the variable **g** is bound to a function of type **int -> int**. The use of the keyword **fun** (as in the succeeding line) provides two conveniences: first, the formal parameters appear to the left of the **=**,

and second, it supports the definition of recursive functions. In the declaration of **g** using the keyword **val**, **g** cannot appear on the right-hand side of the definition. The keyword **fun** was necessary in the recursive definition of **fac**.

In ML all functions take a single parameter. Thus, the declaration of the function

```
fun f x y = x + y + 2
```

is just shorthand for

```
fun f x = fn y => x + y + 2
```

This function has type **int -> int -> int** and when it is applied to a single argument, it returns a function of type **int -> int**. A function, such as **f**, that can be applied to fewer parameters than appear in the declaration is called a **curried function**, after the logician HASKELL Curry.

92.6.4 Pattern Matching

One of the nicest features of ML is its pattern-matching facility. In function definitions, the formal parameter name can be replaced by a pattern. In the introduction to this chapter, the factorial function was written as

```
fun fac 0 = 1
  | fac n = n * fac(n-1)
```

in which factorial is defined by two clauses separated by a **|**. In the first clause, the formal parameter is replaced by the literal **0**. When **fac** is called, if the argument has the value **0**, then the right-hand side of the first clause is evaluated. Otherwise, the formal parameter **n** in the second clause is bound to the value of the argument and the right-hand side of the second clause is evaluated.

Consider a function that computes the sum of the elements of a list.

```
fun sum [] = 0
  | sum l = hd l + sum (tl l)
```

The literal pattern **[]** in the first clause is used to determine if the argument is the empty list. Instead of using **hd** and **tl** to select the components of **l** in the second clause, **l** could be replaced by a pattern that accomplishes the same thing:

```
fun sum [] = 0
  | sum (x::xs) = x + sum xs
```

In this case, the pattern **(x::xs)** matches any nonempty list and binds **x** to the head of the list and **xs** to the tail.

A tuple can also be used as a pattern. It was previously mentioned that

```
fun f x y = x + y + 2
```

is a curried function of type **int -> int -> int**, and that it is legal to apply **f** to just one argument. If the programmer knows that **f** will always be called with both arguments, then it is generally more efficient to define **f** as taking a single argument which is a tuple:

```
fun f (x,y) = x + y + 2
```

In this case, **f** has type **int*int->int** and a call to **f** would look like **f(3,4)**. This example also demonstrates how a pattern is used to access the individual elements of a tuple, in this case as **x** and **y**.

92.6.5 Type Definitions

There are several ways to introduce new type names in ML. The simplest way is to create a type synonym, i.e., to define a new name for an existing type. This is accomplished by a declaration of the form

```
type name = type_exp
```

which introduces the new name *name* for the type described by *type_exp*. Some examples are

```
type foo = int * bool * real
type bar = string
type personnel_record = { name: string, salary: int, ss_num:
                          string }
```

No new type is created. Thus, **foo** and **int*bool*real** describe the same type and can be used interchangeably in the program.

New types are created using the **datatype** construct. In its simplest form, a data type declaration specifies all of the elements of the type, much like an enumerated type in PASCAL or ADA.

```
datatype stoplight = Red | Green | Yellow
```

defines a new type **stoplight** whose values are **Red**, **Green**, and **Yellow**.

In the more general form of a data type declaration, the components on the right-hand side can be *value constructors*. Instead of being values themselves, such as **Red** or **Green**, value constructors take parameters and construct values of the new type. Consider,

```
datatype tree = Empty | Leaf of int | Node of tree * tree
```

Here, **Leaf** is a value constructor taking an integer parameter and **Node** is a value constructor taking a tuple of two trees. **Empty**, like **Red**, **Green**, and **Yellow** previously is simply a value constructor that takes no parameters. The declaration of type **tree** says that a value of that type can be the empty tree, a leaf with an integer label, or an interior node with two subtrees.

The expression **(Leaf 5)** constructs a value of type **tree** which is a leaf node with the label 5. The expression

```
Node (Node (Leaf 5, Node (Leaf 6, Empty)), Leaf 7)
```

constructs the tree shown in Figure 92.2.

Value constructors can be used in patterns, as in

```
fun drive Red = "stop"
  | drive Green = "go"
  | drive Yellow = "go faster"
```

FIGURE 92.2 Tree created by **Node (Node (Leaf 5, Node (Leaf 6, Empty)), Leaf 7)**.

The type of the function **drive** is **stoplight -> string**. Pattern matching can also be used to select out the parameters associated with value constructors. The fringe function, defined by

```
fun fringe Empty = []
  | fringe (Leaf x) = [x]
  | fringe (Node (left,right)) = fringe(left) @ fringe(right)
```

returns a list of the labels associated with the leaves of a tree. If the tree is empty, then the empty list is returned. If the tree consists of just a leaf, then the variable **x** would be bound to the value of the leaf's label and the list containing **x** would be returned. Otherwise, if the tree consists of a node with left and right subtrees, the variables **left** and **right** are bound to those subtrees and their fringes are computed. The two resulting lists are then appended to form the result. The call

```
fringe (Node (Node (Leaf 5, Node (Leaf 6, Empty)), Leaf 7))
```

would return the list **[5,6,7]**.

92.6.6 Type Variables and Parametric Polymorphism

Consider the **length** function, which computes the length of a list:

```
fun length [] = 0
  | length (x::xs) = 1 + length xs
```

What is its type? Clearly, it can take a list of any type, since the type of the elements of the list has no effect on its length. Thus, we say that the type of **length** is

$$\forall \alpha. \alpha \text{ list} \rightarrow \text{int}$$

which means that for all types α , **length** can take an α list and returns an integer. In ML, this type is written

```
'a -> int
```

where the **'** signifies that **a** is a universally quantified type variable rather than some type **a** previously defined.

Because **length** can be applied to many different types of arguments, as in

```
length [1,2,3] + length [[4,5],[6]] + length [true,false,true]
```

we say that **length** is **polymorphic** (meaning many shaped). In ML, any object whose type contains a type variable, such as **'a**, is polymorphic. All others are said to be *monomorphic*. This kind of polymorphism is called *parametric polymorphism* because in some theoretical type models, type variables occur as extra formal parameters in a function definition.

ML supplies a **map** function much like SCHEME's **map**. It can be written as

```
fun map f [] = []
  | map f (x::xs) = f x :: map f xs
```

The type of **map** is **('a -> 'b) -> 'a list -> 'b list**, because for any types **'a** and **'b**, **map** takes a function **f** of type **'a -> 'b** and a list of type **'a list** and applies **f** to each element of the list. The result of each application is of type **b**, and since **map** returns the list of the results, the return type of **map** is **'b list**. The result of

```
map (fn n => n+1) [1,2,3] @ map (fn l => length l)
                               [[2.2,3.3],[4.4]]
```

would be **[2,3,4,2,1]**.

In all the ML examples so far, the programmer never specified the types of the functions, variables, or expressions. If desired, one could do so explicitly, as in

```
val a: int list = [1,2,3]
```

and

```
fun f (x:int) (y:real) = (if x = 1 then y + 1.2 else y - 1.7): real
```

In general, however, the ML compiler can infer the types of the functions and variables by the way they are defined and used. This process is called **type inference** and the ML type system, based on work by Hindley and by Milner, ensures that type inference can be safely performed. Furthermore, the type that is inferred for an object is the most general type possible, allowing that object to be used as polymorphically as possible. For example, if type inference had inferred the type of the **length** function to be **int list->int**, then the length function would have been restricted to lists of integers. Instead, type inference infers the more general type **'a list -> int**, allowing **length** to be used on all types of lists.

92.6.7 Type Constructors

Type variables can also be used to parameterize data type declarations. Earlier, we defined a tree type whose leaves were labeled with integers:

```
datatype tree = Empty | Leaf of int | Node of tree * tree
```

Instead, we can write

```
datatype 'a tree = Empty | Leaf of 'a | Node of 'a tree * 'a tree
```

which says that for all types **'a**, an **'a tree** is either empty, a leaf labeled with a value of type **'a**, or a node with two subtrees of type **'a tree**. In this case, **tree** is a type constructor because many different tree types can be constructed by instantiating **'a** with different types. For example, if the programmer writes

```
Node (Leaf 3.2, Empty)
```

the compiler can infer the type of this expression to be **real tree**. Similarly,

```
Node (Leaf[3,4,5], Leaf[4,5,6])
```

describes an **int list tree**. The type variable **'a** can only be instantiated one way within a single type, so that

```
Node (Leaf 4, Leaf true)
```

is illegal.

Interestingly, the type of the expression

```
Empty
```

is **'a tree**, thus **Empty** is polymorphic but is not a function (another example of this is **[]: 'a list**).

Polymorphic functions work well in the presence of type constructors. The **fringe** function seen earlier,

```
fun fringe Empty = []
  | fringe (Leaf x) = [x]
  | fringe (Node (left,right)) = fringe(left) @ fringe(right)
```

now has type **'a tree -> 'a list** and can work on any kind of tree.

92.6.8 The ML Module System

In order to support large-scale programs and separate compilation, ML provides a sophisticated module system. As in other languages, a module consists of a *body*, a collection of definitions of types, variables, etc., and an *interface*, specifying which components of the body are visible outside the module. In ML, a module body and a module interface are separate entities. Thus, many different module bodies can share the same interface, and different modules might share a body but have different interfaces.

A module interface, called a *signature* in ML, is described by a signature expression of the form

```
sig decl1
    decl2
    ...
    decln
end
```

where each *decl_i* is usually a declaration of the name and type of an object or the name of a type. To give a name to a signature, a declaration of the form

```
signature name = sig_exp
```

is used, where *sig_exp* is a signature expression. For example, the interface for a module implementing a (functional!) stack might be

```
signature STACK = sig
    type 'a stack
    val empty: 'a stack
    val push: ('a * 'a stack) -> 'a stack
    val pop: 'a stack -> ('a * 'a stack)
    val isempty: 'a stack -> bool
    exception stack_underflow
end
```

A module body, known as a *structure* in ML, is described by a structure expression of the form

```
struct def1
    def2
    ...
    defn
end
```

where each *def_i* is a definition. To give a structure a name, a declaration of the form

```
structure name = struct_exp
```

is used, where *struct_exp* is a structure expression or the name of a previously defined structure.

For example, a structure implementing a stack might look like

```
structure StackImp = struct
    exception stack_underflow
    type 'a stack = 'a list
    val empty = []
    fun push(x,s) = x::s
    fun pop [] = raise stack_underflow
      | pop (x::rest) = (x,rest)
    fun isempty [] = true
      | isempty l = false
end
```

At this point, there is no connection between the signature **STACK** and the structure **StackImp**. Thus, all the components of **StackImp** are visible. To create a stack implementation with the signature **STACK**, we can write:

```
structure Stack:STACK = StackImp
```

The signature **STACK** can be reused in a different implementation of a stack, as in

```
structure NewStack : STACK =
  struct
    exception stack_underflow
    datatype 'a stack = empty | non_empty of int * 'a list
    fun push (x,empty) = non_empty (1,[x])
      | push (x,non_empty(n, s)) = non_empty (n+1, x::s)
    fun pop empty = raise stack_underflow
      | pop (non_empty(n,x::rest)) = (x, if n=1 then empty else
                                         non_empty(n-1,rest))

    fun isempty empty = true
      | isempty l = false
  end
```

Once defined, a component x of a module m is referenced by the expression $m.x$. For convenience, the components of a module may be referenced without the module name, if the module is first opened via the command

```
open name
```

where $name$ is the name of the module.

Modules are not values in ML. That is, they cannot be passed to functions, stored in lists, etc. ML does provide something similar to a function from modules to modules. It is called a *functor* and supports code reuse by allowing the definition of a module in terms of other modules. All modules, even those resulting from functor applications, are instantiated at compile time and therefore cannot depend on values computed during execution.

A functor definition has the form

```
functor f(s1 : sig1, ..., sn : sign) : sig_exp = struct_exp
```

where $s_1 \dots s_n$ are the formal parameter names that will be bound to structures in a functor application and $sig_1 \dots sig_n$ are the signatures that $s_1 \dots s_n$ must conform to, respectively. Here, sig_exp is the signature of the result of the functor and $struct_exp$ is the definition of the resulting structure. For example, suppose one wanted to create an implementation of a queue based on an existing stack implementation, such that the signature of a queue is

```
signature QUEUE =
  sig
    exception queue_underflow
    type 'a queue
    val empty: 'a queue
    val enqueue: ('a * 'a queue) -> 'a queue
    val dequeue: 'a queue -> 'a * 'a queue
    val isempty: 'a queue -> bool
  end
```

Next is a functor definition that takes any structure that conforms to the previous **STACK** signature and creates an implementation of a queue, using the data structures and routines supplied by the stack argument.

```
functor MakeQueue(Stack: STACK): QUEUE =
  struct
    exception queue_underflow
    type 'a queue = 'a Stack.stack * 'a Stack.stack
    val empty = (Stack.empty, Stack.empty)

    fun reverse_stack(from, to) =
      if Stack.isempty from then to
      else let val (x, new_from) = Stack.pop from
            in reverse_stack(new_from, Stack.push(x, to))
            end

    fun enqueue(x, (s1, s2)) = (s1, Stack.push(x, s2))

    fun dequeue (s1, s2) =
      if Stack.isempty s1 then
        if Stack.isempty s2 then raise queue_underflow
        else dequeue (reverse_stack (s2, Stack.empty),
                      Stack.empty)
      else
        let val (x, new_s1) = Stack.pop s1
            in (x, (new_s1, s2))
            end

    fun isempty(s1, s2) = Stack.isempty s1 andalso
                          Stack.isempty s2
  end
```

To create an actual queue module the functor must be invoked, as in

```
structure Queue1 = MakeQueue(Stack)
```

Another implementation of a queue, based on a different stack implementation, is created by

```
structure Queue2 = MakeQueue(NewStack)
```

Functors are commonly used in ML to support separate compilation. They allow a module to be written and compiled despite referring to components of modules that are not yet implemented. Note that, for example, the code for the previous functor **Queue** could have been written, type checked, and compiled before any structure with the signature **STACK** was implemented. Only the signature **STACK** had to exist before compiling **Queue**.

92.6.9 Impurities in ML: References and I/O

As previously mentioned, ML supports conventional I/O, which violates referential transparency. For example,

```
val x = (print "hello"; print "world"; true)
```

where **hello world** would be printed and the value of **x** would be **true**. The semicolon is used to separate statements that are executed sequentially.

The other impure feature of ML is *references*. In conventional languages, these would be considered constant pointers to assignable locations. The expression

```
ref exp
```

allocates a new cell c in memory and places the value of exp in c . The address of c is returned as the value of the entire expression. The type of the expression is t **ref**, where t is the type of exp . Given, for example, the declaration

```
val x = ref 6
```

the value of \mathbf{x} is a new cell containing **6**, and the type of \mathbf{x} is **int ref**.

The value stored in this location may be changed, using the expression

```
 $exp_1 := exp_2$ 
```

where the value of exp_1 must be a reference of type **ref** t and t is the type of exp_2 . Evaluating this expression causes the value of exp_2 to be stored in the location denoted by exp_1 . For example,

```
x := 7
```

changes the value referenced by \mathbf{x} to **7**. The dereference operator is **!**. In the expression **!exp**, exp must evaluate to a reference and the value of the entire expression is the value contained in the referenced cell. Thus, after the assignment to \mathbf{x} , the value of **!x** is **7**. Since the value of an expression of type t **ref** is essentially a pointer, references can be used for aliasing. For example, given the code

```
val x = ref 10
val y = x
```

the variable \mathbf{y} , of type **int ref**, would point to the same location (containing **10**) that \mathbf{x} does. Thus, the result of the expression

```
(x := !x+1; !y)
```

would be **11**.

92.7 Nonstrict Functional Languages

Before describing HASKELL in detail, it is worthwhile examining the costs and benefits of a nonstrict language, i.e., a language based on normal-order evaluation. Normal-order evaluation specifies that an argument in a function call is evaluated only when the value of the corresponding formal parameter is needed. In most implementations of nonstrict functional languages, any subsequent reference to the formal parameter uses the already computed value of the argument rather than re-evaluating it. This more efficient mechanism for supporting normal-order evaluation is called **lazy evaluation** (it is also sometimes referred to as *call-by-need*). Nonstrict functional languages are often informally referred to as **lazy functional languages**, even though laziness is a property of the implementation rather than the language.

In a nonstrict language, even using lazy evaluation, there is a significant overhead cost to delaying the evaluation of an actual parameter until the corresponding formal parameter is needed. This cost arises due to the fact that an object representing the delayed argument must be constructed when the function is called. This object might be a closure (i.e., a parameterless procedure, generally known as a *thunk*) that will be invoked when the value of the argument is needed, or it might be a graph representation of the delayed expression (this is found in systems that use a technique called graph reduction). In each case, the overhead cost can be substantial.

The benefit of a nonstrict language is that its programs are more likely to terminate: for example, if the evaluation of an argument might never terminate but the argument is not needed by the function. However, since the vast majority of popular programming languages are strict, it might appear that this particular

termination issue is unimportant. However, when used properly, nonstrictness frees the programmer from worrying about some control issues, such as interleaving the execution of producer and consumer procedures. The other benefit of using a nonstrict language is that it allows the programmer to create infinite data structures. To illustrate this, consider the following definition:

```
fun numsfrom n = n :: numsfrom (n+1)
```

This function, given an integer argument n , creates the list $[n, n + 1, n + 2, \dots]$. In ML, the call

```
numsfrom 1
```

would not terminate until memory was exhausted because all of the (infinite number of) elements of the list would have to be created before the call returned.

In a nonstrict language, the cons function `::` does not evaluate its arguments. Thus, the expression

```
n :: numsfrom (n+1)
```

would create a list whose head is n and whose tail is specified by `numsfrom (n+1)` but is left unevaluated. Only when the value of the tail of this list is demanded using the `tl` function is the call `numsfrom (n+1)` actually evaluated. The result of that call, then, is a list whose head is $(n+1)$ and whose tail is described by the unevaluated expression `numsfrom (n+2)`. In a nonstrict language, the call

```
numsfrom 1
```

would return almost immediately with a delayed list representing $[1, 2, 3, \dots]$. These infinite, but delayed, lists are generally known as **streams**.

The function

```
fun sumstream s 0 = 0
  | sumstream s n = hd s + sumstream (tl s) (n - 1)
```

takes a stream s and an integer n and computes the sum of the first n elements of s . The result of

```
sumstream (numsfrom 1) 10
```

would compute the sum of the first 10 elements of `(numsfrom 1)`, namely, 55.

From a programmer's point of view, the use of infinite data structures provides a nice separation between the production of data (by `numsfrom`, in this case) and the consumption of the data (by `sumstream`). The producer does not need to know how much data the consumer will need, nor does it have to worry about buffering data that is already produced but not consumed. The data is produced only when demanded by the consumer.

A more substantial example is the program that computes the infinite list of primes using the Sieve of Eratosthenes.

```
let fun numsfrom n = n :: numsfrom (n+1)
    fun filter f (x::xs) = if f x then x :: filter f xs
                          else filter f xs
    fun remove_multiples (x :: xs) =
      let fun is_multiple n = (n mod x) <> 0
          in x :: remove_multiples (filter is_mult xs)
          end
in
  remove_multiples (numsfrom 2)
end
```

92.8 HASKELL: A Nonstrict Functional Language

Aside from being a nonstrict functional language, HASKELL features a sophisticated type system that extends the ML-style (i.e., Hindley–Milner) type system to incorporate dynamic overloading.

HASKELL's syntax differs somewhat from that of ML, although the programs have a similar look. A few of the more important syntactic differences are as follows:

- Identifiers representing types and value constructors are capitalized. Identifiers representing type variables and values are not capitalized.
- Function and variable definitions do not begin with a keyword (whereas ML uses **fun** and **val**).
- Type constructors precede their arguments, as in **List Int** (in contrast to **int list** in ML).
- HASKELL uses **:** and **::** in precisely the opposite way from ML. The **:** is the *cons* operator and the **::** is used to associate a type with an expression, as in

```
(4:[5,6]) :: List Int
```

- Indentation can be used to begin and end new blocks. For example, in

```
let f x = let z = x + 3
          in x * y
    y = a * b
in
  f y
```

the indentation specifies that the names **f** and **y** are defined at the same level.

92.8.1 The HASKELL Class System

HASKELL's most interesting feature, other than its nonstrict semantics, is its *class* system for supporting *dynamic overloading* in a systematic way. The term overloading refers to the ability to give the same name to two distinct entities in a program. Overload resolution is the process by which the use of that name is disambiguated. For example, in ADA the programmer can define two or more different functions with the same name. When encountering that name in a function call, the compiler performs overload resolution to determine which function is being called by examining the number and types of the actual parameters. If the compiler is unable to resolve the overloading, the program is rejected. Because the overload resolution occurs at compile time, this kind of overloading is called *static overloading*.

In almost all languages, there is some form of overloading. For example, most languages use **+** as the name of the addition operators for both integers and reals, even though they are different operators. This is the case in ML, for example. However, the mixing of static overloading and type inference causes a problem in ML. Consider the following definition in ML:

```
fun f x y = x + y
```

The ML compiler rejects this definition because it cannot determine which addition operator, integer or real, is specified by **+**. The parameters **x** and **y** are either integers or reals, but it cannot be determined which. The ML programmer has to provide explicit type information, such as:

```
fun f (x:int) y = x + y
```

In the first (erroneous) definition, the type of **f** is clearly not

$$\forall\alpha. \alpha \rightarrow \alpha \rightarrow \alpha$$

since **+** cannot be applied to every type α . We would like to be able to say that **f** is of type

$$\forall\alpha \text{ for which } + \text{ is defined. } \alpha \rightarrow \alpha \rightarrow \alpha$$

and to allow the programmer to define the meaning of **+** for any type (complex numbers, sets, etc.) desired. Then, when **f** is called, the choice of which **+** to use in the body of **f** depends on the types of the arguments to **f**. Since **f** is polymorphic, albeit in a restricted way, it can be applied to many different types of arguments and thus the choice of **+** has to be made at run time. This kind of overloading is called dynamic overloading and is seen, in a different framework, in object-oriented languages.

HASKELL uses type classes to support dynamic overloading. A type class is a way to specify what operations must be supported by a particular collection of types. For example, the equality class, **Eq**, defined in HASKELL by

```
class Eq a where
    (==) :: a->a->Bool
```

specifies that every type **a** in class **Eq** must provide a definition for the infix equality operator **==** of type **a -> a -> Bool**. One can then write a polymorphic function that uses **==**, for example

```
f :: (Eq a) => a->a->Int
f x y = if x == y then 1 else 2
```

The first line gives the type of **f**, which is **a -> a -> Int** for any type **a** in class **Eq**.

The notation (**Eq a**) is called a *context* and indicates that **a** is in class **Eq**. Like ML, HASKELL is designed to support type inference. In fact, the first line declaring the type of **f** can be omitted. The HASKELL compiler will infer that the type of the parameters must be in class **Eq**.

92.8.2 User-Defined Types

New types in HASKELL are defined using the **data** construct which is analogous to the **datatype** construct in ML. For example,

```
data IntTree = Empty | Leaf Int | Node IntTree IntTree
```

defines the same integer-labeled tree type seen earlier. HASKELL also provides type constructors, so

```
data Tree a = Empty | Leaf a | Node (Tree a) (Tree a)
```

defines the **Tree** type constructor parameterized by the label type **a**.

92.8.3 Instance Declarations

Once a new type has been created it can be declared to be an *instance* of a type class, in which case the definition of the required operators must be provided. For example, declaring type **IntTree** to be in class **Eq** might look like

```
instance Eq IntTree where
    Empty == Empty           = True
    Leaf x == Leaf y         = x == y
    (Node l1 r1) == (Node l2 r2) = l1 == l2 && r1 == r2
    t1 == t2                  = false
```

The code following the **where** keyword is simply the definition of the **==** operator using pattern matching on the value constructors of **IntTree**. Since **==** is infix, the definition is in infix form. Once **IntTree** has been declared to be in class **Eq**, an **IntTree** value can be passed to any function expecting a type in class **Eq**.

We would also like to declare that any type constructed from the **Tree** type constructor is in class **Eq**. The declaration

```
instance Eq (Tree a) where
  Empty == Empty           = True
  Leaf x == Leaf y         = x == y
  (Node l1 r1) == (Node l2 r2) = l1 == l2 && r1 == r2
  t1 == t2                  = false
```

is incorrect because the definition of **==** requires, in the second clause, that the labels **x** and **y** be compared using **==**. Thus, not only must **==** be defined on **(Tree a)** for any type **a**, **==** must also be defined on **a**. Thus, **a** must already be an instance of class **Eq**. The correct instance declaration requires a context as follows:

```
instance (Eq a) => Eq (Tree a) where
  Empty == Empty           = True
  Leaf x == Leaf y         = x == y
  (Node l1 r1) == (Node l2 r2) = l1 == l2 && r1 == r2
  t1 == t2                  = false
```

This should be read as “For all types **a**, if **a** is in class **Eq** then **(Tree a)** is in class **Eq** with **==** defined as follows...”

HASKELL also provides a form of inheritance, in which one class can be used to define another class. For example, the class definition

```
class (Eq a) => Ord a where
  (<), (<=), (>=), (>)      :: a->a->Bool
  max, min                  :: a->a->a
```

defines the class **Ord** of ordered types in terms of the class **Eq**. In this case, a type **a** can be in class **Ord** if it is in class **Eq** and supports the additional operators previously mentioned. We say that **Eq** is the *superclass* of **Ord** and **Ord** is the *subclass* of **Eq**.

92.8.4 List Comprehensions in HASKELL

Another nice feature of HASKELL is its *list comprehensions*. These are concise expressions for constructing entire lists, resembling set notation in mathematics. For example, the expression

```
[f x | x <- xs]
```

computes the list of all values returned by **(f x)**, for each **x** taken from the list **xs**. Thus

```
[ x * 2 | x <- numsfrom 1]
```

returns the infinite list **[2, 4, 6, ...]**. Naturally, the elements of the list are not computed until needed, just as in the preceding case of the infinite list resulting from **numsfrom 1**.

List comprehensions can also include guards. For example,

```
psort []      = []
psort (x:xs) = psort [y | y <- xs, y < x] ++ [x] ++
                 psort [y | y <- xs, y >= x]
```

defines the partition sort (often mislabeled quicksort), where **++** is HASKELL's append operator. The first list comprehension in **psort**

```
[y | y <- xs, y < x]
```

contains the guard **y < x**, so that the only elements **y** taken from **xs** are those that are less than **x**.

92.8.5 Functional I/O in HASKELL

In order for HASKELL's I/O facility to maintain referential transparency, the input to a program is considered a stream, a possibly infinite list. Like other infinite lists, the entire input list is not immediately available at the start of execution, but the elements are supplied over the course of the computation: for example, as the user enters data from the keyboard. Similarly, the output of a program is also a stream. A program, then, can be viewed as a mapping from input streams to output streams. In actuality, HASKELL's I/O system is substantially more complicated in order to support error handling, files, and channels. It makes heavy use of *continuations*, and the reader is referred to a nice introduction to the language in Hudak and Fasel [1992].

92.9 Research Issues in Functional Programming

The functional language research community is very active in a number of areas. Of particular interest is improving the speed of functional language implementations. There are two primary approaches to this: through compiler-based program analysis and optimization techniques and through the parallelization of functional programs. Another area of research is to increase the expressiveness of functional languages, particularly in applications in which side effects are seen as necessary in conventional programs. In this section, we provide a brief description of these research areas and refer the reader to the literature in order to gain a deeper understanding of the issues.

92.9.1 Program Analysis and Optimization

Because of the solid mathematical foundation and well-defined semantics of functional languages, functional programs are particularly good candidates for compile-time analysis and optimization. An analysis technique that has been used in a large number of optimizations is *abstract interpretation* (see Abramsky and Hankin [1987]). It is a technique in which the program is executed at compile time, but rather than operating on the usual kinds of values, it operates on, and returns, only particular pieces of information desired by the compiler. If the desired information is sufficiently restricted, or an approximate answer is acceptable, then the program execution can be shown to terminate and is thus useful at compile time. The example generally used to illustrate abstract interpretation is overly trivial but useful nonetheless: the rule of signs in multiplication. This rule determines the sign of the result of a multiplication, using only the signs of the operands:

$$0 \times x = 0 \text{ for any } x$$

$$x \times 0 = 0 \text{ for any } x$$

$$+ \times + = +$$

$$- \times + = -$$

$$+ \times - = -$$

If only the sign of the result of a multiplication is desired, then the rule of signs provides a form of execution that is much less expensive than performing the actual multiplication and then taking the sign of the result.

An early, but still important, application of abstract interpretation arises in *strictness analysis*. Strictness analysis is an analysis used for a nonstrict language in order to transform, where possible, normal-order evaluation into applicative-order evaluation. Essentially, we want to know if a function f will always require the value of its argument, in which case we say that f is *strict*. If we know a function is strict, then we can go ahead and evaluate its argument before calling the function, without changing the result computed by the program.

More formally, we say that f is strict if, even using normal-order evaluation,

$$f(\perp) = \perp$$

where \perp represents a nonterminating computation. Intuitively, this says that if f is applied to an argument whose evaluation would not terminate and yet f does terminate, then it is clear that f does not require the

value of that argument and is thus not strict. Abstract interpretation is used to find the strictness property of a function by executing an abstract version f' of f function over the domain of values $\{0, 1\}$ where 0 represents nontermination and 1 represents possible termination. If

$$f'(0) = 0$$

reflects the behavior of f in the previous equation, then we know that f is strict.

92.9.2 Parallel Functional Programming

The attractiveness of functional languages for writing programs for parallel machines arises from the first Church–Rosser theorem. The theorem states that given a function call, the order in which the arguments and the body of the function are evaluated will not effect the final answer, assuming the program terminates. Thus, given the expression

$$(f\ x) + (g\ y)$$

the expressions $(f\ x)$ and $(g\ y)$ can be evaluated *in parallel*. In this case, it is clear that both operands to $+$ are needed, so that there will be no wasted effort.

There are two major approaches to parallel programming using functional languages (see Kelly [1989] for extended reading in this area). The first involves programming in a standard functional language, such as ML or HASKELL, and using a compiler and run time system that will partition the program into parallel threads and execute them. Because of the Church–Rosser property, it is not difficult for the compiler to determine which expressions can be executed in parallel.

The difficult part is determining the appropriate granularity of the parallel version of the program. Granularity is the measure of the size of the tasks into which the program is decomposed; the finer the granularity, the smaller and more numerous the tasks, and the greater the degree of parallelism. However, there is a cost associated with creating each task, whether due to communication over a network, increased contention for a shared memory, or context switching in the operating system.

The second approach to parallel computing using functional languages involves adding constructs to a functional language for expressing parallelism. These constructs might specify which expressions should be evaluated in parallel (and, thus, which are not worth spawning as their own tasks), which processor an expression should be evaluated on, and, in the case of languages which contain impure features, the creation and use of channels for communication.

92.9.3 Partial Evaluation

Partial evaluation [Bjorner et al. 1988] is the technique where, if part of the input to a program is known at compile time, the program is evaluated as much as possible using the input available. The result is a new version of the program, called the specialized program, that is ready to accept the rest of the input and return the same result as the original program would have on the entire input. The process of specialization creates a more efficient program than the original because the known data have already been integrated into the program, reducing the amount of interpretation that the program has to perform on its input.

92.9.4 State in Functional Programming

An active area of research in functional programming is the development of new techniques for reasoning about state and changes in state in a manner that preserves referential transparency. For example, these techniques, most based on the concept of a monad [Wadler 1992], allow programmers to manipulate arrays in a pure functional language in a style that looks familiar to imperative language programmers [Peyton Jones and Wadler 1993]. Furthermore, this work boosts the efficiency of functional arrays by allowing the arrays to be updated in place, rather than copied each time an update operation is performed (which is normally necessary to preserve referential transparency). This is accomplished by using the type

system to encapsulate the array such that it cannot be shared. Thus, since a previous version of the array can never be referenced (because the array is not shared), the new version of the array can be created simply by modifying the previous version.

Defining Terms

Applicative-order evaluation: An execution order in which the arguments in a function call are evaluated before the body of the function.

First-class object: An object that can be stored in data structures, passed as arguments, and returned as the result of function calls. In functional languages, functions are first-class objects.

Higher order function: A function that takes another function as a parameter or returns a function as its result.

Lambda calculus: A simple syntactic model of computation equal in power to the Turing Machine.

Latent type system: A type system where types are associated with values, not variables. This usually requires run time type checking which is why latently typed languages such as SCHEME are often referred to as *dynamically typed*.

Lazy evaluation: An evaluation technique for nonstrict functional languages.

Lazy functional language: Informal but common name for a nonstrict functional language.

Nonstrict functional languages: A function language adopting normal-order evaluation.

Normal-order evaluation: An execution order in which the arguments in a functional call are only evaluated if and when needed in the body of the function.

Polymorphism: A property of a languages type system in that an objects type may include type variables which can range over an infinite number of types. Most such polymorphic objects are functions, which can be applied to arguments of many different types.

Pure functional languages: Functional languages that provide absolutely no mechanism for performing side effects, and thus exhibit referential transparency.

Referential transparency: The property of a language that states that equal expressions can be interchanged with each other.

Side effect: A change in the value of a variable as the result of evaluating an expression, e.g., if the expression contains an assignment operation.

Strict functional language: A function language adopting applicative-order evaluation.

Type inference: A process in which the compiler determines the types of objects in a program without the programmer having to declare them explicitly.

Further Information

There are several textbooks that provide an overview of the development and use of functional programming languages. Among these are Bird and Wadler [1988], Paulson [1991], Sussman and Abelson [1985], and Ullman [1994]. The reader is also referred to [Hudak 1989], an excellent survey paper. Peyton Jones [1987] provides a description of how functional programming languages are implemented.

There are a number of professional journals that include papers on functional languages. The more eminent of these are *The Journal of Functional Programming*, *ACM Transactions on Programming Languages and Systems*, and *The Journal of LISP and Symbolic Computation*. Furthermore, recent results in functional programming research can be found in the proceedings of several important annual symposia, including The ACM Symposium on Principles of Programming Languages, The International Conference on Functional Programming, and The ACM Symposium on Programming Language Design and Implementation.

93.1 Introduction

Logic programming (LP) is a language paradigm based on logic. Its constructs are Boolean *implications* (e.g., q implies p meaning that p is true if q is true), compositions using the Boolean operators *and* (called conjunctions) and *or* (called disjunctions). LP can also be viewed as a procedural language in which the procedures are actually Boolean functions, the result of a program always being either true or false.

In the case of implications, a major restriction applies: when q implies p , written $p \text{ :- } q$, then q can consist of conjunctions but p has to be a singleton, representing the (sole) Boolean function being defined. The Boolean operator *not* is disallowed but there is a similar construct that may be used in certain cases.

The Boolean functions in LP may contain parameters, and the parameter matching mechanism is called **unification**. This type of general pattern matching implies, for example, that a variable representing a formal parameter may be bound to another variable, or even to a complex data structure, representing an actual parameter (and vice versa). When an LP program yields a *yes* answer, the bindings of the variables are displayed, indicating that those bindings make the program logically correct and provide a solution to the problem expressed as a logic program.

An important recent extension of LP is **constraint LP** (CLP). In this extension, unification can be replaced or complemented by other forms of constraints, depending on the domains of the variables involved. For example, in CLP a relationship such as $X > Y$ can be expressed even in the case where X and Y are unbound real variables. As in LP, a CLP program yields answers expressing that the resulting constraints (e.g., $Z < Y + 4$) must be satisfied for the program to be logically correct.

This chapter includes sections describing the main aspects of LP and CLP. It includes examples, historical remarks, theoretical foundations, implementation techniques, metalevel interpretation, and concludes with the most recent proposed extensions to this language paradigm.

93.2 An Introductory Example

Let us consider a simple program written in PROLOG, the main representative among logic programming languages. The program's objective is to check if a date given by the three parameters: *Month* (a string), *Day*, and *Year* (integers) is valid. For example, *date* (*oct*, 15, 1996) is valid whereas *date* (*june*, 31, 1921) is not. The program can be expressed as:

```
date (Month, Day, Year) :- member (Month, [jan, march, may, july, aug, oct, dec]),
                             comprised (Day, 1,31).
date (Month, Day, Year) :- member (Month, [april, june, oct, sept, nov]),
                             comprised (Day, 1,30).
date (feb, Day, Year) :- leap (Year), comprised (Day, 1,29).
date (feb, Day, Year) :- comprised (Day, 1,28).
comprised (Day, Start, End) :- Day >=Start, Day =<End.
leap (Year) :- (Year/4) × 4 = Year.
```

The variables in the preceding program start with a capital letter, e.g., *Month*; in this simple example the constants either start with small case letters (strings) or are integers. The symbol *:-* can be read as is defined by, and it separates the procedure heading from its body, which consists of calls to other procedures. More precisely, it is convenient to view every procedure as a Boolean function yielding *true* or *false*. The body of such a function is made up of conjunctions of calls to functions. Therefore, a comma separating the calls on the right-hand side correspond to the Boolean operator *and*.

The following remarks also apply to the program. There are multiple definitions of *date*, each of which tests for the corresponding month and the compatible number of days. Therefore, the program is non-deterministic in the sense that several possibilities have to be considered either one at a time, or in parallel. In many cases there might be several solutions to a given program. Also note that the right-hand side of a rule could be empty. In that case, the rule indicates that the left-hand side is always true.

Let us for the time being assume that *member* (*Element*, *List*) is a built-in function testing if an *Element* is a member of a *List*. The Boolean function *leap* tests if its parameter is a multiple of 4. One could also add a function *year* (*Year*), which would test if an integer defined by *Year* is positive. Notice that the ordering of the statements in this particular version of the program is important, since a leap year is tested before a nonleap year. Ideally, pure PROLOG programs should be declarative; from a syntactic point of view, that

means that the order of the rules and the order of the calls on the right-hand sides should not matter. A new version of the program satisfying this criteria is one in which the Boolean function *nonleap* (*Year*) :- (*Year*/4) × 4 = *Year* is called in the definition applicable to the month of February, in the case of a nonleap year.

The preceding program is used with queries (equivalent to main programs) to test the validity of given dates. The answers are either *yes* or *no*. Note that in PROLOG one is allowed to have queries containing variables. In the present example, the query *date* (*X*, 31, 1996) yields as results the successive strings that the variable *X* is bound to for the months that have 31 days. More specifically, the results are:

```
yes X = jan, More?
yes X = march, More?
...
Yes X = dec, More?
No.
```

Similarly, the query *date* (*X*, 29, 1996) yields all the months in a year. Note that the built-in functions such as =< and >= require that their arguments be ground; that is, they cannot contain unbound variables. This is satisfied by the query *date* (*X*, 31, 1996). However, a call *date* (*feb*, *Y*, 1996) entails a problem that provides insight into the desirability of extending PROLOG to handle constraints such as it is done in PROLOG IV. The last query fails in standard PROLOG because the variable *Y* remains unbound. The right answer as provided by a constraint LP processor consists of the two constraints:

```
Yes Y >= 1, Y < 29, More?
No.
```

Similarly, the correct answer to the query *date* (*feb*, *Y*, *Z*) submitted to a CLP processor should yield two pairs of constraints corresponding to leap and nonleap years represented by *Z*. These results are obtained by keeping lists of satisfiable constraints and triggering a failure when the constraints become unsatisfiable. This failure may entail exploring the remaining nondeterministic possibilities.

It is now appropriate to present the recursive Boolean function *member*. It has two parameters: an *Element* and a *List*; the function succeeds if the *Element* appears in the *List*. Lists are represented using the constructor *cons* as in functional languages. This means that a list [*a*, *b*] can be represented by:

$$\text{cons}(a, \text{cons}(b, \text{nil}))$$

Note that the *cons* in the preceding representation is simply any user-selected identifier describing a data structure (or record) consisting of two fields: (1) a string and (2) a pointer to another such record or to *nil*. In the case of lists there are special builtin features such as [*a*, *b*] simplifying their description. The program for *member* consists of two rules:

```
member(X, cons(X, T)).
member(X, cons(Y, T)) :- X /= Y, member(X, T).
```

The first rule states that if the head of a list contains the element *X*, then *member* succeeds. The second rule uses recursion to inspect the remaining elements of the list. Note that the query *member* (*X*, *cons* (*a*, *cons*(*b*, *nil*)), equivalent to *member* (*X*, [*a*, *b*]), provides two solutions: namely, *X* = *a* or *X* = *b*. It should be obvious that *member* (*Y*, [*a*, *a*]) also yields two (identical) solutions.

Finally, notice that *member* can search for more complex data structures. For example, *member* (*member* (*a*, *Y*), *Z*) succeeds if the list *Z* contains an element such as *member* (*a*, *U*); if so, the variable *Y* is bound to the variable *U*. The reader should consider the embedded term *member* as the identifier of a record or data structure having two fields. In contrast, the first identifier *member* represents a Boolean function having two parameters. This example illustrates that, in PROLOG, program and data have the same form.

An inquisitive reader will remark that *member* can also be used to place elements in a list if they are not already present in that list. A clue in understanding this property is that the query *member* (*a*, *Z*) will bind

Z to a record $cons(a, W)$ in which W is a new unbound variable created by the PROLOG processor when applying the first rule defining the Boolean function *member*.

93.3 Features of Logic Programming Languages

Summarized next are some of the features whose combination renders PROLOG unique among languages:

1. Procedures may contain parameters that are both input and output.
2. Procedures may return results containing unbound variables.
3. **Backtracking** is built in, therefore allowing the determination of multiple solutions to a given problem.
4. General pattern-matching capabilities operate in conjunction with a goal-seeking search mechanism.
5. Program and data are presented in similar forms.

The preceding listing of the features of PROLOG does not fully convey the subjective advantages of the language. There are at least three such advantages:

1. Having its foundations in logic, PROLOG encourages the programmer to describe problems in a logical manner that facilitates checking for correctness and, consequently, reduces the debugging effort.
2. The algorithms needed to interpret PROLOG programs are particularly amenable to parallel processing.
3. The conciseness of PROLOG programs, with the resulting decrease in development time, makes it an ideal language for prototyping.

Another important characteristic of PROLOG that deserves extension, and is now being extended, is the ability to postpone variable bindings as much as is deemed necessary (lazy evaluation). Failure and backtracking are triggered only when the interpreter is confronted with a logically unsatisfiable set of constraints. In this respect, PROLOG's notion of variables approaches that used in mathematics.

The price to be paid for the advantages offered by the language amounts to the increasing demands for larger memories and faster central processing units (CPUs). The history of programming language evolution has demonstrated that, with the consistent trend toward less expensive and faster computers with larger memories, this price becomes not only acceptable but also advantageous because the savings achieved by program conciseness and by a reduced programming effort largely compensate for the space and execution time overheads. Furthermore, the quest for increased efficiency of PROLOG programs encourages new and important research in the areas of optimization and parallelism.

93.4 Historical Remarks

The birth of logic programming (LP) can be viewed as the confluence of two different research endeavors: one in artificial or natural language processing, and the other in automatic theorem proving. These endeavors contributed to the genesis of the PROLOG language, the principal representative of LP.

Alain Colmerauer, assisted by Philippe Roussel, is credited as the originator of PROLOG, a language that was first developed in the early 1970s and continues to be substantially extended. Colmerauer's contributions stemmed from his interest in language processing using theorem proving techniques. Robert Kowalski was also a major contributor to the development of LP. Kowalski had an interest in logic and theorem proving [Cohen 1988, Bergin 1996]. In their collaboration, Kowalski and Colmerauer became interested in problem solving and automated reasoning using resolution theorem proving.

Kowalski's main research was based on the work of Alan Robinson [1965]. Robinson had the foresight to distinguish the importance of two components in automatic theorem proving: a single inference rule called *resolution* and the testing for equality of trees called *unification*.

Theorems to be proved using Robinson's approach are placed in a special form consisting of conjunctions of *clauses*. Clauses are disjunctions of positive or negated literals; in the case of Boolean algebra (propositional calculus), the literals correspond to variables. In the more general case of the predicate calculus, literals correspond to a potentially infinite number of Boolean variables, one for each combination of values that the literal has as parameters. A *Horn clause* is one containing (at most) one positive literal; all of the others (if any) are negated.

According to the informal description in the introductory example, a Horn clause corresponds to the definition and body of a Boolean function. The positive literal is the left-hand side of a rule (called *Head*); the negative literals appear on the right-hand side of the rule (called *Body*). A non-Horn clause is one in which (logical) negations can appear qualifying a call in the *Body*. An example of a Horn clause is:

$$\text{date}(\text{feb}, \text{Day}, \text{Year}) \text{ :- leap}(\text{Year}), \text{comprised}(\text{Day}, 1, 29).$$

because it is equivalent to:

$$\text{leap}(\text{Year}) \text{ and } \text{comprised}(\text{Day}, 1, 29) \text{ implies } \text{date}(\text{feb}, \text{Day}, \text{Year})$$

or

$$\text{date}(\text{feb}, \text{Day}, \text{Year}) \text{ or not}(\text{leap}(\text{Year})) \text{ or not}(\text{comprised}(\text{Day}, 1, 29))$$

If one wished to express the clause

$$\text{date}(\text{feb}, \text{Day}, \text{Year}) \text{ :- not } \text{leap}(\text{Year}), \text{comprised}(\text{Day}, 1, 28).$$

in which the *not* is the logical Boolean operation, the preceding example would be logically equivalent to:

$$\text{date}(\text{feb}, \text{Day}, \text{Year}) \text{ and } \text{leap}(\text{Year}) \text{ or } \text{comprised}(\text{Day}, 1, 28)$$

which is not a Horn clause because it has two (positive) elements in the head (and there is no procedural equivalent to it).

Kowalski concentrated his research on reducing the search space in resolution-based theorem proving. With this purpose, he developed with Kuehner a variant of the linear resolution algorithm called SL resolution (for linear resolution with selection function [Kowalski and Kuehner 1970]). Kowalski's view is that, from the automatic theorem-proving perspective, this work paved the way for the development of PROLOG. Having this more efficient (but still general) predicate calculus theorem prover available to them, the Marseilles and Edinburgh groups started using it to experiment with problem-solving tasks. To further increase the efficiency of their prover, the Marseilles group resorted to daring simplifications that would be inadmissible to logicians. These audacious attempts turned out to open new vistas for the future of LP.

Several formulations for solving a given problem were attempted. Almost invariably, the formulations that happened to be written in Horn clause form turned out to be much more natural than those that used non-Horn clauses. A case in which the Horn clause formulation was particularly effective occurred in parsing strings defined by grammar rules. Recall that context-free grammars have a single nonterminal being defined on the left-hand side of each of its rules, therefore establishing a strong similarity with Horn clauses.

The SL inference mechanism applicable to a slight variant of Horn clauses led to the present PROLOG inference mechanism: *selective linear definite* (SLD) clause resolution. The word *definite* refers to Horn clauses with exactly one positive literal, whereas general Horn clauses may contain entirely negative clauses. (Because the term "Horn clause" is more widely used than definite clause, the former is often used to denote the latter.)

As a final historical note one should mention that LP gained renewed impetus by its adoption as the language paradigm for the Japanese Fifth Generation Program. PROLOG and, in particular, its CLP extensions now count on a significant number of loyal and enthusiastic users.

93.5 Resolution and Unification

Resolution and unification appear in different guises in various algorithms used in computer science. This section first describes these two components separately and then their combination as it is used in LP. In doing so it is useful to consider first the case of the propositional calculus (Boolean algebra) in which unification is immaterial. It is well known that there exist algorithms that can always decide if a system of Boolean formulas is satisfiable or not, albeit with exponential complexity.

In terms of the informal example considered in the introduction, one can view resolution as a (nondeterministic) call of a user-defined Boolean function. Unification is the general operation of matching the formal and actual parameters of a call. Consequently, unification does not occur in the case of parameterless Boolean functions.

The *predicate calculus* includes the quantifiers \forall and \exists ; it can be viewed as a general case of the propositional calculus for which each predicate variable (a literal) can represent a potentially infinite number of Boolean variables. Unification is only used in this latter context. Theorem-proving algorithms for the predicate calculus are not guaranteed to provide a yes-or-no answer because they may not terminate.

93.5.1 Resolution

In the propositional calculus, a simple form of resolution is expressed by the inference rule:

$$\begin{aligned} &\text{if } a \rightarrow b \text{ and } b \rightarrow c \text{ then } a \rightarrow c, \text{ or} \\ &(\neg a \vee b) \wedge (\neg b \vee c) \rightarrow (\neg a \vee c) \end{aligned}$$

Recall that *a implies b* is equivalent to *not a or b*. The final disjunction $\neg a \vee c$ is called a *resolvent*. In particular, resolving $a \wedge \neg a$ implies the empty clause (i.e., falsity).

To better understand the meaning of the empty clause, consider the implication $a \rightarrow a$, which is equivalent to *(not a) or a*. This expression is always true; therefore, its negation *not ((not a) or a)* equivalent to *(a and (not a))* is always false. If a Boolean expression is always *true*, its negation is always *false*. Resolution theorem proving consists of showing that if the expression is always true, its negation results in contradictions of the type *(a and (not a))*, which is always false. The empty clause is simply the resolvent of *(a and (not a))*.

Observe the similarity between resolution and the elimination of variables in algebra, for example:

$$a + b = 3 \text{ and } -b + c = 5 \text{ imply } a + c = 8$$

Another intriguing example occurs in matching a procedure definition with its call. Consider, for example,

```
procedure b; a
...
call b; c
```

in which *a* is the body of *b*, and *c* is the code to be executed after the call of *b*. If one views the definition of *b* and its call as complementary, a (pseudo)resolution yields *a; c* in which concatenation is noncommutative and the resolution corresponds to replacing a procedure call by its body. Actually, the last example provides an intuitive procedural view of resolution as used in PROLOG.

In the case of pure PROLOG programs, only Horn clauses are allowed. For example, if *a, b, c, d*, and *f* are Boolean variables (literals), then

$$b \wedge c \wedge d \rightarrow a \quad \text{and} \quad f$$

are readily transformed in Horn clauses because they correspond, respectively, to

$$a \vee \neg b \vee \neg c \vee \neg d \quad \text{and} \quad f$$

where the clause f is called unit clause or a fact. The preceding example is written in PROLOG as

$$a :- b, c, d. \quad \text{and} \quad f.$$

where the symbols $:-$ and “,” correspond to the logical connectors *only if* and *and*. They are read as: a is true only if b and c and d are true. The above conjunction also requires that f be true; equivalently $b \wedge c \wedge d \rightarrow a$ and f are true.

The resolution mechanism applicable to Horn clauses takes as input a conjunction of Horn clauses $H = h_1 \wedge h_2 \wedge \dots \wedge h_n$, and a query Q , which is the negation of a theorem to be proved. Q consists of the negation of a conjunction of positive literals or, equivalently, a disjunction of negated literals. Therefore, a query is itself in a Horn clause form in which the head is empty.

A theorem is proved by contradiction, namely, the goal is to prove that $H \wedge Q$ is inconsistent, implying that the result of successive resolutions involving the negated literals of Q inevitably — in the case of the propositional calculus — leads to falsity (i.e., the empty clause). In other words, if H implies the nonnegated Q is always true, then H and the negated Q is always false.

Consider for example the query *date* (*oct*, 15, 1996) in our introductory example. Its negation is *not date* (*oct*, 15, 1996). This resolves with the first rule yielding the bindings *Month* = *oct*, *Day* = 15, *Year* = 1996. The resultant is the disjunction *not member* (*oct*, [*jan*, *march*, *may*, *july*, *aug*, *oct*., *dec*]) or *not comprised* (15, 1, 31).

Although not elaborated here, the reader can easily find out that the successive resolutions using the definition of *member* will fail because *oct* is a member of the list of months containing 31 days. Similarly, the day 15 is comprised between 1 and 31. Therefore, the empty (falsity) clause will be reached for both disjuncts of the resultant.

In what follows, the resolution inference mechanism is applied to Horn clauses representing a PROLOG program. One concrete syntax for PROLOG rules is given by:

$$\begin{aligned} \langle \text{rule} \rangle &::= \langle \text{clause} \rangle . | \langle \text{unit clause} \rangle . \\ \langle \text{clause} \rangle &::= \langle \text{head} \rangle :- \langle \text{tail} \rangle \\ \langle \text{head} \rangle &::= \langle \text{literal} \rangle \\ \langle \text{tail} \rangle &::= \langle \text{literal} \rangle \{ , \langle \text{literal} \rangle \} \\ \langle \text{unit clause} \rangle &::= \langle \text{literal} \rangle \end{aligned}$$

where the braces $\{ \}$ denote any number of repetitions (including none) of the sequence enclosed by the brackets $\langle \rangle$. First consider the simplest case, where a *literal* is a single letter. For example, consider the following PROLOG program in which rules are numbered for future reference:

1. $a :- b, c, d.$
2. $a :- e, f.$
3. $b :- f.$
4. $e.$
5. $f.$
6. $a :- f.$

In the first rule, a is the $\langle \text{head} \rangle$, and b, c, d is the $\langle \text{tail} \rangle$, also called the *body*. The fourth and fifth rules are unit clauses; that is, the body is empty. A query Q is syntactically equivalent to a $\langle \text{tail} \rangle$. For example, $a, e.$ is a query and it corresponds to the Horn clause $\neg a \vee \neg e$. The result of querying the program is one (or multiple) *yes* or a single *no* answer indicating the success or failure of the query. In this particular example, the query $a, e.$ yields two *yes* answers. Note that a is defined by three rules; the second and the third yield the two solutions; the first fails because c is undefined. The successful sequence of the list of goals is

- Solution 1: $a, e \Rightarrow e, f, e \Rightarrow f, e \Rightarrow e \Rightarrow \text{nil};$
 Solution 2: $a, e \Rightarrow f, e \Rightarrow e \Rightarrow \text{nil}.$

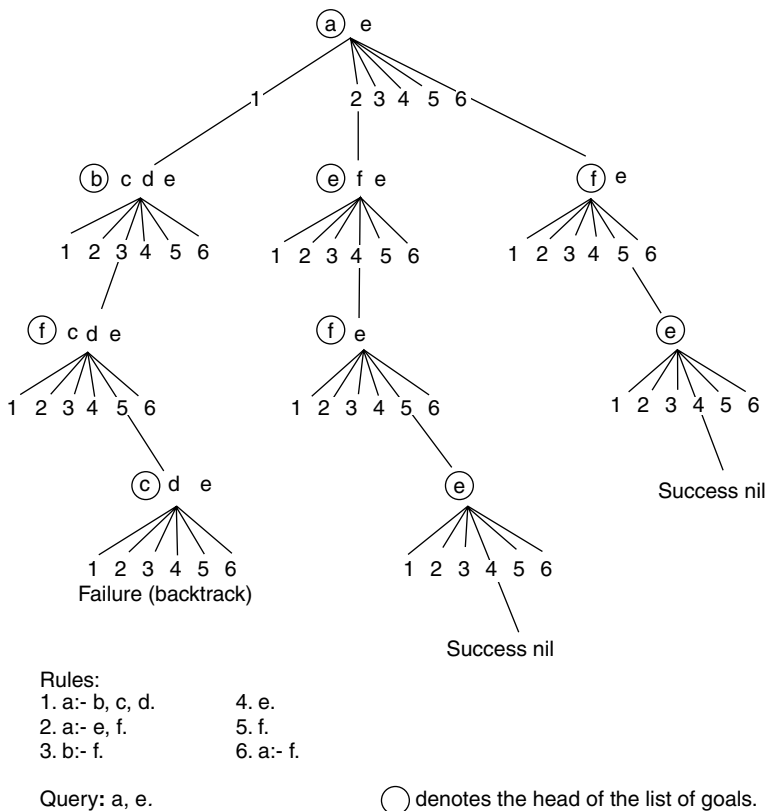

FIGURE 93.1 Tree of choices.

Let us follow in detail the development of the second solution. The negated query *not a or not e* resolves with the sixth rule *a or not f*, yielding the resolvent *not f or not e*. Now the last expression is resolved with the *f* in the fifth rule, yielding *not e* as the resolvent. Finally, *not e* is resolved with the *e* in the fourth rule, yielding the empty clause, which implies the falsity of the negation of the query, using the program rules.

The entire search space is shown in Figure 93.1 in the form of a tree. In nondeterministic algorithms, that tree is called the tree of choices. Its leaves are nodes representing failures or successes. The internal nodes are labeled with the list of goals that remain to be satisfied. Note that if the tree of choices is finite, the order of the goals in the list of goals is irrelevant insofar as the presence and number of solutions are concerned. Figure 93.2 shows a proof tree for the first solution of the example. The proof tree is an *and* tree depicting how the proof has been achieved.

There are three ways of interpreting the semantics of PROLOG rules and queries. The first is based on logic, in this particular case on Boolean algebra. The literals are Boolean variables, and the rules express formulas. The PROLOG program is viewed as the conjunction of formulas it defines. The query *Q* succeeds if it can be implied from the program. In a second (called procedural) interpretation of a PROLOG rule, it is assumed that a *<literal>* is a goal to be satisfied. For example, the first rule states that:

goal a can be satisfied if goals b, c, and d can be satisfied.

The unit clause states that the defined goal can be satisfied. The program defines a conjunction of goals to be satisfied. The query succeeds if the goals can be satisfied using the rules of the program. Finally, a third interpretation is based on the similarity between PROLOG rules and context-free grammar rules. A PROLOG program is associated with a context-free grammar in which a *<literal>* is a nonterminal and a *<rule>* corresponds to a grammar rule in which the *<head>* rewrites into the *<tail>*; a unit

FIGURE 93.2 Proof tree.

clause is viewed as a grammar rule in which a nonterminal rewrites into the empty symbol ϵ . Under this interpretation, a query succeeds if it can be rewritten into the empty string.

Although the preceding three interpretations are all helpful in explaining the semantics of this simplified version of PROLOG, the logic interpretation is the most widely used among theoreticians, and the procedural by language designers and implementors.

The algorithms that test if a query Q can be derived from a Horn clause program P can be classified in various manners. An analogy with parsing algorithms is relevant: P corresponds to a grammar G , and Q corresponds to the string (of nonterminals) to be parsed (i.e., the sequence of nonterminals that may be rewritten into the empty string using G). *Backward-chaining* theorem provers correspond to top-down parsers and are by far the preferred approach presently used in logic programming. *Forward-chaining* provers correspond to bottom-up parsers. Hybrid algorithms have also been proposed.

In a top-down algorithm, the list of goals in a query is examined from left to right and the corresponding (recursive) procedures are successively called, the equivalent of resolution, until the list of goals becomes empty. Note that the algorithm is essentially nondeterministic because there are usually several choices for the goals (see rules 1 and 2). Another nondeterministic choice occurs when selecting the (next) element of the list of goals to be considered after processing a goal.

Notice that if one had a program consisting of the sole rule $a :- a$. and the query a , the top-down approach would not terminate. The program states that either a or $\neg a$ is true. Because the query does not specify a , it could be either true or false. A semantically correct interpreter should provide the following constraints as answers $a = true$ or $a = false$. PROLOG programmers have learned to live with these unpalatable characteristics of top-down provers.

Contrary to what usually happens in parsing, bottom-up provers can be very inefficient unless the algorithm contains selectivity features that prevent the inspection of dead-end paths. In the case of database applications, the bottom-up approach using magic sets has yielded interesting results [Minker 1987].

Also note the correspondence between nondeterministic grammars and nondeterministic PROLOG programs. In many applications the programs can be made deterministic and therefore more efficient. However, ambiguous grammars that correspond to programs having multiple solutions are also useful and therefore nondeterminism has its advantages.

93.5.2 Unification

The operation of unification is akin to that of pattern matching. Robinson's unification algorithm brings rigor to the notion of pattern matching and it has a deep meaning: it replaces a set of fairly intricate predicate calculus axioms specifying the equality of trees by an efficient algorithm, which is easily implementable in a computer. As mentioned earlier, unification can be viewed as a very general matching of actual and formal parameters.

From the logic point of view, unification is used in theorem proving to equate terms that usually result from the elimination of existential quantifiers when placing a predicate calculus formula in clausal form. For example:

$$\forall X \exists Y \text{ such that } p(X, Y) \text{ is always true}$$

is replaced by

$$\forall X p(X, g(X))$$

where $g(x)$ is the Skolem function for y (sometimes referred to as an uninterpreted function symbol). The role of unification is to test the equality of literals containing Skolem functions and, in so doing, bind values to variables.

Consider, for example, the statement “for all positive integer variables X there is always a variable Y representing the successor of X .” The predicate p expressing this statement is $p(X, s(X)) :- integer(X)$, where $s(X)$ is the Skolem function representing Y , the successor of X . This representation is commonly used to specify positive integers from a theoretical perspective. [It is called a Peano representation of integers (e.g., $s(s(0))$ represents the integer 2).]

To show the effect of unification, the definition of a literal in the previous subsection on resolution is now generalized to encompass labeled tree structures.

$$\begin{aligned} \langle literal \rangle &::= \langle composite \rangle \\ \langle composite \rangle &::= \langle functor \rangle (\langle term \rangle \{, \langle term \rangle \}) \mid \langle functor \rangle \\ \langle functor \rangle &::= \langle lower\ case\ identifiers \rangle \\ \langle term \rangle &::= \langle constant \rangle \mid \langle variable \rangle \mid \langle composite \rangle \\ \langle constant \rangle &::= \langle integers\ and\ lower\ case\ identifiers \rangle \\ \langle variable \rangle &::= \langle identifiers\ starting\ with\ an\ upper\ case\ letter\ or_ \rangle \end{aligned}$$

Examples of terms are *constant*, *Var*, 319, *line*(*point*($X, 3$), *point*($4, 3$)). It is usual to refer to a single rule in a PROLOG program as a clause. A PROLOG procedure (or predicate) is defined as the set of rules whose head has the same $\langle functor \rangle$ and arity. Unification tests whether two terms $T1$ and $T2$ can be matched by binding some of the variables in $T1$ and $T2$. The simplest algorithm uses the rules summarized in Table 93.1 to match the terms. If both terms are composite and have the same $\langle functor \rangle$, it recurses on their components. This algorithm only binds variables if it is *absolutely necessary*, so there may be variables that remain unbound. This property is referred to as the most general unifier (mgu).

One can write a recursive function *unify* which, given two terms, tests for the result of unification using the contents of Table 93.1. The unification of the two terms $f(X, g(Y), T)$ and $f(f(a, b), g(g(a, c), Z))$

TABLE 93.1 Summary of Tests for the Unification of Two Terms

Terms 1 ↓, 2 →	$\langle constant \rangle$ C2	$\langle variable \rangle$ X2	$\langle composite \rangle$ T2
$\langle constant \rangle$	<i>succeed if</i>	<i>succeed with</i>	<i>fail</i>
C1	$C1 = C2$	$X2 := C1$	
$\langle variable \rangle$	<i>succeed with</i>	<i>succeed with</i>	<i>succeed with</i>
X1	$X1 := C2$	$X1 := X2$	$X1 := T2$
$\langle composite \rangle$	<i>fail</i>	<i>succeed with</i>	<i>succeed if</i>
T1		$X2 := T1$	(1) <i>T1 and T2 have the same functor and arity</i> (2) <i>the matching of corresponding children succeeds</i>

succeeds with the following bindings $X = f(a, b)$, $Y = g(a, c)$, and $T = Z$. Note that if one had $g(Y, c)$ instead of $g(a, c)$ in the second term, the binding would have been $Y = g(Y, c)$.

PROLOG interpreters would usually carry out this circular binding, but would soon get into difficulties because most implementations of the described unification algorithm cannot handle circular structures (called **infinite trees**). Manipulating these structures (e.g., printing, copying) would result in an infinite loop unless the so-called **occur check** were incorporated to test for circularity. This is an expensive test: unification is linear with the size of the terms unified, and incorporation of the occur check renders unification quadratic.

There are versions of the unification algorithm that use a representation called *solved form*. Essentially, new variables are created whenever necessary to define terms; for example, the system:

$$X1 = f(X2, g(X3, X2)) \quad X5 = g(X4, X2)$$

A solved form is immediately known to be satisfiable because $X2$, $X3$, and $X4$ can be bound to any terms formed by using the function symbols f and g and again replacing (*ad infinitum*) their variable arguments by the functions f and g . This is called an element of the **Herbrand universe** for the given set of terms. The solved form version of the unification algorithm is presented by Lassez in Minker [1987].

To further clarify the notion of solved forms, consider the equation in the domain of reals specified by the single constraint $X + Y = 5$. This is equivalent to $X = 5 - Y$, which is in solved form and satisfiable for any real value of Y . Basically a constraint in solved form contains definitions in terms of free variables, i.e., those that are not constrained. This form is very useful when unification is extended to be applicable to domains other than trees. For example, linear equations may be expressed in solved form.

93.5.3 Combining Resolution and Unification

Consider now general clauses in which the literals contain arguments which are represented by terms. The result of resolving

$$p(\dots) \quad \vee \quad r(\dots)$$

with

$$\neg p(\dots) \quad \vee \quad s(\dots)$$

is

$$r(\dots) \quad \vee \quad s(\dots)$$

if and only if the arguments of p and $\neg p$ are unifiable and the resulting variables are substituted in the corresponding arguments of r and s .

Using programming language terminology, the combination of resolution and unification corresponds to a Boolean function call in which a variable in the head of a rule is matched (i.e., unified) with its corresponding actual parameter; once this is done, the value to which the variable is bound replaces the instances of that variable appearing in the body. Note that a variable can be bound to another variable or to a complex term. Remark also that when unification fails, another head of a rule has to be tried and so on. For example, consider the query $p(a)$ and the program:

$$\begin{aligned} p(b). \\ p(X) : - q(X). \\ q(a). \end{aligned}$$

The first unification of the query $p(a)$ with $p(b)$ fails. The second attempt binds X to a starting a search for $q(a)$ which succeeds. Had the query been $p(Y)$, the two solutions would be $Y = b$ or $Y = a$. The first solution is a consequence of the unit clause $p(b)$, the second follows from binding Y to a (new) variable

X in the second clause. A search is then made for $q(X)$, which succeeds with the last clause, therefore binding both Y and X to a .

From a logical point of view, when the result of a resolution is the empty clause (corresponding to the head of a rule with an empty body) and no more literals remain to be examined, the list of bindings is presented as the answer, that is, the bindings (**constraints**) that result from proving that the query is deducible from the program.

93.6 Procedural Interpretation: Examples

It is worthwhile to first understand the importance of the procedure *append* as used in symbolic functional languages. In PROLOG the word procedure is a commonly used misnomer because it always corresponds to a Boolean function, as mentioned in the introductory example; *append* is often used to concatenate two lists. Because one has to avoid destructive assignments, which have very complex semantic meaning, *append* resorts to copying the first list to be appended and making its last element point to the second list. This preserves the original first list. It should be kept in mind that the avoidance of a destructive assignment forces one to produce results that are *constructed* from a given data using a LISP-like *cons*. Notice that LP also avoids destructive assignment by having variables bound only once during unification.

This section first demonstrates the transformation of a functional specification of *append* into its PROLOG counterpart corresponding to the previous clauses. Examples of inventive usage of *append* are then presented to further illustrate the procedural interpretation of logic programs. Consider the LISP-like function *append* that concatenates two lists, $L1$ and $L2$:

```
function append( $L1, L2: pLIST$ ):  $pLIST$ ;
    if  $L1 = nil$  then append: =  $L2$ 
        else append: = cons (head ( $L1$ ), append (tail ( $L1$ ),  $L2$ ));
```

In the preceding display, $L1$ and $L2$ are pointers to lists; a list is a record containing the two fields *head* and *tail*, which themselves contain pointers to other lists or to atoms. The tail must point to a list or to the special atom *nil*. The constructor *cons* (H, T) creates the list whose *head* and *tail* are, respectively, H and T .

The function *append* can be rewritten into a procedure having an explicit third parameter $L3$ that will contain the desired result. The local variable T is used to store intermediate results.

```
procedure append ( $L1, L2: pLIST$ : var  $L3: pLIST$ );
    begin local  $T: pLIST$ ;
        if  $L1 = nil$  then  $L3 := L2$ 
            else begin append(tail ( $L1$ ),  $L2, T$ );  $L3 := cons$ (head( $L1$ ),  $T$ ) end
        end
```

The former procedure can be transformed into a Boolean function that, in addition to building $L3$, checks if *append* produces the correct result.

```
function append( $L1, L2: pLIST$ : var  $L3: pLIST$ ): Boolean;
    begin local  $H1, T1, T: pLIST$ ;
        if  $L1 = nil$  then begin  $L3 := L2$ ; append := true end
            else if {There exists an  $H1$  and a  $T1$  such that
                 $H1 = head(L1)$  and  $T1 = tail(L1)$ }
                then begin append := append( $T1, L2, T$ );  $L3 := cons$ ( $H1, T$ ) end
                else append := false
            end
```

The Boolean in the conditional surrounded by braces has been presented informally, but it could actually have been programmed in detail. Note that the assignments in the preceding program are executed at most once for each recursive call. The function returns *false* if $L1$ is not a list (e.g., if $L1 = cons(a, b)$ for some atom $b \neq nil$).

One can now transform the last function into a PROLOG-like counterpart in which rules of assignments and conditionals are subsumed by unification and specified by the equality sign. The statement $E1 = E2$ succeeds if $E1$ and $E2$ can be matched. In addition, some of the variables in $E1$ and $E2$ may be bound if necessary.

$$\begin{aligned} &append(L1, L2, L3) \text{ is true if } L1 = nil \text{ and } L3 = L2 \\ &\quad \text{otherwise} \\ &append(L1, L2, L3) \text{ is true} \\ &\quad \text{if } L1 = cons(H1, T1) \text{ and } append(T1, L2, T) \text{ and } L3 = cons(H1, T) \\ &\quad \text{otherwise } append \text{ is false.} \end{aligned}$$

The reader can now compare the preceding results with the previous description of the subset of PROLOG. This comparison yields the PROLOG program

$$\begin{aligned} &append(L1, L2, L3) :- L1 = nil, L3 = L2. \\ &append(L1, L2, L3) :- L1 = cons(H1, T1), append(T1, L2, T), L3 = cons(H1, T). \end{aligned}$$

This version is particularly significant because it clearly separates resolution from unification. In this case, the equality sign is the operator that commands a unification between its left and right operands. This could also be done using the unit clause $unify(X, X)$ and substituting $L1 = nil$ by $unify(L1, nil)$, and so on. Replacing $L1$ and $L3$ with their respective values on the right-hand side of a clause, one obtains:

$$\begin{aligned} &append(nil, L2, L2). \\ &append(cons(H1, T1), L2, cons(H1, T)) :- append(T1, L2, T). \end{aligned}$$

The explicit calls to *unify* have now been replaced by implicit calls that will be triggered by the PROLOG interpreter when it tries to match a goal with the head of a rule. Notice that a *<literal>* now becomes a function name followed by a list of parameters, each of which is syntactically similar to a *<literal>*. In the predicate calculus, the preceding program corresponds to:

$$\begin{aligned} &\forall L2 \text{ } append(nil, L2, L2). \\ &\forall H1, T1, L2, T \text{ } append(cons(H1, T1), L2, cons(H1, T)) \vee \neg append(T1, L2, T) \end{aligned}$$

A word of caution about types is in order. The preceding version of *append*, would produce a perhaps unwanted result if the list $L2$ is a term, say, $g(a)$. For example, $append(nil, g(a), Z)$ would yield as result $Z = g(a)$. To ensure that this result would not be considered valid, one would have to make explicit the calls to functions that test if the two lists to be appended are indeed lists, namely,

$$\begin{aligned} &is_a_list(nil). \\ &is_a_list(cons(H, T)) :- is_a_list(T). \end{aligned}$$

The Edinburgh PROLOG representation of $cons(H, T)$ is $[H | T]$, and nil is $[]$. The Marseilles counterparts are $H.T$ and nil . In the Edinburgh dialect, *append* is presented by

$$\begin{aligned} &append([], L2, L2). \\ &append([H1 | T1], L2, [H1 | T]) :- append(T1, L2, T). \end{aligned}$$

The query applicable to the program that uses the term *cons* is *append (cons (a, cons (b, nil)), cons (c, nil), Z)* and it yields $Z = cons(a, cons(b, cons(c, nil)))$. In Edinburgh PROLOG, the preceding query is stated as *append ([a, b], [c], Z)*, and the result becomes $Z = [a, b, c]$.

A remarkable difference between the original PASCAL-like version and the PROLOG version of *append* is the ability of the latter to determine (unknown) lists that, when appended, yield a given list as a result. For example, the query *append(X, Y, [a])* yields two solutions: $X = [] Y = [a]$ and $X = [a] Y = []$.

The preceding capability is due to the generality of the search and pattern matching mechanism of PROLOG. An often-asked question is: Is the generality useful? The answer is definitely yes! A few examples will provide supporting evidence. The first is a procedure for determining a list *LLL*, which is the concatenation of *L* with *L* the result itself being again concatenated with *L*:

$$triple(L, LLL) :- append(L, LL, LLL), append(L, L, LL).$$

Note that the first *append* is executed even though *LL* has not yet been bound. This amounts to copying the list *L* and having the variable *LL* as its last element. After the second *append* is finished, *LL* is bound, and the list *LLL* becomes fully known. This property of postponing binding times can be very useful. For example, a dictionary may contain entries whose values are unknown. Identical entries will have values that are bound among themselves. When a value is actually determined, all communally unbound variables are bound to that value.

Another interesting example is *sublist(X, Y)*, which is true when *X* is a sublist of *Y*. Let *U* and *W* be the lists at the left and right of the sublist *X*. Then the program becomes:

$$sublist(X, Y) :- append(Z, W, Y), append(U, X, Z).$$

where the variables represent the sublists indicated as follows:

An additional role for *append* is to simulate the behavior of *member* as used in the introductory example. One could state that *member(X, L) :- append(Start, [X|End], L)*, in which *Start* and *End* are variables representing lists which, when surrounding *X*, produce *L*. This approach is expensive because it may use a quadratic number of *conses*.

A final example is a bubblesort program. The specification of two adjacent elements *A* and *B* in a list *L* is done by a call:

$$append(_, [A, B | _], L)$$

The underscores stand for different variables whose names are irrelevant to the computation, and the notation $[A, B | C]$ stands for $cons(A, cons(B, C))$. The rules to bubblesort then become:

$$bsort(L, S) :- append(U, [A, B | X], L), B < A, append(U, [B, A | X], M), bsort(M, S). \\ bsort(L, L).$$

The first *append* generates all pairs of adjacent elements in *L*. The literal $B < A$ is a built-in predicate that tests whether *B* is lexicographically smaller than *A*. (Note that both *A* and *B* must be bound, otherwise a failure occurs! There will be more discussion of this limitation later.) The second *append* reconstructs the modified list, which becomes the argument in a recursive call to *bsort*. If the first clause is no longer applicable, then all pairs of adjacent elements are in order, and the second clause then provides the desired

result. This version of bubblesort is space and time inefficient because U , the initial segment of the list, is copied twice at each level of recursion. However, the brevity of the program is indicative of the savings that can be accrued in programming and debugging. It should be now clear to the reader that the translation of a functional program into its PROLOG counterpart is easily done but the reverse translation becomes more difficult because the functional program has to simulate nondeterminism and backtracking.

A unique property of some PROLOG programs is their ability to perform inverse computations. For example, if $p(X, Y)$ defines a procedure p taking an input X and producing an output Y , it can (in certain cases) determine which input X produces Y . Therefore, if p is a differentiation program, it can also perform integration. This is easier said than done, because the use of impure features and simplifications may result in operations that are not correctly backtrackable.

The inverse computation of parsing is string generation, and parsers are now available to perform both operations. A compiler carefully written in PROLOG can also be useful in decompiling. The difficulties encountered in doing the inverse operations are frequently due to the use of impure features.

93.7 Impure Features

In the previous sections, the so-called pure features of PROLOG were described, namely, those that conform with the logic interpretation. A few impure features have been added to the language to make its use more practical. (This situation parallels the introduction of *setq*, *rplaca*, and other impure LISP functions.) However, a word of warning is in order. Some of these impure features vary from one implementation to another (O'Keefe [1990] is an excellent reference on extralogical features).

The most prominent of these impure features is the *cut*, represented by an exclamation point. Its purpose is to let the programmer change the search control mechanism embodied by the procedure *solve* in Figure 93.3. Reconsider the example in Section 93.5. Assuming that $a :- b, !, c, d.$, then in the forward mode, b, c , and d would, as before, be placed in the list of goals and matched with heads of clauses in the database. If, however, a goal following the *cut* fails (e.g., c , or d), then no further matching of clauses defining a or b would take place. The *cut* is often used to increase the efficiency of programs and to prevent the consideration of alternate solutions. PROLOG purists avoid the use of cuts.

Another useful predicate is *fail*, which automatically triggers a failure. To implement it, one simply forbids its presence in the database. Other built-in predicates that need to be introduced are the input-output commands *read* and *write*.

Once *cut* and *fail* are available, negation by failure is accomplished by the clauses:

$$\begin{aligned} \text{not}(X) &:- X, !, \text{fail}. \\ \text{not}(X). \end{aligned}$$

which fails if X succeeds and vice versa. It is important to note that this artifice does not always follow the rules of true negation in logic. This version of negation illustrates that a term in the head of a rule

```

procedure solve. L: pLIST/;
begin local i: integer;
  if L  $\neq$  nil
  then
    for i := 1 to n do
      if match(head(Rule[i]), head(L)) then
        solve(append(tail(Rule[i]), tail(L)));
      else write('yes')
    end;
end;

```

FIGURE 93.3 An initial version of the interpreter.

can appear in the body as a call to a function; therefore, in PROLOG, program and data have the same form.

The built-in predicates *assert* and *retract* are used to add or remove a clause from the database; they are often used to simulate assignments. For example, the unit clause *value* (*Variable*, *Value*). can be asserted using bound parameters [e.g., *value*(*Z*, 37)]; it can be subsequently retracted to change the actual *Value*, and then reasserted with a new value. Another use of *assert* and *retract* is associated with the built-in function *setof* that collects the multiple answers of a program and places them in a list.

The assignment is introduced using a built-in binary infix operator such as *is*. For example, Y is $X + 1$ is only valid if X has been bound to a number in which case the right-hand side is evaluated and unified with Y ; otherwise the *is* fails. To have a fully backtrackable addition, one would have to use CLP. Note that $I = I + 1$ is invalid in CLP, as it should be. The equality $Z = X + Y$ in CLP is, of course, valid with some or all variables unbound.

93.8 Constraint Logic Programming

Major extensions of the unification component of PROLOG became very significant and resulted in a new area of LP called constraint logic programming or CLP. It may well have had its roots in Colmerauer's approach in generalizing the unification algorithm by making it capable of determining the satisfiability of equalities and disequalities of infinite trees (these are actually graphs containing special loops.) However, the notion of backpropagation (Sussman and Steele) dates back to the 1970s. In the case of PROLOG, the backtracking mode is triggered only in the case of unsatisfiability of a given unification. A logical extension of this approach is to make similar backtracking decisions for other (built-in) predicates, say, inequalities (i.e., \leq , \geq , ...) in the domain of rationals.

The first CLP example presented here is the classic program for computing Fibonacci series. Before presenting the program, it is helpful to consider the program's PROLOG counterpart (the annotation *is* corresponds to an assignment and it has been discussed in [Section 93.7](#)):

```
fib (0,1).
fib (1,1).
fib (N, R) :- N1 is N - 1,
              fib (N1, R1),
              N2 is N - 2,
              fib (N2, R2),
              R is R1 + R2.
```

The *is* predicate prevents the program from being invertible: the query *fib* (10, X) succeeds in producing $X = 89$ as a result, but the query *fib* (Y , 89) yields an error because N is unbound and the assignment to $N1$ is not performed. Note that if we had placed the predicate $N1 \geq 2$ prior to the first recursive call, the query *fib* (Y , 89) would also lead to an error, because the value of N is unbound and the test of inequality cannot be accomplished by the PROLOG interpreter.

The modified CLP version of the program illustrates the invertibility capabilities of CLP interpreters ($N \geq 2$ is a constraint):

```
fib (0,1).
fib (1,1).
fib (N, R1 + R2) :- N >= 2,
                   fib (N - 1, R1),
                   fib (N - 2, R2).
```

The query $?- fib(10, Fib)$ yields $Fib = 89$, and the query $?- fib(N, 89)$ yields $N = 10$. The latter result is accomplished by solving systems of linear equations and inequations that are generated when an explicit or implicit constraint must be satisfied. In this example, the matching of actual and formal parameters results in equations. Let us perform an initial determination of those equations. The query $?- fib(N, 89)$ matches only the third clause. New variables $R1$ and $R2$ are created as well as the constraint $R1 + R2 = 89$. The further constraint $N \geq 2$ is added to the list of satisfiable constraints, which are now $R1 + R2 = 89$ and $N \geq 2$.

The recursive calls of *fib* generate further constraints that are added to the previous ones. These are $N1 = N - 1$, $N2 = N - 2$, and so forth. Recall that each recursive call is equivalent to a call by value in which new variables are created and new constraints are added (see the section on Implementation).

Therefore, unification is replaced by testing the satisfiability of systems of equations and inequations. A nontrivial implementation problem is how to determine if the constraints are satisfiable, only resorting to expensive general methods such as Gaussian elimination and the simplex method as a last resource.

The second example presented is a sorting program. For the purposes of this presentation, it is unnecessary to provide the code of this procedure [Sterling and Shapiro 1994]; *qsort* (L, S) sorts an input list L by constructing the sorted list S . When L is a list of variables, a PROLOG interpreter would fail because unbound variables cannot be compared using the relational operator \leq . In CLP, the query $?- qsort([X1, X2, X3], S)$ yields as result $S = [X1, X2, X3]$, $X1 \leq X2$, $X2 \leq X3$. When requested to provide all solutions, the interpreter will generate all of the permutations of L as well as the applicable constraints.

Jaffar and Lassez [1987] proved that the theoretical foundations of LP languages (see Section 93.11) remain valid for CLP languages. Several CLP languages are now widely used among LP practitioners. Among them one should mention PROLOG III and IV designed by the Marseilles group, CLP(R) designed in Australia and at IBM, CHIP created by members of the European Research Community, and CLP(BNR) designed in Canada at Bell Northern Research.

The subsequent summary describes the main CLP languages and their domains:

- PROLOG IV: trees, reals, intervals, linear constraints, rationals, finite domains (including Booleans), strings
- CLP(R): trees, linear constraints, floating point arithmetic
- CHIP: trees, linear constraints, floating point arithmetic, finite domains
- CLP(BNR): trees, intervals

The languages considering intervals (defined by their lower and upper bounds) deal with numeric non-linear constraints; symbolic linear constraints are handled by the first three languages. (Additional information about interval constraints is provided in Section 93.14.)

93.9 Recent Developments in CLP (2002)

The single most important development in CLP is its amalgamation with an area of artificial intelligence (AI) that has been consistently explored since the late 1970s, namely, Constraint Satisfaction Problems or CSP. This merging has shown to be very fruitful because the two areas CLP and CSP share many common goals, such as concise declarative statements of combinatorial problems and efficient search strategies. In addition, the new combined areas benefit from research that has been done for decades in the field of operations research (OR).

The following subsections summarize the recent developments under the umbrella of the CLP-CSP paradigms. Highly recommended material has appeared in the textbook by Marriot [1998] and in the survey by Rossi [2000]. Research articles have been published in the proceedings of the conferences on Principles and Practice of Constraint Programming, the most recent one held in 2002 [van Hentenryck 2002].

93.9.1 CSP and CLP

Consider a set of constraints C containing a set of variables x_i ; the x_i 's are defined in their respective domains D_i . Usually, D_i is a finite set of integers. A CSP involves assigning values to the variables so that C is satisfied. CSP is known to be an NP-complete problem (see [Chapter 5](#) of this *Handbook*).

Consider now the cases where the constraints C are (1) unary, that is, they contain a single variable (e.g., $x > 0$), and (2) binary, that is, they contain two variables (e.g., $x^2 + y = 92$) and so forth. It is possible to specify a set of constraints by an undirected graph whose nodes designate each variable and an edge specifies a constraint that is applicable between any two variables. This is often called a constraint network.

The notions of node consistency, arc consistency, and path consistency follow from the above concepts. Furthermore, one can also illustrate the concept of constraint propagation, also called narrowing: it amounts to deleting from a given domain the values that do not satisfy the constraints being specified.

More specifically node consistency consists of considering each node of the constraint graph and its associated unary constraints and performing a narrowing: let $c(x_i)$ be the unary constraint applicable to node x_i ; then the values satisfying $\text{not}(c(x_i))$ are deleted from D_i .

Arc consistency consists of considering each edge, the associated binary constraint, and performing a narrowing. In the binary case, the constraints are $c(x_i, x_j)$ and the values satisfying $\text{not}(c(x_i, x_j))$ are deleted from D_i and D_j .

The above can be generalized to define k -consistency by considering constraints involving k variables (the case $k = 3$ is called path consistency, and $k > 3$ hyper-arc consistency).

One should view node and arc consistency as preprocessing the domains of a set of variables in an attempt to eliminate unfeasible values. How much narrowing can be accomplished depends on the constraint problem being considered. However, if after narrowing there remain no feasible values specified for one or more variables, then there is obviously no solution to the given set of constraints.

It is straightforward to write a CLP program that, given the unary and binary constraints pertaining to a problem, would attempt to reduce the domains of its variables. Then one could check if any of the domains becomes empty thus determining that the given constraints are unfeasible. Note that if there is a single value remaining in a domain, then one could replace the corresponding variable by its value and re-attempt narrowing using node and arc consistency in the reduced constraint network. This is a typical situation that can occur in many constraint domains, including the case of systems of linear equations and inequations.

To further narrow the values of the variables, one could resort to k -consistency. However, it can be shown that for k greater or equal to 3, the consistency check is itself exponential. Therefore, one has to ask the question: is it worth to attempt further narrowing, known to be computationally expensive and possibly fruitless, or should one proceed directly to an exhaustive search and determine if a given CSP is satisfiable or not? The answer is, of course, problem dependent.

Another type of narrowing occurs when dealing with interval constraints, those whose variables are integers or floating-point numbers defined within lower and upper bounds. Whenever an arithmetic expression is evaluated, the variables' bounds may narrow according to the operations being performed. This is called *bound consistency*, and as in the case of other type of consistencies, it is incomplete: failures may be detected, (e.g., if the upper bound becomes lower than the lower bound), but bounds may remain unchanged. In those cases, splitting the intervals is the only resource in attempting to solve an interval constraint problem.

Much of the effort in CSP has been done in pruning the search tree by avoiding backtracking as much as possible. The reader is referred to [Chapter 63](#) and [Chapter 67](#) for details on how pruning can be accomplished.

93.9.2 Special Constraints

One can distinguish two kinds of special constraints: the first, called global constraints, are very useful in solving operations research problems; the second, quadratic constraints, can be viewed as an effort to widen the scope of linear constraints without resorting to methods for handling general nonlinear constraints (e.g., interval constraints in [Section 93.14.3](#))

Global constraints are essentially consistency constraints involving many variables and are implemented using specific and efficient algorithms. They perform the narrowing to each variable given as a parameter. A typical example is the predicate *all_different*, having n variables as parameters; *all_different* only succeeds if all its variables are assigned different values within a given domain.

Another useful global constraint is *cumulative*. Its parameters specify (1) the possible starting times for n tasks, (2) their durations, (3) the resources, machines, or personnel needed to perform each task, and (4) the total resources available. This constraint has proven its usefulness in large scheduling problems.

Algorithms for solving linear equations and inequations have been thoroughly studied in algebra and in operations research. The latter field has also evidenced significant interest in quadratic programming, whereby one extends the notion of optimality to quadratic objective functions.

A way of handling quadratic constraints is through the use of interval constraints and linearization, followed by multiple applications of the simplex method. More specifically, one can attempt to linearize quadratic terms by introducing new variables and finding their minimal and maximal values using the classic simplex algorithm. This process is repeated until convergence is reached. (See paper by Lebbah et al. in van Hentenryck [2002]). Therefore, quadratic constraints can be viewed as a variant of global constraints. An earlier interesting algebraic approach to quadratic constraints is described in Pesant [1994].

93.9.3 Control Issues

In LP or CLP, one has limited control of control viewed as a component of the pseudo-equations $LP = logic + control$ or $CLP = constraints + control$. In the LP-CLP paradigm, control is achieved through (1) ordering of rules, (2) ordering of predicates on the right-hand side of a rule, (3) usage of the *cut* or special predicates like *freeze*, and (4) metalevel interpretation. Most processors for LP-CLP utilize a rather rigid, depth-first, top-down search. (A notable exception is the XSB (Stony Brook) PROLOG processor that uses a tabling approach.)

The issues of backtracking and control have been more thoroughly investigated in CSP than in LP-CLP. This is not surprising because general LP-CLP processors usually utilize a fixed set of strategies. Control in CSP is achieved through (1) ordering of variables, (2) ordering of the values to be assigned to each variable, (3) deciding how much backtracking is performed before resuming a forward execution, and (4) utilizing information gathered at failure states to avoid them in future searches.

In CSP processors, efforts have been made to have language constructs that specify various control strategies available to a user. These have been called *indexicals* and dictate the order in which various alternative narrowing methods are applied.

A recent trend in control strategies is to use stochastic searches: random numbers and probability criteria are used to select starting nodes of the search tree; information gathered at failure states is also used to redirect searches. Stochastic searches are not complete (i.e., they do not ensure a solution if one exists). Therefore, one must specify a limited time for performing random searches; once that time is reached, the search can restart using new random numbers and information gathered in previous runs. Stochastic searches have proven highly successful in dealing with very large CSP.

Frequently, problems expressed as CSP have multiple successful and unsuccessful situations that are symmetric. The goal of *symmetry breaking* is to bypass searches that, due to the symmetrical nature of a problem, are uninteresting to pursue. A typical example is the n -queens problem in which a multitude of equivalent symmetrical solutions are found but have to be discarded; the same occurs with unsuccessful configurations that have already been proven to yield no solutions.

93.9.4 Optimization

CSP may have a large number of valid solutions. This parallels the situation where LP-CLP processors are used to solve combinatorial problems. In those cases, it is important to select one or a few among multiple solutions by specifying an objective function that has to be maximized or minimized. In the case of finite domains or interval constraints, one may have to resort to exhaustive searches.

For interval constraints this amounts to splitting a given interval into two or more subintervals. When dealing with small finite domains, one may have to explore each possible value within the domain. The reader is referred to [Chapter 15](#) and [Chapter 63](#) of this Handbook where searches and combinatorial optimization are covered in greater detail. In particular, the *branch-and-bound* strategies are often used in CSP with objective functions. In the CLP paradigm, it is often up to the user to perform optimization searches by developing specific programs.

93.9.5 Soft Constraints

It is not uncommon that, in trying to establish a set of constraints, one is confronted with an over-constrained configuration that is unsatisfiable. It is then relevant to attempt to modify certain constraints so that the system becomes satisfiable.

There are several criteria for “relaxing” an over-constrained system. In general, those criteria involve some sort of optimization; for example, one may choose to violate the least number of individual constraints. Another possibility is to assign a weight to each constraint, specifying the tolerated “degree of unsatisfaction.” In that case, one minimizes some function combining those specified weights.

Alternatively, one can assign probabilities to the desirability that a given constraint should be satisfied and then maximize a function expressing the combined probability for satisfying all the constraints (this is referred to as fuzzy constraints).

The usage of “preferences” is another way of loosening over-constrained systems. Consider, for example, the case of the n -queens problem: one may wish to allow solutions that accept attacking queens provided they are far apart. Whenever there are solutions with non-attacking queens, those are preferred over the ones having attacking but distant queens. Preferences are specified by an ordering stipulating that constraint C_1 is preferable to constraint C_2 (e.g., $C_1 > C_2$).

Recent work in the area of soft constraints provides a general framework for relaxing over-constrained systems (see Bistarelli et al. in van Hentenryck [2002]). That framework ensures that if certain algebraic (semi-ring) properties are respected, one can define soft constraints expressing most variants of the above-illustrated constraint relaxation approaches.

93.9.6 SATisfiability Problems

The satisfiability problem can be described as: given a Boolean formula B with n variables, are there *true* or *false* assignments to the variables that render B true? (See [Chapters 6](#) and [66](#) of this Handbook for further details.) It is usual to have B expressed in Conjunctive Normal Form (CNF), consisting of conjunctions of disjunctions of variables or their negations.

Boolean formulas in CNF can be further transformed into equivalent ones whose disjunctions contain three variables negated or not, or the constants *true* and *false*. That variant of the satisfiability problem is known as 3SAT and enjoys remarkable properties. The class NP-complete (see Chapter 6) congregates combinatorial problems that can be reduced to SAT problems in polynomial time. Therefore, 3SAT can be viewed as a valid standard for studying the practical complexity of hard problems. Furthermore, it is possible to show that 3SAT problems can be transformed into CSP.

Consider a random 3SAT problem with n variables and m clauses. It is intuitive to check that, when n is large and m is small, the likelihood of satisfiability is high. On the other hand, when m is large and n is small, that likelihood is low. The curve expressing the ratio m/n versus the probabilities of satisfaction consists of two relatively flat horizontal components indicating high or low probabilities of satisfaction. It has been empirically determined that in the region around $m/n = 4.5$, the curve decreases sharply; problems in that region have around 50% probability of being satisfiable. These are the computationally intensive problems for 3SAT. The problems where m/n is small or large are in general easily solvable.

The implication of this result is that there are “islands of tractability” within very hard problems. From a theoretical viewpoint, 2SAT is polynomial and the determination of other tractability islands remains of great interest. Unfortunately, the transformation of an NP-complete problem into 3SAT distorts the

corresponding values of the m/n ratio. It has become important to find the boundaries of individual NP problems that allow their solutions using inexpensive, moderate, or expensive computational means.

The term *phasetransition* establishes an analogy between algorithmic complexity and the physical properties of matter where temperatures and pressures are used to distinguish gaseous, liquid, and solid forms of states. Finding the boundary values delimiting regions of computational easiness and difficulty has become one of the important aims of CSP.

93.9.7 Future Developments

The novel and valuable future developments in CLP-CSP appear to be oriented in melding machine learning and data-mining approaches to the existing models. These developments parallel those that have occurred in the area of Inductive Logic Programming (ILP) vis-a-vis LP. In ILP, Prolog programs are generated from positive and negative examples ([Muggleton 1991] and [Bratko 2001]).

In the case of CLP-CSP the major question becomes: *Can constraints be learned or inferred from data?* If that is the case then probabilistic or soft constraints are likely to play important roles in providing answers to that quest.

93.10 Applications

The main areas in which LP and CLP have proved successful are summed up in the following:

Symbolic manipulation. Although LISP and PROLOG are currently the main languages in this area, it is probable that a CLP language may replace PROLOG in the next few years. There is a close relationship between the aims of CLP and symbolic languages such as MAPLE, MATHEMATICA, and MACSYMA.

Numerical analysis and operations research. The proposed CLP languages allow their users to generate and refine hundreds of equations and inequations having special characteristics (e.g., the generation of linear equations approximating Laplace's differential equations). The possibility of expressing inequations in a computer language has attracted the interest of specialists in operations research. Difficult problems in scheduling have been solved using CLP in finite domains.

Combinatorics. Nondeterministic languages such as PROLOG have been successful in the solution of combinatorial problems. The availability of constraints extends the scope of problems that can be expressed by CLP programs.

Artificial intelligence applications. Boolean constraints have been utilized in the design of expert systems. Constraints have also been used in natural language processing and in parsing. The increased potential for invertibility makes CLP languages unique in programming certain applications. For example, the inverse operation of parsing is string generation.

Deductive databases. These applications have attracted a considerable number of researchers and developers who are now extending the database (DB) domains to include constraints. The language DATALOG is the main representative, and its programs contain only variables or constants (no composite terms are allowed).

Engineering applications. The ease with which CLP can be used for generating and refining large numbers of equations and inequations makes it useful in the solution of engineering problems. Ohm's and Kirchhoff's laws can readily be used to generate equations describing the behavior of electrical circuits.

93.11 Theoretical Foundations

This section provides a summary of the fundamental results applicable to logic programs [Apt 1990, Lloyd 1987]. It will be shown later that these results remain applicable to a wide class of constraint logic programs.

The semantics of LP and CLP are usually defined using either logic or sets. In the logic approach, one establishes that given both (1) a Horn clause program P and (2) a query Q , Q can be shown to be a consequence of P . In other words, $\neg P \vee Q$ is always true, or equivalently, using contradiction, $P \wedge \neg Q$ is always false. This relates the logical and operational meaning of programs; that is, that Q is a consequence of P can be proved by a resolution-based **breadth-first** theorem prover. (This is because a **depth-first** prover could loop in trying to determine a first solution, being therefore incapable of finding other solutions that may well exist.)

Logic-based semantics are accomplished in two steps. The first considers that a program yields a *yes* answer. In that case, the results (i.e., the bindings of variables to terms as the result of successive unifications) are the constraints that P and Q must satisfy so that Q becomes deducible from P . This is accomplished by Horn clause resolutions that render $P \wedge \neg Q$ unsatisfiable.

The second step of the proof is concerned with logic programs that yield a *no* answer and therefore do not specify bindings or constraints. In that case, it becomes important to make a stronger statement about the meaning of a clause.

Recall that in the case of *yes* answers, a Horn clause specifies that the *Head* is a consequence of the *Body*, or equivalently that the *Head* is true if the *Body* is true. In the case of a *no* answer, the so-called Clark completion becomes applicable. That means that the *Head* is true *if and only if* the *Body* is true. Then the semantics of programs yielding a *no* answer amount to proving that *not* Q is a consequence of the completion of P . This amounts to considering the implication in *Body implies Head* in every clause of P as being replaced by *Body equivalent to Head*.

It should be noted that the preceding results are only applicable to queries that do not contain logic negation. For example, the query $\neg \text{date}(X, Y, Z)$ in the introductory example is invalid because a negative query is not in Horn clause form. Therefore, only positive queries are allowed and the behavior of the prover satisfies the so-called closed world assumption: only positive queries deducible from the program provide *yes* answers. Recent developments in the so-called nonmonotonic logic extend programs to handle negative queries.

The second approach in defining the semantics of LP and CLP uses sets. Consider the set S_0 of all unit clauses in a program P . This set involves assigning any variables in these unit clauses to elements of the Herbrand universe. Consider then the clauses whose bodies contain elements of that initial set S_0 . Obviously the *Head* of those clauses is now deducible from the program and the new set S_1 is constructed by taking the union of S_0 with the heads of clauses that have been found to be true.

This process continues by computing the sets S_2, S_3 , etc. Notice that $S(i)$ always contains $S(i - 1)$. Eventually these sets will not change because all the logical information about a finite program P is contained in them. This is called a least fixed point. Then Q is a consequence of P if and only if each conjunct in Q is in the least fixed point of P .

Consider, for example, the PROLOG program for adding two positive numbers specified by a successor function $s(X)$ denoting the successor of X :

$$\begin{aligned} & \text{add}(0, X, X). \\ & \text{add}(s(X), Y, s(Z)) :- \text{add}(X, Y, Z). \end{aligned}$$

First notice the similarity of the preceding example with *append*. Adding 0 to a number X yields X (first rule). Adding the successor of X to a number Y amounts to adding one to the result Z obtained by adding X to Y .

In this simple example, the Herbrand universe consists of 0, $s(0)$, $s(s(0))$, and so on, namely, the positive natural numbers including the constant 0. The so-called Herbrand base considers all of the literals (in this case *add*) for which a binding of a variable to elements of the Herbrand universe satisfy the program rules. Using the set approach S_0 consists of all natural numbers because any number can be added to zero. The fixed point corresponds to the infinite set of bindings of X, Y , and Z to elements of the Herbrand universe, which satisfies both rules.

The meaning of a program P and query Q yielding a *no* answer can also be specified using set theory. In that case, one starts with the set corresponding to the Herbrand universe H_0 . Then this set is reduced to a

smaller set by using once the rules in P . Call this new set $H1$. By applying again the rules in P , one obtains $H2$, and so on. In this case there is not necessarily a fixed point Hn . The property pertaining to programs yielding *no* answers then consists of the statement: *not* Q is a logical consequence of the completion of Q if and only if some conjunct of Q is not a member of Hn .

In addition to programs yielding *yes* or *no* answers, there are those which loop. The halting problem tells us that we cannot hope to detect all of the programs which will eventually loop. Let us consider, as an example, the program P_1 :

$$p(a).$$

$$p(b) :- \neg p(b).$$

As expected, the queries $Q_1 : p(a)$ and $Q_2 : p(c)$ yield, respectively, *yes* and *no* because $p(a)$ is a consequence of P_1 , and $\neg p(c)$ is a consequence of the completion of p_1 ; that is,

$$p(X) \equiv (X = a) \vee (X = b \wedge p(b))$$

However, the interpreter will loop for the query $Q_3 : p(b)$, or when all solutions of $Q_4 : p(X)$ are requested.

As mentioned earlier, the preceding theoretical results can be extended to CLP languages. Jaffar and Lassez [1987] established two conditions that a CLP extension to PROLOG must satisfy so that the semantic meaning (using logic or sets) is still applicable. The first is that the replacement of unification by an algorithm that tests the satisfiability of constraints should always yield a *yes* or *no* answer. This property is called *satisfaction-completeness* and it is obviously satisfied by the unification algorithm in the domain of trees. Similarly, the property applies to systems of linear equations in the domain of rationals and even to polynomial equations but with a significantly larger computational cost.

The second of Jaffar and Lassez's conditions is called *solution-compactness*. It basically states that elements of a domain (say, irrational numbers) can be defined by a potentially infinite number of more stringent constraints that bound their actual values by increasingly finer approximations. For example, the real numbers satisfy this requirement. For more detail on Jaffar and Lassez's theory, see Jaffar and Maher [1994] and Cohen [1990]. Existing CLP languages satisfy the two conditions established by Jaffar and Lassez.

The beauty of the Jaffar and Lassez metatheory is that they have established conditions under which the basic theorems of logic programming remain valid, provided that the set of proposed axioms specifying constraints satisfy the described properties.

A convenient (although incomplete) taxonomy for CLP languages is to classify them according to their domains or combinations thereof. One can have CLP (rationals), or CLP (Booleans, reals). PROLOG can be described as CLP (trees) and CLP (R) as CLP (reals, trees). A complete specification of CLP language would also have to include the predicates and operations allowed in establishing valid constraints.

From the language-design perspective, the designer would have to demonstrate the correctness of an efficient algorithm implementing the test for constraint satisfiability. This is equivalent to proving the satisfiability of the constraints specified by the axioms.

93.12 Metalevel Interpretation

Metalevel interpretation allows the description of interpreters for the languages (such as LISP or PROLOG), using the languages themselves. In PROLOG, the metalevel interpreter for pure programs consists of a few lines of code. The procedure `solve` has as a parameter a list of PROLOG goals to be processed. The interpreter assumes that the program rules are stored as unit clauses:

$$\text{clause}(\text{Head}, \text{Body}).$$

each corresponding to a rule: $\text{Head} :- \text{Body}$, where Head is a literal and Body is a list of literals. Unit clauses are stored as $\text{clause}(\text{Head}, [])$. The interpreter is:

$$\text{solve}([]).$$

$$\text{solve}([\text{Goal} | \text{Restgoal}]) :- \text{solve}(\text{Goal}), \text{solve}(\text{Restgoal}).$$

$$\text{solve}(\text{Goal}) :- \text{clause}(\text{Goal}, \text{Body}), \text{solve}(\text{Body}).$$

The first rule states that an empty list of goals is logically correct. (In that case, the interpreter should print the latest bindings of the variables.) The second rule states that when processing (i.e., *solving*) a list of goals, the *head* and then the *tail* of the list should be processed. The third rule specifies that when a single *Goal* is to be processed, one has to look-up the database containing the clauses and process the *Body* of the applicable clause. In the preceding interpreter, metainterpreter unification is implicit. One could write metainterpreters in which the built-in unification is replaced by an explicit sequence of PROLOG constructs using the impure features.

A very useful extension often incorporated into interpreters is the notion of co-routining, or lazy evaluation. The built-in procedure *freeze*(*X*, *P*) tests whether the variable *X* has been bound. If so, *P* is executed; otherwise, the pair (*X*, *P*) is placed in a freezer. As soon as *X* becomes bound, *P* is placed at the head of the list of goals for immediate execution.

The procedure *freeze* can be easily implemented by expressing it as a variant of *solve* also written in PROLOG. Although this metalevel programming will of course considerably slow down the execution, this capability can and has been used for fast prototyping extensions to the language [Sterling and Shapiro 1994, Cohen 1990].

Another important application of metalevel programming is partial evaluation. Its objective is to transform a given program (a set of procedures) into an optimized version in which one of the procedures has one or more parameters that are bound to a known value. An example of partial evaluation is the automatic translation of a simple (inefficient) pattern matching algorithm which tests if a given pattern appears in a text. When the pattern is known, a partial evaluator applied to the simple matching algorithm produces the equivalent of the more sophisticated Knuth–Morris–Pratt pattern matching algorithm.

In a metalevel interpreter for a CLP language, a rule is represented by: *clause* (*Head*, *Body*, *Constraints*). Corresponding to a rule: *Head* :- *Body* {*Constraints*}.

The modified procedure *solve* contains three parameters: (1) the list of goals to be processed, (2) the current set of constraints, and (3) the new set of constraints obtained by updating the previous set. The metalevel interpreter for CLP, written in PROLOG becomes:

```

solve ([ ], C, C).
solve ([Goal | Restgoal], Previous_C, New_C) :-
    solve (Goal, Previous_C, Temp_C),
    solve (Restgoal, Temp_C, New_C).
solve (Goal, Previous_C, New_C) :-
    clause (Goal, Body, Current_C),
    merge_constraints (Previous_C, Current_C, Temp_C),
    solve (Body, Temp_C, New_C).

```

The heart of the interpreter is the procedure *merge_constraints*, which merges two sets of constraints: (1) the previous constraints, *Previous_C*, and (2) the constraints introduced by the current clause, *Current_C*. If there is no solution to this new set of constraints, the procedure fails; otherwise, it simplifies the resulting constraints, and it binds any variables that have been constrained to take a unique value. For example, the constraints $X \leq 0 \wedge X \geq 0$ simplify to the constraint $X = 0$, which implies that *X* can now be bound to 0.

The design considerations that influence the implementation of this procedure will be discussed in [Section 93.13](#). Note that the controversial unit logical inference steps per second (LIPS), often used to estimate the speed of PROLOG processors, loses its significance in the case of a constraint language. The number of LIPS is established by counting how many times per second the procedure *clause* is activated; in the case of CLP, this time to process *clause* and *merge_constraints* may vary significantly, depending on the constraints being processed.

93.13 Implementation

It is worthwhile to present the basic LP implementation features by describing an interpreter for the simplified PROLOG of Section 93.5 written in a Pascal or C-like language. The reader should note the similarities between the metalevel interpreter *solve* of the previous section and the one about to be described.

The rules will be stored sequentially in a database implemented as a one-dimensional array $Rule[1..n]$ and containing pointers to a special type of linear list. Such a list is a record with two fields, the first storing a letter and the second being either *nil* or a pointer to a linear list. Let the (pointer) function *cons* be the constructor of a list element, and assume that its fields are accessible via the (pointer) functions *head* and *tail*. The first rule is stored in the database by

$$Rule[1] := cons('a', cons('b', cons('c', cons('d', nil)))).$$

The fifth rule defining a unit clause is stored as $Rule[5] := cons('e', nil)$. Similar assignments are used to store the remaining rules.

The procedure *solve* that has as a parameter a pointer to a linear list is capable of determining whether or not a query is successful. The query itself is the list with which *solve* is first called. The procedure uses two auxiliary procedures *match* and *append*; *match*(*A*, *B*) simply tests if the alphanumeric *A* equals the alphanumeric *B*; *append*(*L1*, *L2*) produces the list representing the concatenation of *L1* with *L2* (this is equivalent to the familiar *append* function in LISP: it basically copies *L1* and makes its last element point to *L2*).

The procedure *solve*, written in a Pascal-like language, appears in Figure 93.3. Recall that the variable *n* represents the number of rules stored in the array *Rule*. The procedure performs a depth-first search of the problem space where the local variable is used for continuing the search in case of a failure. The head of the list of goals *L* is matched with the head of each rule. If a match is found, the procedure is called recursively with a new list of goals formed by adding (through a call of *append*) the elements of the tail of the matching rule to the goals that remain to be satisfied. When the list of goals is *nil*, all goals have been satisfied and a success message is issued. If the attempts to match fail, the search is continued in the previous recursion level until the zeroeth level is reached, in which case no more solutions are possible. For example, the query *a, e*. is expressed by $solve(cons('a', cons('e', nil)))$ and yields the two solutions presented in Section 93.5 on resolution of Horn clauses.

Note that if the tree of choices is finite, the order of the goals in the list of goals is irrelevant insofar as the presence and number of solutions are concerned. Thus, the order of the parameters of *append* in Figure 93.3 could be switched, and the two existing solutions would still be found. Note that if the last rule were replaced by *a :- f, a.*, the tree of choices would be infinite and solutions similar to the first solution would be found repeatedly. The procedure *solve* in Figure 93.3 can handle these situations by generating an infinite sequence of solutions. However, had the preceding rule appeared as the first one, the procedure *solve* would also loop, but without yielding any solutions. This last example shows how important the ordering of the rules is to the outcome of a query. This explains Kowalski's dictum program = logic + control, in which control stands for the ordering and (impure) control features such as the cut [Kowalski 1979].

It is not difficult to write a recursive function *unify*, which, given two terms, tests for the result of unification using the contents of Table 93.1 (Section 93.5). For this purpose, one has to select a suitable data structure. In a sophisticated version, terms are represented by variable-sized records containing pointers to other records, to constants, or to variables. Remark that the extensive updating of linked data structures inevitably leads to unreferenced structures that can be recovered by a garbage collection. It is frequently used in most PROLOG and CLP processors.

A simpler data structure uses linked lists and the so-called Cambridge Polish notation. For example, the term $f(X, g(Y, c))$ is represented by $(f(var\ x)(g(var\ y)(const\ c)))$, which can be constructed with *conses*.

As mentioned in Section 93.5, if the result of unification results in the binding $Y := g(Y, c)$, then (most) PROLOG interpreters would soon get into difficulties because most implementations of the described unification algorithm cannot handle circular structures. Manipulating these structures (e.g., printing,

copying) would result in an infinite loop unless the so-called occur check is incorporated to test for circularity.

The additional machinery needed to incorporate unification into the procedure *solve* of Figure 93.3 is described in Cohen [1985]. An important remark is in order: when introducing unification, it is necessary to *copy* the clauses in the program and introduce new variables (which correspond to parameters that should be called by value). The frequent copying and updating of lists makes it almost mandatory to use garbage collection, which is often incorporated to LP processors.

93.13.1 Warren Abstract Machine (WAM)

D.H.D. Warren, a pioneer in the compilation of PROLOG programs, proposed in 1983 a set of primitive instructions that can be generated by a PROLOG compiler, usually written using PROLOG. (Warren's approach parallels that of P-code used in early Pascal compilers.) The **Warren abstract machine** (WAM) primitives can be efficiently interpreted using specific machines.

The main data structures used by the WAM are (1) the recursion stack, (2) the heap, and (3) the trail. The heap is used for storing terms and the trail for backtracking purposes. The WAM uses the copying approach mentioned in the beginning of this section. A local garbage collector takes advantage of the cut by freeing space in the trail.

The WAM has been used extensively by various groups developing PROLOG compilers. Its primitives are of great efficiency in implementing features such as tail-recursion elimination, indexing of the head of the clause to be considered when processing a goal, the cut, and other extralogical features of PROLOG. A useful reference in describing the WAM is the one by Ait-Kaci [1991]. A recent reference on implementation is by Van Roy [1994].

93.13.2 Parallelism

Whereas for most languages it is fairly difficult to write programs that automatically take advantage of operations and instructions that can be executed in parallel, PROLOG offers an abundance of opportunities for parallelization. There are at least three possibilities for performing PROLOG operations in parallel:

1. *Unification*. Because this is one of the most frequent operations in running PROLOG programs, it would seem worthwhile to search for efficient parallel unification algorithms. Some work has already been done in this area [Jaffar et al. 1992]. However, the results have not been encouraging.
2. *And-parallelism*. This consists of simultaneously executing each procedure in the tail of a clause. For example, in $a(X, Y, U) :- b(X, Z), c(X, Y), d(T, U)$, an attempt is made to continue the execution in parallel for the clauses defining b , c , and d . The first two share the common variable X ; therefore, if unification fails in one but not in the other, or if the unification yields different bindings, then some of the labor done in parallel is lost. However, the last clause in the tail can be executed independently because it does not share variables with the other two.
3. *Or-parallelism*. When a given predicate is defined by several rules, it is possible to attempt to apply the rules simultaneously. This is the most common type of parallelism used in PROLOG processors.

Kergommeaux and Codognet [1994] is a recommended survey of parallelism in PROLOG.

93.13.3 Design and Implementation Issues in Constraint Logic Programming

There is an important implementation consideration that appears to be fulfilled in both CLP(R) and PROLOG IV: the efficiency of processing PROLOG programs (without constraints) should approach that of current PROLOG interpreters; that is, the overhead for *recognizing* more general constraints should be small.

There are three factors that should be considered when selecting algorithms for testing the satisfiability of systems of constraints used in conjunction with CLP processors. They are (1) incrementality, (2) simplification, and (3) canonical forms. The first is a desirable property that allows an increase in efficiency

of multiple tests of satisfiability (by avoiding recomputations). This can be explained in terms of the metalevel interpreter for CLP languages described in [Section 93.11](#): if the current system of constraints S is known to be satisfiable, the test of satisfiability should be incremental, minimizing the computational effort required to check if the formula remains satisfiable or not. Classical PROLOG interpreters have this property because previously performed unifications are not recomputed at each inference step. There are modifications of Gaussian methods for solving linear equations that also satisfy this property. This is accomplished by introducing temporary variables and replacing the original system of equations by an equivalent solved form (see [Section 93.5](#)): *variable = linear terms involving only the temporary variables*.

The simplex method can also be modified to satisfy incrementality. Similarly, the SL resolution method for testing the satisfiability of Boolean equations and the Gröbner method for testing the satisfiability of polynomial equations have this property.

In nearly all the domains considered in CLP, it may be possible to replace a set of constraints by a simpler set. This simplification can be time-consuming, but is sometimes necessary. The implementor of CLP languages may have to make a difficult choice as to what level of simplification should occur at each step verifying constraint satisfaction. It may turn out that a system of constraints eventually becomes unsatisfiable, and all of the work done in simplification is lost. When a final result has to be output, it becomes essential to simplify it and present it to the reader in the clearest, most readable form.

An important function of simplification is to detect the assignment of a variable to a single value (e.g., from $X \geq 1$ and $X \leq 1$ one infers $X = 1$). This property is essential when implementing a modified simplex method that detects when a variable is assigned to a single value. Note that this detection is necessary when using lazy evaluation.

The incremental algorithms for testing the satisfiability of linear equations and inequations, as well as that used in the Gröbner method for polynomial equations, are capable of discarding redundant equations; therefore, they perform some simplifications [Sato and Aiba 1993].

The canonical (solved) forms referred to earlier in this section can be viewed as (internal) representations of the constraints which facilitate both the tests of satisfiability and the ensuing simplifications. For example, in the case of the Gröbner method for solving polynomial equations, the input polynomials are internally represented in a normal form, such that variables are lexicographically ordered and the terms of the polynomials are ordered according to their degrees. This ordering is essential in performing the required computations. Also note that if two seemingly different constraints have the same canonical form, only one of them needs to be considered. Therefore, the choice of appropriate canonical forms deserves an important consideration in the implementation of CLP languages [Jaffar and Maher 1994].

93.13.4 Optimization Using Abstract Interpretation

Abstract interpretation is an enticing area of computer science initially developed by Cousot and Cousot [1992]; it consists of considering a subdomain of the variables of a program (usually a Boolean variable, e.g., one representing the evenness or oddness of the final result). Program operations and constructs are performed using only the desired subdomain. Cousot proved that if certain conditions are applicable to the subdomains and the operations acting on their variables, the execution is guaranteed to terminate. Dataflow analyses, partial evaluation, detection of safe parallelism, etc. can be viewed as instances of abstract interpretation. The research group at the University of Louvain, Belgium, has been active in exploring the capabilities of abstract interpretation in LP and CLP.

93.14 Research Issues

It is worthwhile to classify the numerous extensions of PROLOG into three main categories, namely, those related to (1) resolution beyond Horn clauses, (2) unification, and (3) others (e.g., concurrency). Major extensions of the unification became very significant and resulted in a new area of LP called constraint logic programming or CLP that was dealt with in [Section 93.8](#); nevertheless, the more recent addition to CLP dealing with the domain of intervals is discussed in this section.

93.14.1 Resolution Beyond Horn Clauses

Several researchers have suggested extensions for dealing with more general clauses and for developing semantics for negation that are more general than that of negation by failure (see Section 93.7). Experience has shown that the most general extension, that is, to the general predicate calculus, poses difficult combinatorial search problems. Nevertheless, substantial progress has been made in extending LP beyond pure Horn clauses. Two such extensions deserve mention: stratified programs and generalized predicate calculus formulas in the *body* part of a clause.

Stratified programs are variants of Horn clause programs that are particularly applicable in deductive databases; true negation may appear in the body of clauses, provided that it satisfies certain conditions. These stratified programs have clean semantics based on logic and avoid the undesirable features of negation by failure. (See Minker [1987].)

To briefly describe the second extension, it is worthwhile to recall that the procedural interpretation of resolution applied to Horn clauses is based on the substitution model: a procedure call consists of replacing the call by the body of the procedure in which the formal parameters are substituted by the actual parameters via unification. The generalization proposed by Ueda and others can use the substitution model to deal with the clauses of the type *head* :-, (a general formula in the predicate calculus containing quantifiers and negation).

93.14.2 Concurrent Logic Programming and Constraint Logic Programming

A significant extension of LP has been pursued by several groups. A premise of their effort can be stated as: a programming language worth its salt should be expressive enough to allow its users to write complex but efficient operating systems software (as is the case of the C language). With that goal in mind, they incorporated into LP the concepts of **don't care nondeterminism** as advocated by Dijkstra. The resulting languages are called concurrent LP languages. The variants proposed by these groups were implemented and refined; they have now converged to a common model that is a specialized version of the original designs.

Most of these concurrent languages use special punctuation marks “?” and “|”. The question mark is a shorthand notation for *freezes*. For example, the literal $p(X?, Y)$ can be viewed as a form of *freeze* ($X, p(X, Y)$). The vertical bar is called *commit* and usually appears once in the tail of clauses defining a given procedure. Consider, for example,

$$a :- b, c \mid d, e.$$
$$a :- p \mid q.$$

The literals b, c , and d, e are executed using *and* parallelism. However, the computation using *or* parallelism for the two clauses defining a continues only with the clause that first reaches the *commit* sign. For example, if the computation of b, c proceeds faster than p , then the second clause is abandoned, and execution continues with d, e only (see Saraswat 1993).

93.14.3 Interval Constraints

The domain of interval arithmetic has become a very fruitful area of research in CLP. Older has been a pioneer in this area [Older and Vellino 1993]. This domain specifies reals as being defined between lower and upper bounds that can be large integers or rational numbers. The theory of solving most nonlinear and trigonometric equations using intervals guarantees that *if* there is a solution, that solution must lie within the computed intervals. Furthermore, it is also guaranteed that *no* solution exists outside the computed interval or unions of intervals.

The computations involve the operation of *narrowing* that consists of finding new bounds for a quantity denoting the result of an operation (say, +, *, sin, etc.) involving operands, which are also defined by their lower and upper bounds. The narrowing operation also involves intersecting intervals obtained by various computations defining the same variable. The intersection may well fail (e.g., the equality operation

applying to operands whose intervals are disjoint). The narrowing is guaranteed to either converge or fail. This, however, may not be sufficient to find possible solutions of interest. One can nevertheless split a given interval into two or more unions of intervals and proceed to find a more precise solution, if one exists. This is akin to enumeration of results in CLP.

The process of splitting is a **don't know nondeterministic** choice, an existing component of LP. The failure of the narrowing operation is analogous to that encountered in CLP when a constraint is unsatisfiable and backtracking occurs. Therefore, there is a natural interaction between LP and the domain of intervals.

Interval arithmetic is known to yield valuable results in computing the satisfiability of nonlinear constraints or in the case of finite domains. Its use in linear constraints is an active area of research because results indicate a poor convergence of narrowing. In the case of polynomial constraints interval arithmetic may well be a strong competitor to Gröebner base techniques.

93.14.4 Constraint Logic Programming Language Design

A current challenge in the design and implementation of CLP is to blend computations in different domains in a harmonious and sound manner. For example, the reals can be represented by intervals whose bounds are floating-point numbers (these have to be carefully implemented to retain soundness due to rounding operations). Actually, floating-point numbers are nothing more than (approximate) very large integers or fractions. This set is, of course, a superset of finite domains, which in turn is a superset of Booleans. Problems in CLP language design that still remain to be solved include how to handle the interaction of these different domains and subdomains. This situation is further complicated by efficiency considerations. Linear inequations, equations, and disequations can be efficiently solved using rational arithmetic but research remains to be done in adapting simplex-like methods to deal with interval arithmetic.

93.15 Conclusion

As in most sciences, there has always been a valuable symbiosis among the theoretical and experimental practitioners of computer science, including, of course, those working in logic programming. Three examples come to mind: the elimination of the occur test in unifications, the cut, and the *not* operator as defined in PROLOG. These features were created by practical programmers and are here to stay. They provide a vast amount of food for thought for theoreticians. As mentioned earlier, the elimination of the occur test was instrumental in the development of algorithms for unification of **infinite trees**. Although the concept of the cut has resisted repeated attempts for a clean semantic definition, its use is unavoidable in increasing the efficiency of programs. Finally, PROLOG's *not* operator has played a key role in extending logic programs beyond Horn clauses.

CLP is one of the most promising and stimulating new areas in computer science. It amalgamates the knowledge and experience gained in areas as varied as numerical analysis, operations research, artificial languages, symbolic processing, artificial intelligence, logic, and mathematics.

During the past 20 years, LP has followed a creative and productive course. It is not unusual for a fundamental scientific endeavor to branch out into many interesting subfields. An interesting aspect of these developments is that LP's original body of knowledge actually branched into subareas, which joined previously existing research areas. For example, CLP is being merged with the area of constraint satisfaction problems (CSP); LP researchers are interested in modal, temporal, intuitionistic, and linear logic; relational database research now includes constraints; operations research and CLP have found previously unexplored similarities, and so on.

The several subfields of LP now include research on CLP in various domains, typing, non-monotonic reasoning, inductive LP, semantics, concurrency, nonstandard logic, abstract interpretation, partial evaluation, blending with functional and with object-oriented language paradigms. It will not be surprising if each of these subfields will become fairly independent from their LP roots and the various specialized groups will organize autonomous journals and conferences. The available literature on LP is abundant and it is likely to be followed by a plentiful number of publications in its autonomous subfields.

Defining Terms

Backtracking: A manner to handle (*don't know*) nondeterministic situations by considering *one* choice at a time and storing information which is necessary to restore a given state of the computation. PROLOG interpreters often use backtracking to implement nondeterministic situations.

Breadth first: A method for traversing trees in which all of the children of a node are considered simultaneously. OR-Parallel PROLOG interpreters use breadth-first traversal.

Clause: A general normal form for expressing predicate calculus formulas. It is a disjunction of literals ($P_1 \vee P_2 \vee \dots$) whose arguments are terms. The terms are usually introduced by eliminating existential quantifiers.

Constraint logic programming languages: PROLOG-like languages in which unification is replaced or complemented by constraint solving in various domains.

Constraints: Special predicates whose satisfiability can be established for various domains. Unification can be viewed as equality constraints in the domain of trees.

Cut: An annotation used in PROLOG programs to bypass certain nondeterministic computations.

Depth first: A method for traversing trees in which the leftmost branches are considered first. Most sequential PROLOG interpreters use depth-first traversal.

Don't care nondeterminism: The arbitrary choice of one among multiple possible continuations for a computation.

Don't know nondeterminism: Situations in which there are equally valid choices in pursuing a computation.

Herbrand universe: The set of all terms that can be constructed by combining the terms and constants which appear in a logic formula.

Horn clause: A clause containing (at most) one positive literal. The term *definite clause* is used to denote a clause with exactly one positive literal. PROLOG programs can be viewed as a set of definite clauses in which the positive literal is the head of the rule and the negative literals constitute the body or tail of the rule.

Infinite trees: Trees that can be unified by special unification algorithms which bypass the occur-check. These trees constitute a new domain, different from that of usual PROLOG trees.

Metalevel interpreter: An interpreter written in L for the language L .

Occur-check: A test performed during unification to ensure that a given variable is not defined in terms of itself [e.g., $X = f(X)$ is detected by an occur-check, and unification fails].

Predicate calculus: A calculus for expressing logic statements. Its formulas involve:

- *atoms:* $P(T_1, T_2, \dots)$ where P is a predicate symbol and the T_i are terms.
- *Boolean connectives:* conjunction (\wedge), disjunction (\vee), implication (\rightarrow), and negation (\neg).
- *literals:* atoms or their negations.
- *quantifiers:* for all (\forall), there exists (\exists).
- *terms* (also called *trees*): constructed from constants, variables, and function symbols.

Resolution: A single inference step used to prove the validity of predicate calculus formulas expressed as clauses. In its simplest version: $P \vee Q$ and $\neg P \vee R$ imply $Q \vee R$, which is called the resolvent.

SLD resolution: Selective linear resolution for definite clauses inference step used in proving the validity of Horn clauses.

Unification: Matching of terms used in a resolution step. It basically consists of testing the satisfiability or the equality of trees whose leaves may contain variables. Unification can also be viewed as a general parameter matching mechanism.

Warren abstract machine (WAM): An intermediate (low-level) language that is often used as an object language for compiling PROLOG programs. Its objective is to allow the compilation of efficient PROLOG code.

Further Information

There are several journals specializing in LP and CLP. Among them we mention the *Journal of Logic Programming* (North-Holland), *New Generation Computing* (Springer-Verlag), and *Constraint* (Kluwer).

Most of the conference proceedings have been published by MIT Press. Recent proceedings on constraints have been published in the Lecture Notes in Computer Science (LNCS) series published by Springer-Verlag. A newsletter is also available (Logic Programming Newsletter, alp@doc.ic.ac.uk)

Among the references provided, the following relate to CLP languages: PROLOG III [Colmerauer 1990], CLP(R) [Jaffar et al. 1992], CHIP [Dincbas et al. 1988], CAL [Sato and Aiba 1993], finite domains [Van Hentenryck 1989], and Intervals [Older and Vellino 1993]. The recommended textbooks include Clocksin and Mellish [1984] and Sterling and Shapiro [1994]. The theoretical aspects of LP are well covered in Apt [1990] and Lloyd [1987] and implementation in Ait-Kaci [1991], Kergommeaux and Codognet [1994], Van Roy [1994], and Warren [1983].

Scripting Languages

94.1 Introduction

According to WebMonkey [10]:

“A scripting language is a simple programming language used to write an executable list of commands, called a script. A scripting language is a high-level command language that is interpreted rather than compiled, and is translated on the fly rather than first translated entirely. JavaScript, Perl, VBscript, and AppleScript are scripting languages rather than general-purpose programming languages.”

The major characteristic of scripting languages is that they often serve as *glue* for connecting existing components or applications together. Scripting languages usually have powerful string processing operations, because text strings are a fairly universal communication medium.

Scripting languages, in the form of job command languages, have existed from the time of the earliest operating systems. However, these early scripting languages lacked variables, conditional statements, and loops. With the advent of Unix [5] in the 1970s, job command languages began to emerge as true scripting languages. Both the early Bourne shell and later C shell had variables and control flow constructs. Later Unix scripting languages included sed and AWK [3]. While early Unix scripting languages had support for variables, conditional statements, and loops, later versions added support for functions, procedures, and parameters.

One characteristic of scripting languages is that they are usually interpreted rather than requiring compilation. For example, Perl is dynamically compiled to byte code and then interpreted; however, there are also compilers for Perl that produce an executable. Most conventional programming languages are compiled to an executable. However, the conventional programming languages Java and C# are compiled to byte code and then interpreted. While Perl does not require compilation, Java and C# do. A more extensive discussion of compilation versus interpretation can be found in [Chapter 99](#).

Another characteristic of scripting languages is that variables need not be declared and are *typeless* (or *dynamically typed*). By this we mean that the programmer does not declare a variable to be of a fixed type (typeless), but rather the type of the variable is allowed to vary according to the type of the value currently

assigned (dynamically typed). Thus, values have associated with them a runtime type identification. Typed values also appear in non-scripting languages; for example, Java associates type identifiers with objects and Lisp (a language used in artificial intelligence) does so for all values.

However, most conventional programming languages (including Java) require that each variable be explicitly declared and that a type be associated with the variable. Such languages are said to be *statically typed*, in that the association of a type with a variable is done in the source code. This allows the compiler to check the usage of a variable at compile time to ensure that the operations performed on a variable are consistent with its type. In the development of large programs there is an enormous economic benefit to the early detection and correction of errors.

In contrast, the necessity to declare each variable and associate with it a static type adds statements to a program. In a large program, the cost to write these extra statements is negligible. However, most scripts are relatively small, intended primarily to connect or *glue* applications or components together. Many scripts are only a printed page or two of text. The hallmark of a scripting language is to facilitate directness of expression in the process of getting disparate applications or components to communicate. Brevity of expression and a simple development cycle is preferred for these simple tasks. Hence, scripting languages prefer dynamically typed variables and interpretation.

There is clearly a runtime performance penalty for this flexibility. However, for most scripted applications, most of the time is spent in the underlying components, which are commonly written in conventional programming languages and thus compiled. Offsetting the performance penalty is the dramatic increase in computer power and the subsequent decline in cost per computer instruction executed. A script that might have taken minutes or hours to run a decade ago is often instantaneous on a modern processor. Thus, faster processors are a major factor in enabling the effectiveness of scripting technology.

At the current time, scripting languages and conventional programming languages are complementary in nature. Conventional programming languages are used to develop large components or applications in which efficiency is a major consideration. In contrast, scripting languages are used to develop applications in which the primary task is to provide the ability for existing applications to communicate with each other. In the latter case, either computer efficiency is not a major issue or most of the time is spent in the preexisting applications. Scripting languages promote rapid development because of their use of interpretation and dynamic typing.

Many argue that scripting is a technology whose time has come. Certainly, the use of scripting languages has increased dramatically in the last decade. While conventional programming languages will continue to be used for creating components for some time, the preferred method of integrating components is to use scripting.

A number of developments appear to be driving this trend toward the use of scripting languages. First, the systems task of installing and maintaining applications has increased enormously. Two decades ago, a company would typically have had a single, central computer on which all applications would be run. Commands for installing and updating an application would have been entered manually. Today, such a company has hundreds or thousands of personal computers. The cost of having a systems staff person enter a sequence of commands on each of thousands of computers is unworkable. Instead, scripts are used. Scripting languages that are prototypical of this area include Perl, Python, and Rexx. In [Section 94.2](#), we examine Perl.

Before the widespread adoption of personal computer software, a company deployed applications on its single, central computer that were customized, either by developing the application internally or by acquiring an industry-specific application. With the widespread deployment of personal computers, cost considerations have led to an increased use of commercial, off-the-shelf software. If the company needs to customize the application, an event-driven scripting language such as Tcl/Tk or Visual Basic is often used. [Section 94.3](#) examines a typical usage of Tcl/Tk.

Another major driving force in the increasing use of scripting languages has been the Web. Companies have found great benefit in making their own computer applications more accessible by exposing them to the Web via a scripting language. Also, there has been a demand for simple Web applications, such as putting the company phone book online. More complex applications would include retail shopping via the

Web; for efficiency reasons, these larger, complex Web applications are often programmed in conventional programming languages such as Java.

Originally, many simple Web applications were programmed using system scripting languages such as Perl via the Common Gateway Interface (CGI). More recently, scripting languages specifically designed for Web applications have been developed, including PHP and ColdFusion. In [Section 94.4](#) we examine the language PHP via a simple Web application.

Until fairly recently, scripting languages have often been thought of as niche languages: Perl, Python, or Rexx for systems tasks, Tcl/Tk or Visual Basic for simple GUIs, PHP or ColdFusion for Web pages. However, there is an increasing preference for scripting languages over conventional programming languages even when creating components. One cause of this trend is that many scripting languages now support object-oriented programming. An example is Perl, whose version 5 now supports object-oriented programming. One recent scripting language, namely Ruby, is a pure object-oriented language, much like Smalltalk.

The reason for this trend is clear: economics. Computers are constantly getting faster (and thus, cheaper), while people are getting relatively more expensive. Also, the skill level required to develop small scripts is considerably less than that required to develop large programs in conventional programming languages. Thus, more and more applications will be developed using scripting languages.

94.2 Perl

“Larry Wall ... created Perl when he was trying to produce some reports from a Usenet-news-like hierarchy of files for a bug-reporting system, and *awk* ran out of steam. Larry, being the lazy programmer that he is, decided to over-kill the problem with a general purpose tool that he could use in at least one other place. The result was the first version of Perl.” [8]

Although Perl has its roots as a Unix scripting language, it is now widely available for most major computing systems, including Linux, Macintosh, and Windows. In this section we focus on the use of Perl as a typical scripting language for gluing applications together. Such applications include systems administration tasks, string processing, etc. Other scripting languages such as Python, Rexx, and Tcl can be used as well.

The authors themselves have used such scripting languages for:

- Systems administration tasks on a network of Unix computers, including:
 - Setting up new user accounts, including e-mail aliases and creating home directories
 - Running backups
 - Reconfiguring servers
 - Installing software
- Class management, including:
 - Converting electronic class rolls (off a mainframe computer) to a more convenient form
 - Managing an e-mail alias for each class
 - Grading support
- Replacing programs previously written in conventional programming languages such as C and Pascal. Such programs fall into a variety of subject domains, including simple utility programs, computer science research, etc.
- Web software (using the CGI interface), including:
 - Running the program portion of a national computer conference
 - Helping to manage the authors’ home Web site
 - Running an annual survey

FIGURE 94.1 Spreadsheet Containing Grade Information.

As a typical systems (or utility) usage, we present one of our classroom management scripts. The problem is to maintain a grade book consisting of numeric grades earned by each student on each assignment, quiz, test, and exam. Each grade may have different weights; for example, an exam may be more heavily weighted than a quiz. We would also like to provide a secure way for students to electronically access their grade records.

Specialized Web servers built for schools and universities, such as Blackboard and WebCt, provide such facilities through Web site login. However, the system described here evolved before the use of the Web became widespread. It relies instead on the use of e-mail to send grades to each student after each assignment or test is recorded.

We use a spreadsheet to do the grade management itself, one spreadsheet per class. An example spreadsheet is given in Figure 94.1. In this spreadsheet, column one is used for student names and column two is used for e-mail addresses. The rightmost two columns are weighted totals and averages. The intervening columns are used for grades on assignments and tests; at any point in time, any number of grade columns may be blank (empty).

Similarly, a perusal of the rows reveals that the first row is used for a descriptive title for each grade, and the second row for the maximum points for each grade. The last row is used to compute class averages for each assignment or test. The intervening rows contain the students records, one row per student.

The problem is to move the grade values from the spreadsheet to the e-mail system. The process consists of exporting the data in textual form from the spreadsheet and then using a Perl script to generate the e-mail. The spreadsheet output form used is comma-separated values, but using a colon as a field separator (because student names often have commas in them). We have found over the years that each spreadsheet application has its own, often unique definition of the format of comma-separated values. For our current spreadsheet the third row would appear as:

```
"Snoopy" : "snoopy@wm.edu" : 24 : 90 : : 114 : 91.2
```

In the remainder of this section, we describe a Perl script to solve this problem as a means of examining some of the features of the Perl language. Familiarity with programming, particularly the C language, is assumed. Finally, we summarize some of the features of Perl.

In Unix/Linux, a script may be marked as being executable, in which case the first line of the Perl script is a comment that gives the full path name of the Perl interpreter:

```
#!/usr/bin/perl
```

The sharp sign is the comment symbol, with comments terminating at the end of line. The exclamation mark is required by Unix/Linux to indicate that this comment is giving the path of the Perl interpreter.

In Windows or Mac OS (prior to Mac OS X), the Perl interpreter would be explicitly invoked and passed the script as an argument.

Next we set any global constants that are likely to change. For this script, there is only one, namely, the field separator character; currently, we use a colon for the field separator because student names often contain commas:

```
$sep = ":";
```

Perl variables that take on a scalar value such as a number or string must be prefixed with a dollar sign. Perl statements end with a semicolon. Note that the scalar variable `$sep` is not declared and has the type of its current value.

Next we read the header row and the max values row, do some processing of each, split each row into fields (original columns), and store each field into an array. Because the processing of each line is identical, we use a subroutine:

```
@title = &readSplit();
@max = &readSplit();
push(@max, "100");
```

In Perl, array variables are prefixed with an at symbol and subroutine calls with an ampersand. The third line above adds the string value denoting 100% to the end of the maximum grade value array.

Although it physically appears at the end of the script, we next examine the `readSplit` subroutine:

```
sub readSplit {
    $_ = <>;
    chomp;
    tr /"//d;
    return split(/$sep/);
}
```

The first line of the subroutine reads a line from the file `STDIN` (file handles are enclosed in the less-than-greater-than symbols and `STDIN` is the default file handle for input) and assigns it to the default scalar named `$_`. By default, the first command line argument to the script is opened using the file handle `STDIN`. The second line deletes the end of line character or characters from the line; because no subject or target is specified, the default scalar is used. The third line deletes all double quotes from the line. Finally, the `split` operator is used to split the fields of the default scalar into an array, which is then returned.

This subroutine highlights Perl's cryptic style, including the implicit use of the default scalar in the second through last lines of the subroutine. Similarly, the parentheses are unnecessary in the invocation of `split`; we tend to use parentheses even when unnecessary, as we believe it improves the readability of the script. While some programmers love Perl's brevity of expression, others feel the need for extra syntactic sugar to improve readability. One of the hallmarks of Perl as a language is its many alternative ways of doing the same thing.

Next, we get to the portion of the script that reads and processes each student. At first glance, it would appear that the e-mail message could be generated as each student record is read. Unfortunately, the class average for each grade is in the last line of input. So the line for each student is read, the end of line deleted, double quotes deleted, and the line stored in the student array, which is neither declared nor initialized. The loop terminates when the end of file is reached on `STDIN`:

```
while (<>) {
    chomp;
    tr /"//d;
    push(@student, $_);
}
@ave = split(/$sep/, pop(@student));
```

The last line removes the class averages from the last line of the student array and splits the fields (columns) into an average array, one field per array position.

Finally, we traverse the student array generating an e-mail for each student using Perl's `foreach` loop:

```
foreach (@student) {
    &sendMail(split(/$sep/));
}
exit;
```

Because no iteration variable is explicitly stated for the loop, the default scalar variable is used. The `exit` is unnecessary, but it serves to visually separate Perl's main program from its subroutines.

All that remains is to examine the subroutine that actually sends the e-mail message to each student:

```
sub sendMail {
    $name = shift;
    $email = shift;
    open(MAIL, "| mail -s Grades $email")
        || die "Cannot fork mail: $!\n";
    print MAIL "Re: Grades for $name\n\n";
    print MAIL "GRADE\t\tYOUR\tMAX\tCLASS\n";
    print MAIL "NAME\t\tSCORE\tSCORE\tAVE\n\n";

    $i = 1;
    foreach (@_) {
        $i++;
        next unless $title[$i];
        print MAIL "$title[$i]\t";
        print MAIL "\t" if length($title[$i]) < 8;
        if (/^\d/) { print MAIL int($_ + 0.5); }
        else { print MAIL $_; }
        print MAIL "\t$max[$i]\t";
        print MAIL int($ave[$i] + 0.5), "\n";
    }
    close(MAIL);
}
```

Perl does not declare formal parameters for its subroutines. Instead, actual arguments are passed through the default array `@_`. So the first two lines shift off the array the first two values passed, namely, the student's name and e-mail address.

The third line opens the file handle `MAIL` for output and pipes it to the Unix/Linux mail command. If the open fails, then the program dies with a descriptive message. The next three lines write some preliminary information that is part of the e-mail message, including column headers. The final line of the subroutine closes the file `MAIL`.

The `foreach` loop writes the grade information to the e-mail message, one grade per iteration. The first actual grade corresponds to the third column of the spreadsheet; like C, Perl uses zero-based arrays, so the first index used for the `title`, `max`, and `ave` arrays is two. Note that array references (e.g., line 2 of the loop) are made using C's bracket notation, but the subscripted array reference is treated as a scalar, and, hence starts with a dollar sign rather than an at sign. This is a common point of confusion for Perl novices.

The second line of the `foreach` skips the remainder for the loop if there is no grade title, implying that the grade column is empty. The fifth and the last lines of the loop convert numbers with decimal places to rounded whole numbers; the test used in the `if` in the fifth line is a pattern that tests whether the value starts with a digit.

We have presented a typical glue program in order to discuss some of the salient features of Perl. In roughly 36 lines of Perl (not counting blank lines, comment lines, and closing brace lines), we have presented a script that takes a spreadsheet containing student grade information and e-mails each student his or her grades, together with individual, assignment, and class averages. Roughly half the lines of code are devoted to generating the information in the e-mail message itself.

This typical glue script linking two disparate applications exposes many commonly used features of Perl:

- Perl supports a wide variety of alternative ways of coding the same basic idea. This makes Perl a more difficult language to learn. It also makes it more difficult to read Perl code, because the code can use unfamiliar features.
- Perl does not require declaration of variables and supports dynamic typing. The same value can be treated either as a string or as a number (provided it can be interpreted as a valid number).
- Perl supports a wide variety of string operations. It also supports pattern matching as found in the Unix utilities `grep` and `sed`.
- Many Unix utilities such as `tr` are included as Perl operators.
- Convenient access is provided for executing system utilities, either providing its input or capturing its output.
- Perl provides both dynamically sized arrays and associative arrays (hash tables).

Despite some of the criticisms above, Perl is one of the most widely used scripting languages for non-GUI applications. In the next section, we explore scripting GUI applications.

94.3 Tcl/Tk

In the late 1980s, John Ousterhout and his students found themselves repeatedly developing interactive tools for integrated circuit design. This activity led Ousterhout to perceive the need for a re-usable scripting language built as an extensible C library package, and he developed the Tcl language as a result. The introduction of HyperCard by Apple Computer in 1987 provided the impetus for Ousterhout to develop a component-based graphical toolkit, Tk, based on Tcl and the X11 windowing system.

Tcl/Tk [6] has grown into a scripting language framework within which graphical user interfaces can be easily developed. Perhaps the most widely used Tcl/Tk application is the `exmh` mail user interface that is included in most Linux distributions, written by Brent Welsh (a Ph.D. student of Ousterhout's). The authors of this article have used Tcl/Tk to produce X11 GUIs in class management tools for configuring course submission software [2] and in the debugging tool for the BACI mutual exclusion toolbox [1].

In the remainder of this section we present a GUI program derived from a more extensive one developed for configuring a student project submission system [2]. A class roll supplied by the Registrar contains the student's first and last names, but does not contain the student's login name for the Computer Science LAN. The program discussed here searches the system login name file for a first and/or last name fragment and lists the login name and full name fields of all entries that match the name fragments. For example, [Figure 94.2](#) shows the result of a (case-insensitive) search for the first name string `bill`. [Figure 94.3](#) shows the result of a subsequent search for the last name `noonan`.

On many UNIX systems, user information is kept in a system text file named `/etc/passwd`. A typical line of this file has the form:

```
bynum:abcdefghij:34:20:Bill Bynum:/home/f85/bynum:/bin/tcsh
```

The fields of each line of `/etc/passwd` are colon separated, as in the spreadsheet example discussed in [Section 94.2](#). The contents of these fields are login name (user id), encrypted password, user id number, group id number, user's full name, login directory, and default shell.

In this application a search is initiated by clicking the `Find` button. The results pane is cleared by clicking the `Clear` button. The program is terminated by clicking the `Quit` button.

FIGURE 94.2 Searching for first name bill in /etc/passwd.

FIGURE 94.3 Searching for last name noonan in /etc/passwd.

To illustrate the capabilities offered by Tcl/Tk for handling keyboard events, this program binds the Tab keypress event so that the keyboard-oriented user can use the Tab key and the space bar to interact with the program, rather than having to alternate between the keyboard and mouse. When the program begins, the first name entry field is the focus of the window. When the user presses the Tab key, the focus shifts to the last name entry field. A subsequent press of the Tab key shifts the focus to the Find button. Another Tab press shifts the focus to the Clear button. Subsequent Tab keypresses shift the focus to the Quit button and then back to the first name entry field. The user can cause a button press from the keyboard by pressing the space bar when the window focus is on the button.

In the subsections that follow, we present each of the parts of the program, starting with the main program. We conclude by comparing Tcl/Tk with Perl.

94.3.1 The Main Program

The main program is quite modest, consisting of only five lines:

```
#!/usr/bin/wish
option add *Font "-misc-fixed-medium-r-normal-*-*-*-*-*-*-*-*"
wm withdraw .
lookup_uids
exit
```

Like the Perl script in [Section 94.2](#), the first line gives the path to the interpreter to be used, in this case the Tk WIndowing SHell. The second line establishes the font to be used in the window created by the application. In the absence of any action by the user, the windowing shell puts up a default window for the application to use. The third line instructs the user's window manager not to show this default window, because the parameterless `lookup_uids` procedure called in the fourth line will create its own window. The `exit` statement in the fifth line terminates the program and the windowing shell. As with Perl, the sharp sign is the comment symbol, with comments terminating at the end of line.

94.3.2 The `lookup_uids` Procedure

The `lookup_uids` procedure is mainly responsible for laying out the widgets seen in [Figures 94.2](#) and [94.3](#). Unlike Perl, procedures in Tcl/Tk use formal parameter lists much as in C. The `lookup_uids` procedure has no parameters, so its header has an empty list of formal parameters. The rightmost left brace begins the source block for the procedure and its matching right brace ends the procedure:

```
proc lookup_uids { } {
    toplevel .luu
    wm title .luu "Look Up User ID in /etc/passwd"
    wm geometry .luu +250+50
    # insert code discussed below
} ;# lookup_uids
```

First, the procedure describes the position of the window in the window hierarchy (“`toplevel`”) and gives the title of the window and its geometry.

Next, the procedure builds the window used by the application from top to bottom in horizontal strips, using the default Tcl/Tk geometry manager called the “`packer`.” Tcl/Tk frames are used for the more complicated horizontal strips that contain several widgets.

The first widget placed in the window is an explanatory label:

```
label .luu.l1 -text "Search /etc/passwd for first and/or last name"
pack .luu.l1 -side top -anchor w -padx 1
```

Notice that the label is constructed with the `label` statement, and then the label is packed into the `.luu` window on the “`top`” side of the window and is anchored on the left (or “`west`”) side (that is, is left-justified in the window). The `padx` option of the `pack` statement adds a 1-pixel horizontal (x) pad on each side of the label in the window.

The first frame of the window `.luu.f1` holds the properly labeled entry widgets for the first and last names to be searched for, plus the `Find` button. First, the frame must be declared; then widgets are added to the frame from left to right, starting with the label for the first name entry widget and the entry widget.

```
# frame .luu.f1 holds the first & last name and the Find button
frame .luu.f1
label .luu.f1.l1 -text "First name"
pack .luu.f1.l1 -side left -in .luu.f1 -anchor w -padx 1 -pady 3
entry .luu.f1.e1 -relief sunken -width 10 -textvariable lfname
pack .luu.f1.e1 -in .luu.f1 -side left -padx 1 -pady 3
```

The `label` command labels the entry field for the first name. In the following `pack` command, the `-in` option tells the packer to place the label in the `.luu.f1` frame. The `entry` command creates a user-modifiable text field where the user can enter the first name of the person whose login name is to be searched for. The `-textvariable lfname` option of this command creates a global variable `lfname`, which holds the text the user enters. The `pack` command is required to pack the first name entry field in the frame to the right of the label.

The label and entry for the last name field are created and packed into the frame in a similar manner:

```
label .luu.f1.l2 -text "Last name"
pack .luu.f1.l2 -side left -in .luu.f1 -anchor w -padx 5 -pady 3
entry .luu.f1.e2 -relief sunken -width 10 -textvariable lname
pack .luu.f1.e2 -side left -in .luu.f1 -padx 1 -pady 3
```

The `.luu.f1` frame is completed with the addition of the Find button:

```
button .luu.f1.b -text Find -command {lookup_by_name}
pack .luu.f1.b -side left -in .luu.f1 -padx 1 -pady 3
pack .luu.f1 -side top -fill x -expand true
```

Construction of the button widget is accomplished with the `button` command. The `-text Find` option specifies the text that should appear on the button. The `-command` option specifies the procedure that should be called when the button is clicked, `lookup_by_name` in this case, which will be discussed below.

The scrollable pane where the search results are displayed is created in the `.luu.f2` frame. Construction is started by declaring the frame and then packing a “Search Results” label to identify the frame to the user.

```
# frame .luu.f2 holds the scrollable results window
frame .luu.f2
label .luu.f2.l -text "Search Results"
pack .luu.f2.l -in .luu.f2 -side top
```

The label is centered in the window, because no other widgets are packed with it and no `-anchor` is used.

The scrollable area is created with a combination of the `listbox` and `scrollbar` commands to create and interlink the `listbox` and `scrollbar` widgets.

```
listbox .luu.f2.lb -width 40 -height 5 -yscrollcommand .luu.f2.sy set
pack .luu.f2.lb -side left -fill both -expand true -in .luu.f2
scrollbar .luu.f2.sy -orient vert -command .luu.f2.lb yview
pack .luu.f2.sy -side right -fill y -in .luu.f2
pack .luu.f2 -side top -fill both -expand true
```

A `listbox` widget displays a collection of strings, allowing the user to scroll the list. The `-yscrollcommand` option identifies the `scrollbar` widget that will scroll the `listbox` widget. Whenever the view in the `listbox` changes, the `listbox` calls the `.luu.f2.sy set` command with the four numbers: the total number of entries currently in the `listbox`, the number of entries that fit in the window at any one time, and the indices of the entries currently visible in the window.

The next frame holds the Clear button:

```
# frame .luu.f3 holds the Clear button
frame .luu.f3
button .luu.f3.b -text Clear -command { .luu.f2.lb delete 0 end; \
    if [info exists puid] { unset puid }; \
    if [info exists pname] { unset pname } }
pack .luu.f3.b -in .luu.f3 -side right -anchor e -padx 1 -pady 3
pack .luu.f3 -side top -expand true -fill x
```

The `-command` option of the `button` command illustrates that the command activated by clicking a button can be given directly by code snippet, instead of a procedure call, as we saw in the creation of the Find button above. The `.luu.f2.lb delete 0 end;` command deletes all text from the beginning of the `.luu.f2.lb` `listbox` to the end. The backslash at the end of the line is the Tk line continuation character.

The `if [info exists puid] { unset puid }` command is an if statement where the variable `puid` is checked for existence with the built-in `info` function. The `set` command is the assignment

operator, and the `unset` command is its inverse. These two `if` statements ensure that the `puid` and `pname` global variables are cleared.

The last widget to be added to the window is the `Quit` button:

```
button .luu.qb -text "Quit" -command { destroy .luu }
pack .luu.qb -side top -fill x -expand true
```

The `Quit` button spans the window because of the `-fill x` option in the `pack` statement.

Finally, we add a series of bindings of the window widgets to `Tab` keypress events so that the user can cycle through the widgets of the window by pressing the `Tab` key.

```
bind .luu.f1.e1 <Tab> \
    { focus .luu.f1.e2; .luu.f1.e2 select range 0 end; break }
    # select what's in the .luu.f1.e2 field so user can change it
bind .luu.f1.e2 <Tab> { focus .luu.f1.b; break }
bind .luu.f1.b <Tab> { focus .luu.f3.b; break }
bind .luu.f3.b <Tab> { focus .luu.qb; break }
bind .luu.qb <Tab> \
    { focus .luu.f1.e1; .luu.f1.e1 select range 0 end; break }
```

The first `bind` command specifies that when the cursor is in the `.luu.f1.e1` first name entry widget and a `Tab` keypress event occurs, then the window focus should shift to the `.luu.f1.e2` last name entry widget and the text in that widget from first to last character should be selected, allowing the user to edit the existing text in the widget. The `break` command terminates the current binding and suppresses bindings from any remaining widgets in the binding list. The `bind .luu.f1.b` is the only statement that really needs a `break` statement. If this `break` statement were missing, the focus would shift to the next element of the window, the first line of the `.luu.lb` listbox instead of jumping over the intermediate widgets to the `Clear` button.

The `lookup_uids` procedure ends with the statements:

```
# start with the first name entry field
focus .luu.f1.e1
# wait here for the window .luu to be destroyed
tkwait window .luu
```

The `focus` command sets the window focus in the first name entry field, where the user can enter the student's first name. The `tkwait` statement causes the procedure's thread of execution to wait at this point until the window is destroyed. If the statement were not present, the procedure would probably terminate before (or soon after) the window that it creates is displayed. Recall that the command action of the `Quit` button was also to destroy the window. When the user clicks the `Quit` button, the `.luu` window disappears, the `lookup_uids` procedure returns to the `exit` statement in the main program, and the program terminates.

94.3.3 The `lookup_by_name` Procedure

The purpose of `lookup_by_name` procedure is to display any matches found in the scrollable text widget. The procedure is parameterless, using the global variables `lfname`, `llname`, `pname`, and `puid` for its input parameters. It is unnecessary to declare local variables that are used in a procedure; by default, all variables used in a procedure are local, unless they are explicitly declared as global.

```
proc lookup_by_name { } {
    global lfname
    global llname
    global pname
    global puid
```

```

    set ret [find_uid_from_name $lfname $llname]
    # set and if statements -- see below
} ;# lookup_by_name

```

The `set` command is the assignment statement. In this case, the actual work of looking up the first name and last name strings is performed by the `find_uid_from_name` procedure with the two parameters `$lfname` and `$llname`. Like Perl, the `$` symbol indicates the current values of the variables. The square brackets signify a function call. The result of the call is stored in the `ret` variable.

The remainder of the procedure consists of an `if` statement to deal with the different possible values of the `ret` value returned by the call:

```

if {$ret == 0} {
    puts "firstname: \"$lfname\" lastname: \"$llname\" was not found"
} elseif {$ret >= 1} {
    for {set i 0} { $i < $ret} {incr i} {
        .luu.f2.lb insert end [format "%-10s %-20s" $puid($i) $pname($i)]
        .luu.f2.lb see end
    }
} else {
    ;# should never happen
    puts "Weird return: $ret"
}

```

In case the value returned is zero, the message that the first name/last name combination was not found in is written with a `puts` statement to standard output; in the original application, this message is displayed in a pop-up window. The use of `puts` considerably simplifies this example.

The results of a successful search in `find_uid_from_name` call are passed back to this procedure through the `puid` and `pname` variables. These variables are actually Tcl/Tk associative arrays, indexed by the strings 0, 1, and so on. The syntax of the Tcl/Tk for loop is quite similar to the syntax of the C for loop. The `{set i 0}` sets the loop variable to zero at the beginning of the loop. The `{ $i < $ret }` is the continuation test of the loop, and the `{incr i}` instruction is the action performed each time the body of the loop is executed; in this case, the action consists of incrementing the loop variable by one. The `.luu.f2.lb see end` makes sure that the listbox keeps the last line of the listbox visible.

The `find_uid_from_name` procedure never returns a negative value, so the final `else` should never be executed. Its inclusion here is strictly a good defensive strategy.

94.3.4 The `find_uid_from_name` Procedure

The `find_uid_from_name` procedure performs all the non-GUI real work of searching the login name file for matches:

```

proc find_uid_from_name { fname lname } {
    global puid
    global pname
    if [info exists puid] { unset puid } ;# clear global arrays
    if [info exists pname] { unset pname }
    if [catch [list exec grep -i "$fname $lname" /etc/passwd] pwinfo ] {
        return 0
    } else { ;# got a hit
        # split result of grep into lines
        set lnamelist [split $pwinfo "\n"]
        # first look through to see if we get an exact first/last name
        # match. If so, then return the uid and first/last name
    }
}

```

```

# in puid(0) and pname(0)
for {set i 0} { $i < [llength $lname] } { incr i } {
    set pentry [lindex $lname $i]
    set pline [split $pentry : ]
    set tuid($i) [ lindex $pline 0 ]
    set tname($i) [lindex $pline 4]
    if { "$fname" == "[lindex $tname($i) 0]" } {
        if { "$lname" == "[lindex $tname($i) 1]" } {
            set puid(0) $tuid($i)
            set pname(0) $tname($i)
            return 1
        }
    } ;# if exact match
} ;# for
# return all hits in the puid and pname arrays
set lastuid $i
for {set i 0} { $i < $lastuid } { incr i } {
    set puid($i) $tuid($i)
    set pname($i) $tname($i)
}
return $lastuid
} ;# end else got a hit
} ;# find_uid_from_name

```

The procedure first globalizes the `puid` and `pname` arrays that will be used to return the search results to its caller. The first two `if` statements clear the two arrays with the `unset` command.

The `catch` statement is the exception-handling statement. It has two arguments. The first argument is a **list** (a blank-separated collection of words) for the Tcl/Tk interpreter to execute and the second argument is a variable into which the result of the execution is placed. If there is an error in executing the first argument, then the `catch` statement returns **true** (or 1) and the second argument contains the error message from the execution; otherwise, `catch` returns 0 and leaves the result of the execution in the second argument. In this function, the `catch` clause simply returns 0 to the procedure's caller if there is an error.

On the other hand, if the execution of the case-insensitive `grep` of `/etc/passwd` is successful, then the thread of execution moves to the `else` clause. The `lname` list variable is created by splitting the string returned by the `grep` on the newline character (`\n`). The first `for` loop looks through the `lname` list of lines for a first name/last name match. The `llength` function returns the length of a list. The `set pentry` statement stores the *i*-th element of the `lname` list in the `pentry` variable. The `set pline` creates the `pline` line from `/etc/passwd` on the colon symbol. The *i*-th entry of the `tuid` array is obtained from the 0-th entry of the `pline` list, and the first/last name list is stored into the *i*-th entry of the `tname` array from the 4-th entry of the `pline` list.

On the other hand, if the first `for` loop terminates without finding such a match, then the second `for` loop transfers the matches that were found to the `puid` and `pname` arrays and returns the number of matches found.

94.3.5 Summary

In this section we have presented a typical GUI-based event-driven application in the scripting language Tcl/TK in order to demonstrate features of the language. Of the approximately 80 lines of code, approximately 70% are devoted to various aspects of the GUI. In the actual application, the percentage is higher due to the use of pop-up windows and the omission of some features.

We note both similarities and differences when comparing Tcl/Tk to Perl:

- Unlike Perl, Tcl/Tk does not offer the programmer a wide variety of different ways of coding the same construct. Although the programming functionality offered by Tcl/Tk is comparable to that of Perl, Tcl/Tk usually offers only one way to code each construct.
- Like Perl, Tcl/Tk does not require declaration of variables and supports dynamic typing.
- Tcl/Tk, like Perl, supports a wide variety of string operations, although some programmers feel that the Tcl/Tk string operations are more awkward to use.
- Like most scripting languages, a convenient method is provided to execute system utilities, supplying input and capturing their output.
- Tcl/Tk, like Perl, provides dynamically sized arrays and associative arrays.
- Unlike Perl, Tcl/Tk subroutines use formal parameters to declare the arguments in the subroutine source. Also the actual parameters are passed explicitly in the call, rather than passing the parameters through a default array.
- Although not explicitly event-driven, both Perl and Python provide an interface to the Tk toolkit in order to support the development of GUI-based applications.

In the next section, we explore a language explicitly developed for supporting server-side Web applications.

94.4 PHP

According to its developer, Rasmus Lerdorf, the motivation for developing PHP [4] was the following:

“As the Web caught on, the number of non-coders creating Web content grew exponentially. . . . But soon they were asked to add dynamic content to their sites. . . . This is where PHP found its niche. . . . I had written all sorts of CGI [Common Gateway Interface] programs in C, and found that I was writing the same code over and over. What I needed was a simple wrapper that would enable me to separate the HTML portion of my CGI scripts from my C code . . . This concept became PHP.”

PHP was initially developed by in 1994, but within a few years usage grew beyond the abilities of a single developer, so it became an open-source product. PHP is a server-side scripting language intended as an alternative to using CGI programming. As such, PHP is intended for Web pages with dynamic content, including forms processing and database access.

At our site PHP is installed on the university’s main Web server. Typical PHP usage includes:

- Dynamic content such as including an image or news item of the day.
- Forms processing, including forms validation.
- Database access, using several distinct databases.

The PHP processor takes a document file as input and produces HTML as output. Like JavaScript, the input file consists of a mixture of HTML and PHP script code, which is marked by special HTML-like tags. The major difference from JavaScript is that in the case of PHP the script is executed on the server, not on the client. This provides a level of security that is unachievable with JavaScript, since the PHP script is never downloaded to the Web browser. This is particularly important in the case of database access and updating.

The PHP processor operate in two modes of operation. It begins in copy mode in which HTML tags and text directly to the output. When it encounters the special tags:

```
<?
# one or more lines of PHP script
?>
```

the PHP processor switches to script mode, which interprets the script. The output from the script, whatever is written to `STDOUT`, replaces the script in the resulting HTML page. As with Perl, the hash mark is used to denote a comment, which continues until the end of the line.

As in the two previous sections, we will use a single example as a vehicle for exploring the features of PHP. Familiarity with both HTML tags and C programming is presumed. In this example, we examine the use of a PHP script in conjunction with a database to produce department directories, one each for the faculty, staff, and graduate teaching assistants. The directory desired is specified as a parameter in the URL; for example,

```
http://www.cs.wm.edu/people/index.php?id=Faculty
```

The script then accesses the appropriate database table, in this case the faculty table, and generates the appropriate HTML output.

Because these directories are fairly static, the question arises: why not maintain the information as static HTML pages. One answer is that in the current setup the staff people who maintain this information only deal with a form that interfaces to the database; they need not know or care about HTML. Second, using PHP allows the Webmaster to more easily maintain a consistent look and feel to these Web pages. Third, the information is used in other portions of the Web site.

A PHP page begins in HTML mode; this would be used to set up the page in a site-specific standard format, including the title, background color, navigation buttons, etc. Because HTML lacks an include facility, a common use of PHP is to set up the page via parameterized header and trailer files. In this case, we begin by including a header:

```
<? $title = $id;
    include "header.inc";
?>
```

The header expects a `title` variable to be set. In this case, the value comes from the variable whose name is identical to the parameter in the URL.

Before we begin setting up the body of the page, we want to check the `id` parameter for a valid value. Because this value is used to access a database table, a malicious user could attempt to attack the database by providing an unexpected value:

```
<? if (!ereg(" :Faculty:Staff:GradTA:", " :$id:"))
    errorPage($id);
?>
```

In this case, we test the value supplied for the `id` parameter using a pattern match against the three legal values. If the pattern match fails, an error routine is called, which generates an error page and exits with no further processing.

Otherwise, database access code is included, which sets the name of the database, security information including `userid` and `password`, etc.:

```
<? include "dbaccess.inc";
    $result = mysql_query("select * from $id");
?>
```

The `select` SQL statement is shown, which in this example accesses the faculty directory in the database.

At the current time, each of these three database tables contains the following information for each person:

- The person's name
- A URL, if they have a home page
- Their office address
- Their phone number
- Their e-mail address

The information is to be generated as an HTML table with one row per person. Each column should have an appropriate heading. So the next part of the script is pure HTML code:

```
<center>
<table cellspacing=5 cellpadding=5 border=2>
<tr align=left><th>Name</th><th>Office</th>
    <th>Phone</th><th>Email</th></tr>
```

Next comes the main logic of the script. A `while` loop is used to fetch one row of the result of the SQL query representing one person. That result is returned as an array, so the `list` function is used to assign the array values to conveniently named variables. The body of the loop consists mostly of print statements to write the appropriate columns:

```
<? while (list($name,$url,$office,$phone,$email)
    =mysql_fetch_array($result)) {
    print "<tr align=left>\n";
    $lname = $name;
    if ($url != "")
        $lname = "<a href=$url>$name</a>";
    print "<td>$lname</td>\n";
    print "<td>$office</td>\n";
    print "<td>$phone</td>\n";
    print "<td><a href=mailto:$email>$email</a></td>\n";
    print "</tr>\n";
}
?>
```

As with Perl, variable references may be freely embedded in double-quoted strings. The name field is made into a link if the person has a non-empty URL field.

All that remains is to close the `table` and `center` HTML tags and invoke the standard Web site trailer:

```
</table>
</center>
<? include "trailer.inc"; ?>
```

This script is a typical example of server-side scripting and exposes commonly used features:

- PHP scripts freely alternate between pure HTML and PHP.
- PHP does not require the declaration of variables and supports dynamic typing. The same value can be treated both as a string and as a number (provided it can be interpreted as a valid number).
- PHP supports a wide variety of string operations. It also supports pattern matching as found in the Unix utilities `grep` and `sed`.
- PHP provides both dynamically sized arrays and associative arrays (hash tables).
- PHP directly supports accessing information from a database.
- Security is a major concern in Web scripting.

PHP and Macromedia's ColdFusion are widely used for producing dynamic Web content. Their ability to freely switch between HTML coding and scripting makes them very useful for Web scripting.

94.5 Summary

In the past 15 years, scripting languages have emerged as more than merely enhanced job command languages. In this chapter we have explored the usage of scripting for gluing components together, for building simple GUI interfaces, and for developing Web applications. The phenomenal increase in computer power has enabled the use of scripting for developing relatively small applications. We expect the trend toward using scripting languages over conventional programming languages for application development to continue.

Defining Terms

Common Gateway Interface (CGI): CGI is essentially what a Web server must provide in order to allow an external script or program to create Web pages:

- An environment containing server information, including the HTTP request
- An input file containing form data if the request used the post method
- An output file for the CGI program to write its response; this output is returned as the resulting Web page

Dynamically typed: In a dynamically typed language, each value is typed; a variable has the type of its current value. *See also* typeless.

Script: A program written in a scripting language.

Scripting: The act of writing a program in a scripting language.

Statically typed: In a statically typed language each variable be explicitly declared and that a type be associated with the variable. This allows the compiler to check the usage of a variable at compile time to ensure that the operations performed on a variable are consistent with its type.

Typeless: From a programmer's perspective, the variables in a dynamically typed language appear to be typeless in that there types are not declared.

Further Information

The computer section of your favorite bookstore is a good place to find books on the more popular scripting languages. Online bookstores such as amazon.com or buy.com contain more extensive collections but lack the ability to peruse books of interest.

There is also a great deal of information available on the Web. For perusing information in general, we recommend Yahoo. For general searching about a specific scripting language, we recommend Google.

The standard reference book on Perl is [9], although some programmers find it a bit overwhelming. Many more gentle introductions to Perl are available, including [8]. To obtain more information on Perl or to obtain a Perl distribution, see the Web site www.perl.org. The online comprehensive Perl archive for contributed programs and packages is at www.cpan.org.

The standard reference book on Tcl/Tk is [6], although some programmers find it a bit overwhelming. The online Tcl developer's exchange is at www.tcl.tk.

There are many good books on PHP. The official PHP Web site is at www.php.net. There is an excellent online tutorial at www.phpbuilder.com.

Finally, an excellent online resource for open source scripting languages is www.devshed.com.

 - Interactive Games: Tic-Tac-Toe
 - Automated Teller Machine
 - Home Security Alarm System

The *event-driven* programming paradigm turns the fundamental model of computation inside out, in that event-driven programs do not predict the control sequence that will occur. Instead, they are written in a way that the program reacts reasonably to any particular sequence of events that may occur once execution begins. In this way, the input data govern the particular sequence of control that is actually carried out by the program. Moreover, execution of an event-driven program does not typically terminate; such a program is designed to run for an arbitrary period of time, often indefinitely.

The most widespread example of an event-driven program is the mouse- and windows-driven graphical user interface (GUI) found on most desktop and laptop computers in use today. Event-driven programs also drive Web-based applications. For example, an on-line student registration system must be prepared to interact with a student no matter what her next action is: adding a course, dropping a course, determining the classroom where a course meets, and so forth. An on-line airline reservation system, similarly, must be prepared to respond to various sequences of user events, like changing the date of travel, the destination city, or the seating preference.

Although the event-driven programming paradigm has been in use much longer than the Web, it has only recently become prominent in the eyes of programmers because of the Web. Before the Web (if we can imagine such a time!), event-driven programs were found embedded in a variety of vehicles and devices, such as airplanes and home security systems. In these environments, the events that trigger programmed responses include a change in direction, wind speed, or temperature; by their nature, these events also do not occur in any predictable order.

To provide effective support for event-driven programming, some languages have developed some basic terminology and principles of design. Most recently, these principles have appeared in Java, although other languages, like Visual Basic and Tcl/Tk, also support event-driven programming. In this chapter, we use Java as the primary vehicle for illustrating the principles and practice of event-driven programming.

95.1 Foundations: The Event Model

The traditional programming paradigms have more clearly defined lineage than the event-driven paradigm. For example, functional programming has clear and traceable roots in the lambda calculus, as logic programming has in Horn clause logic. However, event-driven programming is in a more infantile stage of development, so its theoretical foundations are less clear and not as universally understood or accepted at this time.

One model of event-driven programming, offered by Stein [1999], explains event-driven programming by contrasting it with the traditional view of computation (which embodies the imperative, functional, and object-oriented paradigms) [Stein 1999, p. 1]:

“Computation is a function from its input to its output. It is made up of a sequence of functional steps that produce — at its end — some result as its goal. . . . These steps are combined by temporal sequencing.”

Stein argues that modern computations are embedded in physical environments where the temporal sequencing of events is unpredictable and (potentially) without an end. In order to cope with this unpredictability, Stein claims that computation needs to be modeled as *interaction* [Stein 1999, p. 8]:

“Computation is a community of ‘persistent entities coupled together by their ongoing interactive behavior. . . .’ Beginning and end, when present, are special cases that can often be ignored.”

This view is well supported by the wide range of applications for which computer programs are now being designed, including robotics, video games, global positioning systems, and home security alarm systems.

A more extreme view is offered by Wegner [1997], who claims that interaction is a fundamentally more powerful metaphor than the traditional notion of algorithm (i.e., anything that can be modeled by a Turing machine). This view, which claims that there are interactive programs representative of a more powerful genre that cannot be systematically reduced to Turing machines, has received considerable recent discussion in the literature. Wegner has made efforts to further develop the underlying theory that would support it [Wegner 1999]. If successful, this work may have significant and long-lasting impact on our fundamental understanding of computing theory.

These concerns notwithstanding, the Wegner–Stein approach to describing computation as interaction provides a fairly rigorous foundation for modeling event-driven programming as it is practiced today.

95.2 The Event-Driven Programming Paradigm

The event-driven paradigm is different from the imperative paradigm in a way that is summarized in Figure 95.1.

Here, we see that the imperative paradigm models a computation as a series of steps that have a discrete beginning and ending in time. Input is generally gathered near the beginning of the time period, and results

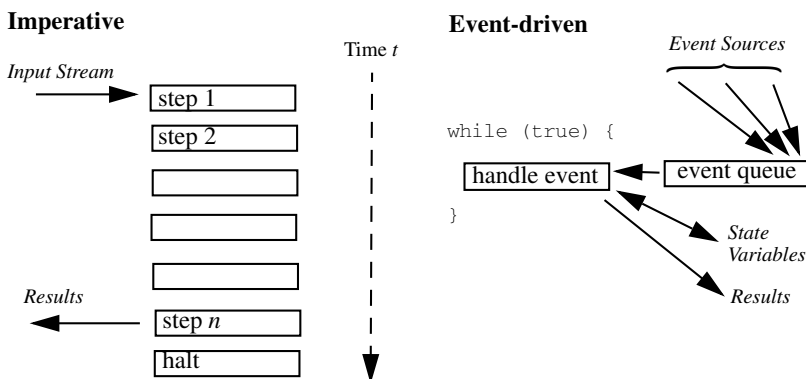

FIGURE 95.1 The imperative and event-driven paradigms contrasted.

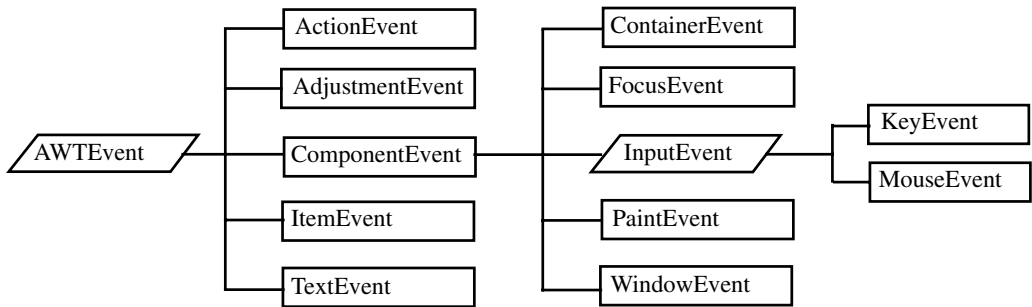

FIGURE 95.2 Java class AWTEvent and its subclasses.*

are generally emitted near the end. Some variations, of course, would have input and results continuously occurring, but nevertheless, the process has a distinct ending time.

In contrast, the input to an event-driven program comes from different autonomous *event sources*, which may be sensors on a robot or buttons in an interactive frame in a Web browser. These events occur asynchronously, so each one enters an event queue whenever it occurs. As time passes, a simple control loop receives the next event by removing it from this queue and handling it. In the process of handling the event, the program may consult and/or change the value of a *state variable* or even produce intermediate *results*. Importantly, we see that the event-driven program is designed to run forever, with no predefined stopping point, as appears in an imperative program.

Java provides direct support for event-driven programming by providing certain classes and methods that can be used to design an interaction. When we design an interaction, our program must classify the events that can occur, associate those event occurrences with specific objects in the frame, and then handle each event effectively when it does occur.

The types of events that can occur in Java are defined by the subclasses of the predefined abstract class AWTEvent. These subclasses are summarized in Figure 95.2.

Every event source in an interaction can generate an event that is a member of one of these classes. For instance, if a button is an event source, it generates events that are members of the `ActionEvent` class. We shall discuss the details of this relationship below.

The objects themselves that can be event sources are members of subclasses of the abstract class `Component`. A summary of these classes is given in Figure 95.3.

Here we see, for example, that any button be selected by the user in an interaction is declared as a variable in the `Button` class.

In order for a program to handle an event, it must be equipped with appropriate listeners that will recognize when a particular event, such as a click, has occurred on an object that is an *event source*. The `EventListener` class contains subclasses that play this role for each of the event classes identified previously. These are summarized in Figure 95.4.

For example, to equip a button so that the program can “hear” an occurrence of that button’s selection, the program needs to send it the message `addActionListener`. If this is not done, button events will not be heard by the program. This is more fully discussed in Section 95.3.

Finally, in order to respond to events that are initiated by objects in these classes, we need to implement special methods called *handlers*. Each class of events predefines the name(s) of the handler(s) that can be written for it. A summary of the handlers that are preidentified for button selections, choice (menu) selections, text typing, and mouse events is given in Figure 95.5.

In the next section, we illustrate how these classes come together to support the event-driven design process in Java.

*In these class diagrams, abstract classes are enclosed in parallelograms, while nonabstract classes are enclosed in rectangles.

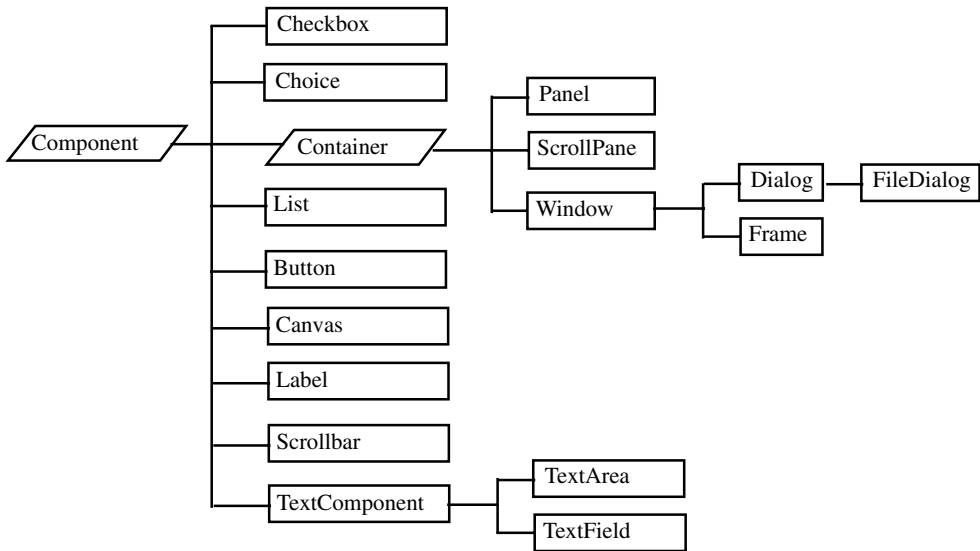

FIGURE 95.3 Subclasses of Component that can be sources of events.

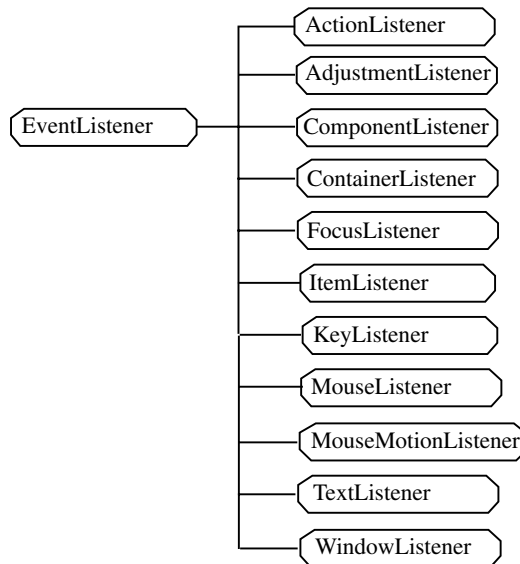

FIGURE 95.4 Java EventListener class interface and its subclasses.*

95.3 Applets

An *applet* is a Java program that runs inside a Web browser. It provides a framework for programmers to design event-driven programs where the source of the events is the user interface.

Because they are designed to react to events rather than initiate them, applets have a slightly different structure than Java applications; this structure is sketched in [Figure 95.6](#). The first three lines shown

*Enclosing a class in a hexagon distinguishes it as a class interface, rather than a regular class.

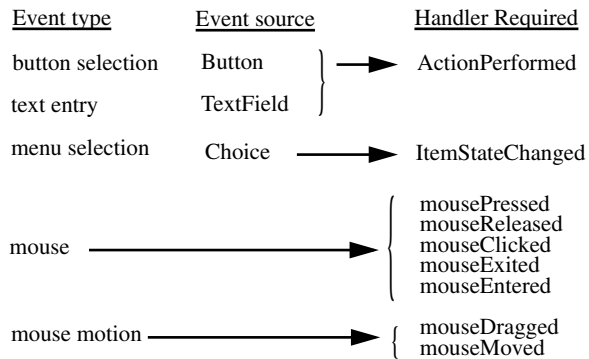

FIGURE 95.5 Handlers required for button, menu, text typing, and mouse events.

```

import java.applet.*;
import java.awt.*;
import java.awt.event.*;
public class <classname> extends Applet
    implements <listeners>{
    <state variable declarations>
    public void init (){
        <code to initialize the applet>
    }
    <event handlers>
}

```

FIGURE 95.6 Overall structure of a Java applet.

in this figure are necessary to provide access to the Java class libraries, where the various event-driven programming classes are located.

The *<state variable declarations>* define various objects that can be placed in the applet, as well as other values that help the program remember what has occurred so far. As with any other class, these variables collectively define the *state* of the interaction, just as in Java application programs. Moreover, variables may also represent buttons, menus, text fields, and other objects that have special functions as the program and the user interact.

An applet is different from other classes in that it has no constructor. Instead, when the applet begins executing, the `init` method is executed first. It has the responsibility of placing objects in the frame, such as buttons, choices, labels, and text fields. In this sense, the `init` method takes the place of a constructor. The `init` method also attaches specific event listeners to different objects in the frame, so that these objects can be equipped with “ears” that recognize when they have been selected by the user. Event listeners are nothing more than objects that implement a particular interface; they can be the applet itself, as indicated above, or they can be separate classes. As we will see, such classes often need access to various applet methods, so they are commonly implemented as inner classes.

As a GUI, an applet often has a `paint` method, which is invoked whenever the applet needs to repaint itself. This can occur for a number of reasons: a window partially obscured the applet for a time, the applet was first iconified and then deiconified, etc. Components such as buttons, text fields, etc., will repaint themselves. However, anything done directly to the frame using `Graphics` methods will be lost during a repaint operation if not done in the `paint` method. Other major applet methods, `start`, `stop`, and `destroy`, are not discussed here.

For each specific kind of event (like a button selection, a mouse click, or a menu choice selection), the program must implement a special method called an *<event handler>*. The purpose of the handler is to change the state of the interaction so that it “remembers” that such an event has occurred. One handler is programmed to respond to the user’s pressing the mouse button, while another may respond to the user’s selecting a button in the frame. Whenever such an event actually occurs, its associated handler is executed one time.

The *<listeners>* that appear in the heading of the applet identify the *kinds* of events to which the applet is prepared to respond. Usually, four different kinds of user-initiated events can be handled by an applet:

Mouse motion events — Handled by the `MouseMotionListener`

Mouse events — Handled by the `MouseListener`

Button and text field selections — Handled by the `ActionListener`

Selections from a menu of choices — Handled by the `ItemListener`

Importantly, the program cannot know, or predict, the order in which these different events will occur or the number of times each one will be repeated; it must be prepared for all possibilities. That is the essence of event-driven programming.

95.4 Event Handling

In this section, we describe the basic Java programming considerations for responding to various types of user-initiated events that occur while an applet is running — mouse events, button selections, text areas, and choice (menu) selections.

95.4.1 Mouse Clicks

For the program to handle mouse clicks, the `MouseListener` interface must be implemented, either by the applet itself or by a mouse handler class. If the listener is being handled directly by the applet, then the applet must specify the listener in its `implements` clause and activate the listener, usually inside the `init` method:

```
public class MyApplet extends Applet implements MouseListener {
    public void init() {
        ...
        addMouseListener(this);
        ...
    }
}
```

The alternative is to use a separate class to handle mouse clicks. Commonly, this class is an inner class to the applet, so that the mouse handler has access to all of the applet’s methods, particularly the graphics context:

```
public class MyApplet extends Applet {
    public void init() {
        ...
        addMouseListener(new MouseHandler());
        ...
    }
    private class MouseHandler implements MouseListener {
        ...
    }
}
```

If an external class is used, it is common for the applet to pass itself in the call to the mouse handler constructor; the applet object can then be saved to an instance variable of the mouse handler class.

Whichever alternative is used, all of the following methods must be added to the class that implements the `MouseListener`, and at least one must have some statements that respond to the event that it represents:

```
public void mousePressed(MouseEvent e) { }
public void mouseReleased(MouseEvent e) { }
public void mouseClicked(MouseEvent e) { }
public void mouseExited(MouseEvent e) { }
public void mouseEntered(MouseEvent e) { }
```

An advantage to using a separate class is that Java provides a `MouseAdapter` class, which is precisely the trivial implementation of `MouseListener` given previously. This means that the separate class can extend the `MouseAdapter` class (which an applet cannot do), overriding exactly the methods for which actions are to be provided. In most instances, this is usually only the `mouseClicked` method.

```
public class MyApplet extends Applet {
    public void init() {
        ...
        addMouseListener(new MouseHandler());
        ...
    }
    private class MouseHandler extends MouseAdapter {
        public void mouseClicked(MouseEvent e) {
            <action>
        }
    }
}
```

For instance, the typical response to a mouse event is to capture the $x - y$ pixel coordinates where that event occurred on the frame. To do this, we use the `getX` and `getY` methods of the `MouseEvent` class. For example, the following handler responds to a mouse click by storing the $x - y$ coordinates of the click in the applet's instance variables `x` and `y`.

```
public void mouseClicked(MouseEvent e) {
    x = e.getX();
    y = e.getY();
}
```

95.4.2 Mouse Motion

Similar to mouse clicks, for the program to handle mouse motion, the `MouseMotionListener` interface must be implemented either by the applet itself or by a mouse motion handler class. To activate the listener, the following calls must be placed inside the `init` method:

```
addMouseMotionListener(<listener>);
```

The class that implements the listener must implement all of the following methods; at least one must have some statements that respond to the event that it represents:

```
public void mouseDragged(MouseEvent e) { }
public void mouseMoved(MouseEvent e) { }
```

An advantage to using a separate class is that Java provides a `MouseMotionAdapter` class, which is precisely the trivial implementation of `MouseMotionListener` given previously. This means that the

separate class can extend the `MouseMotionAdapter` class (which an applet cannot do), overriding exactly the methods for which actions are to be provided. In most instances, this is usually only the `mouseDragged` method.

95.4.3 Buttons

A button is an object on the screen which is named and can be selected by a mouse click. Because any number of variables can be declared with class `Button` and placed in the applet, button handlers are usually implemented via a separate class, rather than by the applet itself. A button is declared and initialized as follows:

```
Button <variable> = new Button(<string>);
```

Here is an example:

```
Button clearButton = new Button("Clear");
```

A button is placed in the applet by including the following inside the `init` method:

```
add(<variable>);
```

For example:

```
add(clearButton);
```

To be useful, a button must have a listener attached so that the button responds to mouse clicks. This is normally done by including the following inside the applet's `init` method:

```
<variable>.addActionListener(<listener>);
```

For example:

```
clearButton.addActionListener(new ClearButtonHandler());
```

The class that handles the user's selection of the button must implement the `ActionListener` interface. The listener class must implement an `actionPerformed` method to handle the button selection event:

```
public void actionPerformed (ActionEvent e) {  
    if (e.getSource() == <variable>) {  
        <action>  
    }  
}
```

Here, the `<variable>` refers to the name of the `Button` variable as declared and initialized, and `<action>` defines what to do whenever that event occurs. If unique handlers are created for each button, the `if` test to determine which button was selected can be omitted; this is normally preferred. Following, for example, is a handler written as an inner class to the applet class that clears the screen whenever the `clearButton` is clicked by the user:

```
private class ClearButtonHandler implements ActionListener {  
    public void actionPerformed(ActionEvent e) {  
        repaint();  
    }  
}
```

Note that the `repaint` method is an applet method; thus, this class works as written only if it is an inner class to applet. Using an external class requires writing a constructor that takes the applet as an argument. Using our `ClearButton` as an example, the `addActionListener` code in applet's `init` method would appear as follows:

```
clearButton.addActionListener(new ClearButtonHandler(this));
```

The button handler class would then appear as:

```
public class ClearButtonHandler implements ActionListener {
    Applet applet;
    public ClearButtonHandler(Applet a) { applet = a; }
    public void actionPerformed(ActionEvent e) {
        applet.repaint();
    }
}
```

Note that using an external class makes it more difficult for a listener class to determine which button was selected, because the buttons themselves are declared within the applet class.

95.4.4 Labels, TextAreas, and TextFields

A label is an object whose string value can be placed inside a frame to label another object, such as a `TextField`. It can be added to the frame from within the `init` method. For example, the statement

```
add(new Label("Fahrenheit"));
```

would place the message *Fahrenheit* in the frame. Labels cannot have a listener attached to them.

A `TextArea` is a rectangular object on the screen which is named and can accept or display text messages. It is a scrollable object, so users have a complete record of the text. A `TextField` is an object into which the user can type a single line of text from the keyboard; it raises an `ActionEvent` when the user presses the Enter key at the end of the line. `TextAreas` and `TextFields` are declared as follows:

```
TextArea <variable> ;
TextField <variable> ;
```

For example:

```
TextArea echoArea;
TextField typing;
```

`TextArea` and `TextField` objects are normally placed in the applet as part of the `init` method in your program. Initialization requires the number of lines of text (for `TextAreas`) and the number of characters per line to be specified.

```
<variable1> = new TextArea(<lines>, <chars>);
add(<variable1>);
<variable2> = new TextField(<chars>);
add(<variable2>);
```

For example:

```
echoArea = new TextArea(5, 40);
add(echoArea);
typing = new TextField(40);
add(typing);
```

In this example, we declare and place a 5-line by 40-character `TextArea` and a 40-character `TextField` in the current frame.

When the user types in the `TextField` and hits the Enter key, the applet can handle that event by writing additional code in its `actionPerformed` event handler:

```

public void actionPerformed (actionEvent e) {
    if (e.getSource() == <variable>) {
        String s = <variable>.getText();
        <action>
    }
}

```

Here, *<variable>* refers to the name of the `TextArea` variable that was declared and placed in the frame by the `init` method, like `typing` in the example. When the event occurs, the string value typed in the text area is assigned to the variable *s* and the *<action>* is then executed.

A better solution is to use an internal class that listens specifically to the `TextField` typing:

```

private class TextHandler implements ActionListener {
    public void actionPerformed (actionEvent e) {
        String s = <variable>.getText();
        <action>
    }
}

```

In this case, the handler need not check for the source of the triggering event; it must be the user pressing the Enter key in the `TextField` typing.

As an example of an *<action>*, the user's typing can be immediately echoed in the `TextArea` by concatenating it with all the text that is already there. The `append` method is useful for this purpose:

```

echoArea.append(s + "\n");

```

If this line is added as the *<action>* in the previous code, the user's typing will be echoed on a new line inside the `TextArea` object named `echoArea`.

95.4.5 Choices

A choice is an object on the screen that offers several options to be selected by the user. It is like a pull-down menu, but it can be placed anywhere within the applet, not just at the top. A choice is declared as follows:

```

Choice <variable> ;

```

For example:

```

Choice choice;

```

The choice is named and placed in the frame as part of the `init` method in your program. The different selections are assigned to the `Choice` variable using the `addItem` method, and interaction is triggered by adding a listener to the frame for the choice.

```

<variable> = new Choice();
<variable>.addItem(<string1>);
...
add(<variable>);
<variable>.addItemListener(<listener>);

```

For example:

```

choice = new Button();
choice.addItem("North");
choice.addItem("East");
choice.addItem("South");
choice.addItem("West");
add(choice);
choice.addItemListener(new Choice Handler());

```

In this case, an inner class to the applet itself is assumed to be handling the choice event. The applet or item listener event handler must implement the `ItemListener` interface. When the user selects one of the choices, the event is handled by an `itemStateChanged` method:

```
private class ChoiceHandler implements ItemListener {
    public void itemStateChanged (ItemEvent e) {
        String s = (String)e.getItem();
        if (s.equals(<string1>) {
            <action1> in response to a selection of <string1>
        }
        else if (s.equals(<string2>) {
            <action2> in response to a selection of <string2>
        }
        ...
    }
}
```

When the event of selecting a choice occurs, this handler is executed. The string `s` gets the value of the choice the user selected, which is passed to the handler by way of the method call `e.getItem()`. This choice is used in a series of if statements to select the appropriate `<action>`.

95.5 Example: A Simple GUI Interface

The process of event-driven program design involves anticipating the various states and state transitions that can occur as the program runs.

Consider the design of a simple drawing tool, in which the user can draw rectangles and type texts in arbitrary locations of the frame. The user should be able to accomplish this as simply as possible, so providing buttons, menus, and text typing areas and handling mouse click actions on the screen are essential. An initial frame design to support this activity is shown in Figure 95.7.

This frame has four objects: a `Clear` button, a `Choice` menu, a `TextArea` for communicating with the user as events are initiated, and a `TextField` in which the user can enter messages. Thus, we

FIGURE 95.7 Initial frame design for a graphical drawing tool.

```

// Variables used by the Applet -- this is the "state"
    int lastX = 0;           //first click's x-y coordinates
    int lastY = 0;
    int clickBumber = 0;    // most recent click; odd or even
    Choice choice;
    TextArea echoArea;
    TextField typing;

```

FIGURE 95.8 Code to define the state for the interaction.

can begin our design of defining the state of the computation with the following objects and interpretations:

choice — The user can select Nothing, Rectangle, or Message from this menu.

echoArea — This is a `TextArea` for reporting the most recent event that has occurred.

typing — This is a `TextField` for entering user input.

The button need not be part of the global state, because its function is merely to clear the screen, and this can be done completely within the event handler for the button. No other object or handler need be aware of the Clear button.

The state of the computation for this problem must also keep track of all information that is relevant to the user's accomplishing the next task, be it drawing a rectangle or locating a text somewhere in the frame. To draw a rectangle, the system must have two pieces of information: the $x - y$ coordinates of the upper left-hand corner of the rectangle and the $x - y$ coordinates of the lower right. These two points can be retrieved via a mouse event and the `mouseClicked` handler, but the first $x - y$ coordinate pair must be stored globally within the applet's state. Furthermore, a count of the mouse clicks must also be stored globally, so that the first click can be distinguished from the second in determining the corners of the rectangle. Thus, additional global state information includes

```

lastX, lastY X-y coordinates of last mouse click
clickNumber The number of mouse clicks (odd or even)

```

The x and y coordinates of a mouse click are reported in the `TextArea` by the program whenever a mouse click event occurs. Informative messages to the user are also displayed there.

The code that defines the state is shown in Figure 95.8, and the code that initializes the interaction is shown in Figure 95.9.

```

//Variables used by the Applet --- this is the "state"
    int lastX = 0;//first click's x-y coordinates
    int lastY = 0;
    int clickBumber = 0;//most recent click; odd or even
    Choice choice;
    TextArea echoArea;
    TextField typing;
//Initialize the frame: establish the objects and their listeners
public void init() {
//Set the background color and listen for the mouse
    setBackground(Color.white);
    addMouseListener(new MouseHandler());
//Create a button and add it to the Frame.
    Button clearButton = new Button("Clear");
    clearButton.setForeground(Color.black);
    clearButton.setBackground(Color.lightGray);

```

```

// Initialize the frame: establish the objects and their listeners
public void init () {

    // Set the background color and listen for the mouse
    setBackground (Color.White);
    addMouseListener (new MouseHandler());

    // Create a button and add it to the Frame.
    Button clearButton = new Button ("Clear");
    clearButton.setForeground (Color.black) ;
    clearButton.setBackground (Color.lightGray) ;
    add (clearButton) ;
    clearButton.addActionListener (new ClearButtonHandler() ) ;

    // Create a menu of user choices and add it to the Frame.
    choice = new Choice () ;
    choice.addItem ("Nothing") ;
    choice.addItem ("Rectangle");
    choice.addItem ("Message");
    add(choice);
    choice.AddItemListener (new ChoiceHandler());

    // Create a TextField and a TextArea and add them to the Frame.
    typing = new TextField (40);
    add(typing);
    typing.addActionListener (new TestHandler());
    echoArea = new TextArea (2, 40);
    echoArea.setEditable(false);
    add(echoArea);
}

```

FIGURE 95.9 Code to initialize the interaction.

```

add(clearButton);
clearButton.addActionListener(new ClearButtonHandler());
//Create a menu of user choices and add it to the Frame.
choice = new Choice();
choice.addItem("Nothing");
choice.addItem("Rectangle");
choice.addItem("Message");
add(choice);
choice.addItemListener(new ChoiceHandler());
//Create a TextField and a TextArea and add them to the Frame.
typing = new TextField(40);
add(typing);
typing.addActionListener(new TextHandler());
echoArea = new TextArea(2, 40);
echoArea.setEditable(false);
add(echoArea);
}

```

Designing the event handlers is a more intricate process. For each event that occurs, an appropriate handler must contain code to distinguish that event from the rest and then change the state and/or generate output into the frame appropriately. Consider the following scenario.

FIGURE 95.10 First step in an interaction: the user selects Rectangle from the menu.

```
public void itemStateChanged (ItemEvent e) {
    String currentChoice = (String) (e.getItem());
    echoArea.setText ("Choice selected: " + currentChoice);
    clickNumber = 0;
    // prepare to handle first mouse click for this choice
    if (currentChoice.equals("Rectangle"))
        echoArea.append(
            "\nClick to set upper left corner of the rectangle");
    else if (currentChoice.equals ("Message"))
        echoArea.append(
            "\nEnter a message in the text area");
}
}
```

FIGURE 95.11 ItemStateChanged handler for this interaction.

The user first selects Rectangle from the Choice menu. To properly handle that event, the system must store that selection and then prompt the user to click the mouse at the point where the upper left-hand corner of the rectangle should be drawn, as shown in Figure 95.10.

What code do we write to respond to this selection? We write code inside an `itemStateChanged` event handler of the `ChoiceHandler` class, because the object selected, `choice`, is a `Choice`. The complete `itemStateChanged` handler for this problem is shown in Figure 95.11.

```
//Called when the user makes a Choice selection
private class ChoiceHandler implements ItemListener {
    public void itemStateChanged (ItemEvent e) {
        String currentChoice = (String) (e.getItem());
        echoArea.setText("Choice selected: " + currentChoice);
        clickNumber = 0;
        //prepare to handle first mouse click for this choice
        if (currentChoice.equals("Rectangle"))
            echoArea.append(
                "\nClick to set upper left corner of the rectangle");
        else if (currentChoice.equals("Message"))
```

```

private class MouseHandler extends MouseAdapter {
    public void mouseClicked(MouseEvent e) {
        int x = e.getX();
        int y = e.getY();
        echoArea.setText ("Mouse Clicked at " +
                          e.getX() + " , " + e.getY() + "\n");
        Graphics g = getGraphics();
        if (choice.getSelectedItem().equals("Rectangle")) {
            clickNumber = clickNumber + 1;
            // is it the first click?
            if (clickNumber % 2 == 1) {
                echoArea.setText
                    ("Click to set lower right corner of the rectangle");
                lastX = x;
                lastY = y;
            }
            // or the second?
            else g.drawRect(Math.min(lastX,x), Math.min(lastY,y),
                            Math.abs(x-lastX), Math.abs(y-lastY));
        }
        // for a message, display it
        else if (choice.getSelectedItem().equals("Message"))
            g.drawString(currentMessage, x, y);
    }
}

```

FIGURE 95.12 Details of the mouseClicked handler for this interaction.

```

echoArea.append(
    "\nEnter a message in the text area");
}
}

```

While this code is a bit obscure, it does reveal that the `itemStateChanged` handler must prepare for *any* menu event that can occur. It distinguishes among the possibilities by checking the parameter `e` for the item selected, which is assigned to the state variable `currentChoice`. If the choice is a `Rectangle`, the handler dutifully prompts the user to click to set the location where the upper left-hand corner of the rectangle should be located in the frame. If the choice is a `Message`, a different prompt goes to the user. In either case, this handler echoes the nature of this event in the `echoArea`.

Assuming that the user clicks the mouse in the frame, the system must respond by storing the $x - y$ coordinates of that click in the applet's state variables `lastX`, `lastY` and prompt the user to click to set the lower right-hand corner of the desired rectangle. But that should be done *only* if the current choice is a `Rectangle`. By the time the mouse click event happens, the only source of information about what event immediately preceded it comes from the applet's state. That is, the click could have been preceded by a different event, which should provoke a different response from the interaction. Where is this all sorted out? In the `mouseClicked` handler, as shown in Figure 95.12.

```

private class MouseHandler extends MouseAdapter {
    public void mouseClicked(MouseEvent e) {
        int x = e.getX();
        int y = e.getY();
        echoArea.setText("Mouse Clicked at " +

```

```

e.getX() + , " " + e.getY() + "\n");
Graphics g = getGraphics();
if (choice.getSelectedItem().equals("Rectangle")) {
    clickNumber = clickNumber + 1;
//is it the first click?
    if (clickNumber% 2 == 1) {
        echoArea.setText
        ("Click to set lower right corner of the rectangle");
        lastX = x;
        lastY = y;
    }
//or the second?
    else g.drawRect(Math.min(lastX,x), Math.min(lastY,y),
    Math.abs(x-lastX), Math.abs(y-lastY));
}
//for a message, display it
else if (choice.getSelectedItem().equals("Message"))
g.drawString(currentMessage, x, y);
}
}

```

This handler must also be prepared for anything, because it doesn't implicitly know what events occurred immediately before this particular mouse click. The state variable `clickNumber` helps to sort things out, because its update value will have an odd number for the first click of a pair and an even number for the second. Thus, the upper left-hand corner of a rectangle is indicated for odd values, and the drawing of a complete rectangle, using the x and y coordinates of the current click together with the x and y coordinates of the previous click (stored in `lastX` and `lastY`), is indicated for even clicks.

The remainder of this event handler should be fairly readable. The effect of drawing a rectangle after the user has clicked twice is shown in Figure 95.13. Here, the arrow in the figure shows the location of the second click, whose x and y coordinates are 215 and 204, respectively.

The next task in designing this interaction is to implement the event handler that responds to the user's selecting the Clear button or typing text in the typing area. The `actionPerformed` method for this event is shown in Figure 95.14. Note here the simplicity of attaching a unique handler to the Clear button;

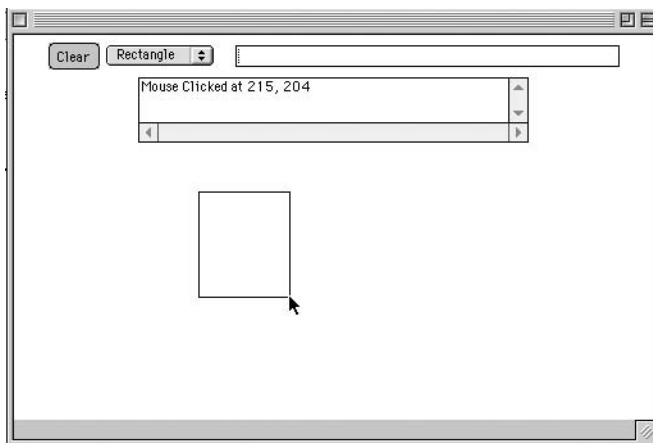

FIGURE 95.13 Effect of selecting Rectangle choice and clicking the mouse twice.

```

private class ClearButtonHandler implements ActionListener {
    public void actionPerformed (ActionEvent e) {
        echoArea.setText ("Clear button selected ");
        repaint();
    }
}

```

FIGURE 95.14 ActionPerformed handler for the Clear button.

```

private class TextHandler implements ActionListener {
    public void actionPerformed (ActionEvent e) {
        echoArea.setText ("Text entered: " + typing.getText());
        if (choice.getSelectedItem().equals("Message"))
            echoArea.append("\nNow click to place this message");
    }
}

```

FIGURE 95.15 ActionPerformed handler for the Enter key in the typing area.

it does not have to test what triggered the event (the button or the Enter key in the typing area), merely to clear the screen via a repaint.

```

private class ClearButtonHandler implements ActionListener {
    public void actionPerformed (ActionEvent e) {
        echoArea.setText("Clear button selected ");
        repaint();
    }
}

```

Responding to text typed by the user is straightforward, needing only to store the text for later use and prompting the user to click the mouse to locate the text in the frame, as shown in Figure 95.15.

```

private class TextHandler implements ActionListener {
    public void actionPerformed (ActionEvent e) {
        echoArea.setText("Text entered: " + typing.getText());
        if (choice.getSelectedItem().equals("Message"))
            echoArea.append("\nNow click to place this message");
    }
}

```

Note that both the `TextHandler` and `ClearButtonHandler` classes implement the `ActionListener` interface and both have `actionPerformed` methods. Neither handler has to be aware of the other, as each is listening for separate events.

The net effect of typing text and clicking to locate it below the rectangle that had been placed in the frame is shown in [Figure 95.16](#). There, the location of the mouse click is indicated by the arrow in the figure, which is at $x - y$ coordinates 162 and 221.

This sketch provides a concrete example of the process of designing an event-driven program. The program runs indefinitely — the user can spend hours drawing rectangles, placing messages, and clearing the frame, and only the user decides what event sequence will occur at any particular point in time.

The observant reader will have noticed that this applet has no paint method. Thus, iconifying the window or overlaying another window on top of this window will eventually necessitate a repaint, causing

FIGURE 95.16 Net effect of user's placing a text in the frame.

all the drawing of rectangles and placing of messages to disappear. If the applet must be able to repaint what has been drawn to the screen, then the applet must remember what it wrote to the screen. We will see examples of this in later programs.

95.6 Event-Driven Applications

Event-driven programs occur in many domains besides those which are Web-based. Here are three examples (and an example of a Web-based program):

- Web-based interactive games
- Automated teller machines (ATMs)
- Home security alarm systems
- A supermarket checkout station

In this section, we briefly describe the first three of these interactions, focusing on their state variables and the kinds of events that should be handled in the event loop to maintain integrity among the state variables.

95.6.1 Interactive Games: Tic-Tac-Toe

Consider designing an event-driven program that monitors an interactive game between two people. For example, the game tic-tac-toe has a 3×3 board and two players, who alternate turns. Each turn forces the board into a new state, which differs from the old state by the contents of one square. A game is over either when the board is full or when one of the players has placed three markers (X or O) in a row, either horizontally, vertically, or diagonally. The interaction can run indefinitely, since the players can clear the board and start a new game at any time. Thus, the state of a tic-tac-toe game naturally includes the following:

- The state of the board
- Whose turn it is
- Whether the game is over
- A New Game button that clears the board and starts a new game

An event in this setting is either a player move (clicking the mouse in an unoccupied square to place the next X or O) or a player selecting the New Game button. The sequencing of these events is entirely unpredictable by the program — either one is equally likely while a game is going on.

The results displayed by the program are the board itself and a message area which is used to report whose turn it is, the winner, and other information as the game proceeds. The major visual design element for this game is a 3×3 grid:

Each player takes a turn by clicking the mouse to place an X or an O on one of the unoccupied squares; player X goes first. The winner is the player who first places three Xs or 3 Os in a row, either horizontally, vertically, or diagonally. A tie game occurs when the board is full and no one has three Xs or Os in a row.

The program can use a `TextArea` for displaying appropriate messages (for instance, when a player attempts to make an illegal move). It should allow each player to click on an empty square and replace that square with an X or an O. The program thus keeps track of whose turn it is and reports that information in the `TextArea` at the beginning of each turn. Thus, the state variables for this game include the following:

- A `Grid` variable for the 3×3 board

- A `TextArea` variable for sending messages to the players

- A variable that determines whose turn it is, which flips back and forth whenever a player has completed a legal move

The central event-driven code for this game appears in the handler for mouse clicks. Some of these clicks reflect legal moves (i.e., a mouse click from a player on an unoccupied square of the board), and others reflect illegal moves (e.g., a mouse click outside the board). Another distinct event is the selection of the Clear button to signal ending the game. These events can occur in any order, so the program must be equipped to handle them sensibly, change the state appropriately, and detect when the game is over.

95.6.2 Automated Teller Machine

An ATM is driven by a program that runs 7 days a week and 24 hours a day. The program must be able to interact with each user who has a proper ATM bank card, and it helps the machine conduct transactions with the user. The essential elements of a typical ATM display are shown in Figure 95.17. (In practice, the details are different, but the elements shown here are adequate to characterize what happens during an ATM transaction).

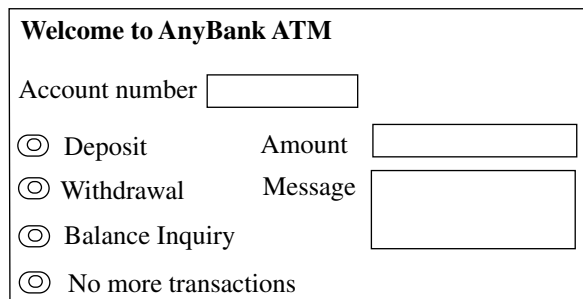

FIGURE 95.17 Elements of a typical ATM transaction user interface.

The state of this interaction is captured partially by the objects in this display and partially by other information that relates to the particular user who is at the machine. A basic collection of state variables required for an ATM transaction includes the following:

Account — The user's account number

Type — The type of transaction (deposit, withdrawal, etc.)

Amount — The amount of the transaction

Message — A message from the bank to the user

Balance — The user account's available balance

The last variable in this list, the available balance, brings into play a new dimension for event-driven programming. That is, the program must interact not only with the user but also with the bank's database of all its accounts and current balances. A program that interacts with such a database, which may reside on an entirely different computer, or *server*, on the bank's network, is called a *client-server* application. Client-server applications exist in a wide variety of systems, including airline reservation systems, on-line textbook ordering systems, and inventory systems. They are discussed more directly in other chapters of this Handbook.

In this example, we can characterize the different events that can occur, together with how they should be handled (that is, the effect they should have on the state of the interaction).

Event: User enters an account number (swipes her card).

Handled by: Program checks that account is a valid number, sets balance, and issues the message "Choose a transaction."

Event: User selects a button (deposit, withdrawal, etc.).

Handled by: Program checks to see that a valid account has been entered.

If so: Save the type of button selected.

If deposit or withdrawal, issue the message "Enter an amount."

If Balance Inquiry, display the balance.

If No more transactions, clear the account.

If not, issue the Message "Enter an account number."

Event: User enters an amount.

Handled by: Program checks that user has selected a deposit or withdrawal type.

If deposit, add the amount to the balance.

If withdrawal:

If balance is greater than amount, subtract amount from balance.

Otherwise, issue the message "Insufficient funds."

Otherwise, issue the message "Select a transaction type (deposit or withdrawal)."

The key insight with this design is that the system does not anticipate the type of transaction or the order in which the events will occur. It responds to every different possibility and updates the state of the interaction appropriately.

95.6.3 Home Security Alarm System

Home security systems provide homeowners with a modest warning that an unwanted event, such as a break-in, fire, or flood, has occurred. These systems are programmed to react to sensors that can detect smoke, water, or motion, and are placed strategically around the house. They can be programmed by homeowners so that their own motion about the house is not taken as an unwanted break-in. They also can be connected to the local fire and police stations so that notification of an unwanted event can receive immediate response.

The overall design for such a system is sketched in [Figure 95.18](#).

Here, the sensors and the user interface supply events to the program; alarms and the user interface receive responses from the program. Responses at the user interface are displayed on an LCD display.

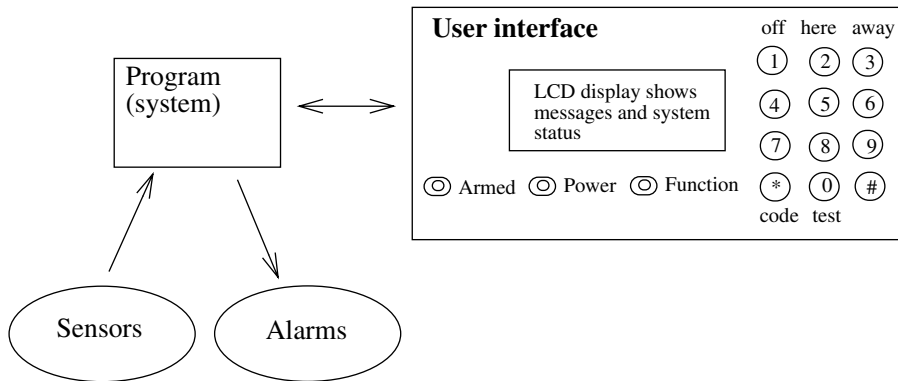

FIGURE 95.18 Overall design of a home security system.

Because this system must be able to receive handle events in parallel (e.g., signals from two different sensors may occur simultaneously), the program must embody both the event-driven paradigm discussed in this chapter and the parallel programming paradigm (discussed in [Chapter 96](#)). We ignore the parallel programming dimensions of this problem in the current discussion.

The state variables for this program are several:

- Password** — The user’s password
- User** — The state of the user (here or away)
- Armed** — The state of the system (armed or unarmed)
- Sensors** — The state of each sensor (active or inactive)
- Alarms** — The state of each alarm (active or inactive)
- Message** — A message from the system to the control panel

Here are some of the events that can reasonably occur, with a sketch of what should happen to the state in response to each event.

Event: User enters password.

Handled by: Program checks that password is valid and displays message.

Event: User enters function “away.”

Handled by: Program checks that password has been entered and changes the state of all sensors to “active,” the state of the system to “armed,” and displays message.

Event: Sensor receives signal.

Handled by: If system is armed, program sends appropriate alarm and displays a message.

Event: User enters function “test.”

Handled by: Program disarms system.

Event: User enters function “here.”

Handled by: Program disables motion-detection sensors, enables all others, and changes state of the system to “armed.”

In these examples, we have greatly generalized the details in order to simplify the discussion and focus on the main ideas about event-driven programming that these problems evoke. Interested readers should consult the references for more detailed discussions of event-driven programming applications.

96.1 Introduction

Concurrent computing is the use of multiple, simultaneously executing processes or tasks to compute an answer or solve a problem. The original motivation for the development of concurrent computing techniques was for timesharing multiple users or jobs on a single computer. Modern workstations use this approach in a substantial manner. Another advantage of concurrent computing, and the reason for much of the current attention to the subject, is that it seems obvious that solving a problem using multiple computers is faster than using just one. Similarly, there is a powerful economic argument for using multiple inexpensive computers to solve a problem that normally requires an expensive supercomputer. Additionally, the use of multiple computers can provide fault tolerance.

Moreover, there is an additional powerful argument for concurrent computing—the world is inherently concurrent. Just as each of us engages in a large number of concurrent tasks (hearing while seeing while reading, etc.), operating systems need to handle multiple, simultaneously executing tasks; robots need to engage in a multiplicity of actions; database systems must simultaneously handle large numbers of users accessing and updating information; etc. Often, breaking a problem into concurrent tasks provides a simpler, more straightforward solution.

As an example, consider Conway's problem: input is in the form of 80-character records (card images in the original problem, which gives an idea of how long it has been around); output is to be in the form of 120-character records; each pair of dollar signs, '\$\$', is to be replaced by a single dollar sign, '\$'; and a space, ' ', is to be added at the end of each input record. In principle, a sequential solution may be developed, but the complications introduced require complex and non-obvious buffer manipulations. Moreover, a

concurrent solution consisting of three processes is both simpler and more elegant. The three processes execute within infinite loops performing the following actions:

1. Process1 reads 80-character records into an 81-character buffer, places a space character in location 81, and then outputs single characters from the buffer sequentially.
2. Process2 reads single characters and copies them to output, but uses a simple state machine to substitute a single '\$' for two consecutive '\$\$'.
3. Process3 reads single characters, saves them in a buffer, and outputs 120-character records.

To develop an implementable solution, we need to decide how the independently executing processes communicate. A simple, widely used approach is to add two buffers: Buffer1 stores output characters from Process1 to be input to Process2; Buffer2 stores output characters from Process2 to be input to Process3. For simplicity, assume that Buffer1 and Buffer2 each hold a single character. Thus:

1. Process1 reads 80-character records into an 81-character internal buffer, places a space character in location 81, and sequentially places in Buffer1 single characters from the internal buffer.
2. Process2 reads single characters from Buffer1 and places them into Buffer2, but uses a simple state machine to substitute a single '\$' for two consecutive '\$\$'.
3. Process3 reads single characters from Buffer2, saves them in an internal 120-character buffer, and outputs 120-character records.

This solution demonstrates the essence of the concurrent paradigm: individual sequential processes that cooperate to solve a problem. The exemplified concurrency is pipelined concurrency, where the input of all processes but the first is provided by another process. Cooperation, in this and all other cases, requires that the processes:

1. Share information and resources
2. Not interfere during access to shared information or resources

In the Conway solution, information is readily shared via the buffers. The chief problem is to ensure that concurrent accesses to the two buffers do not conflict; for example, Process2 does not attempt to retrieve a character from Buffer1 before it has been placed there by Process1 (which would lead to garbage characters), and Process1 does not attempt to place a character into Buffer1 before the previous character has been retrieved by Process2 (which would lead to lost characters).

A simpler example of interference is provided by the following simple program (where the statements within the `cobegin-coend` pair are to be executed simultaneously):

```
x := 0
cobegin
  x := x + 1
  x := x + 2
coend
```

Consider the value of `x` at the end of execution. Because each assignment statement is actually a sequence of machine-level instructions, various interleavings of the execution of these instructions result in different final values for `x` (i.e., 1, 2, or 3). Clearly, this is unacceptable!

In each of these examples, it is clear that there are *critical regions* in which two (or more) processes have sections of code that may not be executed concurrently; we must have *mutual exclusion* between the critical regions. In the Conway example, critical regions include:

- Process1 placing a value into Buffer1
- Process2 retrieving a value from Buffer1
- Process2 placing a value into Buffer2
- Process3 retrieving a value from Buffer2

In the simple example above, each of the two assignment statements are critical regions. The essence of avoiding interference is to discover the critical regions and isolate them. This isolation takes the form of an “entry protocol” to announce entry into a critical region and an “exit protocol” to announce that the execution of the critical region has completed (below the ‘#’ introduces a comment and the ‘...’ represents the appropriate program code):

```
# entry protocol
...
# critical region code
...
# exit protocol
...
```

This is the basic model used by the *busy-wait* and *semaphore* approaches (discussed below). It is a low-level model in the sense that careful attention must be paid to the placement of the entry and exit protocols to ensure that critical regions are properly protected.

There are other implementation approaches to concurrency that solve the critical region problem by prohibiting any direct interference between concurrent processes. This is done by not allowing any sharing of variables. The *monitor* approach places all shared variables and other resources under the control of a single monitor module, which is accessed by only a single process at a time. The *message-passing* approach is to share information only through messages passed from process to process. Both of these approaches are discussed in this chapter.

As well as avoiding interference in data access, we must avoid interference in the sharing of resources (e.g., keyboard input for multiple processes). Also, we must ensure that any physical actions of concurrent processes, such as movement of robotic arms, are appropriately synchronized.

Thus, to develop concurrent solutions, we require notations to:

1. Specify which portions of our processes can run concurrently
2. Specify which information and resources are to be shared
3. Prevent interference by concurrent processes by ensuring mutual exclusion
4. Synchronize concurrent processes at appropriate points

Further, any proposed solution to a concurrent problem must have certain properties (see, for example, [Ben-Ari, 1990]):

1. Safety: this property must always be true; examples include:
 - a. Non-interference
 - b. No *deadlock*, which occurs when no process can continue because all processes are waiting upon conditions that can never occur
 - c. Partial correctness: whenever the program terminates, it has the correct answer
2. Liveness: this property must be true eventually; examples include:
 - a. Program terminates (if it also has the correct answer, this is total correctness)
 - b. No *race*: nondeterministic behavior caused by concurrently executing processes
 - c. *Fairness*: each process has an opportunity to execute (this is affected by implementation and process/thread scheduling)

The verification or proof that solutions satisfy these properties is vastly complicated by the concurrent execution of code: particular orderings of code execution may exhibit interference or deadlock while others proceed nicely to termination. Returning to Conway’s problem, suppose the execution of Process1 and Process2 are matched evenly so that each character placed by Process1 into Buffer1 is retrieved by Process2 before Process1 is ready to output another character. In this case, when tested, the program exhibits the desired correctness properties, lack of deadlock, etc. But if, due to a variation in processor workload or type, Process1 runs faster, then characters will be overwritten and lost; on the other hand, if Process2 runs faster, characters will be repeated. The fact that we tested the program under one particular set

of circumstances (even for all possible inputs) is irrelevant to this issue. Sufficient testing is impossible because of the exponential explosion in the number of possible interleavings of instruction execution that can occur. The only fully satisfactory approach is to use formal methods (techniques that are still predominantly under development), which are touched on later in this chapter.

This chapter focuses on the software architectures used for concurrency, using a set of archetypical problems and their solutions for illustration. These problems are chosen because of the frequency with which they arise in computing; careful study of actual problems frequently leads to the realization that a seemingly complicated problem is, at heart, one of these archetypes. First, we briefly explore hardware architectures and their impact on software.

96.2 Hardware Architectures

Hardware can influence synchronization and communication primarily with respect to efficiency. *Multiprogramming* is the interleaving of the execution of multiple programs on a processor; on a uniprocessor, a time-sharing operating system implements multiprogramming. Although such an approach on a uniprocessor does not provide the execution speedup discussed in the introduction, it does provide the possibility of elegance and simplicity in problem solution, which is the second argument for the concurrent paradigm.

By employing multiple computers, we have *multiprocessing*, or parallel processing. Multiprocessing can involve multiple computers working on the same program or on different programs at the same time. If a multiprocessor system is built so that processors share memory, then processes can communicate via global variables stored in shared memory; otherwise, they communicate via messages passed from process to process. In contrast to a multiprocessor system, a distributed system is comprised of multiple computers that are remote from each other. This chapter focuses on multiprogramming and multiprocessing systems with a short introduction to the additional problems associated with distributed systems. In addition (but outside the scope of this chapter), a wide variety of hybrid hardware/software approaches exist.

96.3 Software Architectures

To specify a software architecture for implementing concurrency, we must provide the syntax and semantics to:

1. Specify which information and resources are to be shared
2. Specify which portions of processes can run concurrently
3. Prevent interference by concurrent processes by ensuring mutual exclusion
4. Synchronize concurrent processes at appropriate points

The first feature requires no special notation (shared variables are simply global), and the third and fourth are usually merged into one. A large number of software mechanisms have been proposed to support these features; in this chapter we explore the most widely used among them:

1. *Busy-wait*: implementable on virtually any processor without operating system support; this is concurrency without abstractions
2. *Semaphores*: historically the oldest satisfactory mechanism
3. *Monitors*: modules that encapsulate concurrent access to shared data
4. *Message passing*: a higher-level abstraction widely used in distributed systems

The references at the end of the chapter provide pointers to a number of other mechanisms, such as Unix fork/join, conditional critical regions, etc.

96.3.1 Busy-Wait: Concurrency without Abstractions

To illustrate the busy-wait mechanism, we use (following [Ben-Ari, 1982], a very simple example consisting of two concurrent processes, each with a single critical region. The only assumption made is that each memory access is atomic; that is, it proceeds without interruption. Our task is to ensure mutual exclusion; the purpose of the exercise is to demonstrate the care with which a solution must be crafted to ensure the safety and liveness properties discussed above.

Our first approach, which follows, is to ensure that the processes, p_1 and p_2 , simply take turns in their critical regions.

```
global var turn := 1

process p1
  while true do ->
    # non-critical region
    ...
    # entry protocol
    while turn = 2 do ->
      <nothing>                                # wait for turn
    # critical region
    ...
    # exit protocol
    turn := 2
    # rest of computation
    ...
end p1

process p2
  while true do ->
    # non-critical region
    ...
    # entry protocol
    while turn = 1 do ->
      <nothing>                                # wait for turn
    # critical region
    ...
    # exit protocol
    turn := 1
    # rest of computation
    ...
end p2
```

This approach meets the desired properties but has a fundamental flaw: processes must take turns entering their critical regions. If p_1 is ready and needs to execute its critical region at a higher frequency than p_2 , it cannot. The processes are an example of *co-routines*, historically one of the first approaches to concurrency.

If we modify the solution to allow each process to proceed into its critical region if the other process is not in its critical region, and to then notify the other process, we obtain the following (where c_i is used to signify that p_i is in its critical region):

```
global var c1 := false, c2 := false

process p1
  while true do ->
```

```

# non-critical region
...
# entry protocol
while c2 do ->
  <nothing>           # wait for turn
  c1 := true         # p1 in critical region
# critical region
...
# exit protocol
  c1 := false       # p1 out of critical region
# non-critical region
end p1

process p2
  while true do ->
    # non-critical region
    ...
    # entry protocol
    while c1 do ->
      <nothing>       # wait for turn
      c2 := true     # p2 in critical region
    # critical region
    ...
    # exit protocol
      c2 := false   # p2 out of critical region
    # non-critical region
  end p2

```

Now, however, we have the possibility that the mutual exclusion requirement of the critical region can be violated; that is, both processes can be in their critical regions at the same time. (For example, suppose both *c1* and *c2* are false; *p1* checks *c2* via the loop and decides that it may enter its critical region; before it sets *c1* to true, *p2* checks *c1* via its loop and decides that it may enter its critical region).

As shown next, this disastrous possibility can be eliminated by having a process announce its intent to enter into its critical region before checking whether it can enter:

```

global var c1 := false, c2 := false

process p1
  while true do ->
    # non-critical region
    ...
    # entry protocol
    c1 := true       # signal intent to enter
    while c2 do ->
      <nothing>     # wait for turn
    # critical region
    ...
    # exit protocol
    c1 := false     # p1 out of critical region
  # non-critical region
end p1
process p2

```

```

while true do ->
  # non-critical region
  ...
  # entry protocol
  c2 := true           # signal intent to enter
  while c1 do ->
    <nothing>         # wait for turn
  # critical region
  ...
  # exit protocol
  c2 := false         # p1 out of critical region
  # non-critical region
end p2

```

But now we have raised the possibility of a race (when p1 sets c1 to true *and* p2 sets c2 to true).

A possible solution to this difficulty, which appears below, moves the announcement statement into the loop, together with a random delay:

```

global var c1 := false, c2 := false

process p1
  while true do ->
    # non-critical region
    ...
    # entry protocol
    c1 := true         # signal intent to enter
    while c2 do ->
      c1 := false     # give up intent if p2 already
                      # in critical region

      <delay>
      c1 := true     # try again
    # critical region
    ...
    # exit protocol
    c1 := false     # p1 out of critical region
  # non-critical region
  ...
end p1

process p2
  while true do ->
    # non-critical region
    ...
    # entry protocol
    c2 := true         # signal intent to enter
    while c1 do ->
      c2 := false     # give up intent if p1 already
                      # in critical region

      <delay>
      c2 := true     # try again
    # critical region
    ...
    # exit protocol

```

```

        c2 := false                # p2 out of critical region
        # non-critical region
        ...
    end p2

```

But this is not a satisfactory solution because it exhibits a race in the (unlikely) situation that the two loops proceed in perfect synchronization.

A valid solution, such as that which appears below, can be developed by returning to the concept of taking turns when applicable, which ensures mutual exclusion while not requiring alternating turns (thus allowing true concurrency):

```

global var c1 := false, c2 := false, turn := 1

process p1
    while true do ->
        # non-critical region
        ...
        # entry protocol
        c1 := true                # signal intent to enter
        turn := 2                # give p2 priority
        while c2 and turn = 2 do ->
            <nothing>            # wait if p2 in critical region
        # critical region
        ...
        # exit protocol
        c1 := false              # p1 out of critical region
        # non-critical region
        ...
    end p1
process p2
    while true do ->
        # non-critical region
        ...
        # entry protocol
        c2 := true                # signal intent to enter
        turn := 1                # give p1 priority
        while c1 and turn = 1 do ->
            <nothing>            # wait if p2 in critical region
        # critical region
        ...
        # exit protocol
        c2 := false              # p1 out of critical region
        # non-critical region
        ...
    end p2

```

This solution is due to Peterson [1983]; the first valid solution was presented by Dekker.

The importance of the busy-wait approach is threefold:

1. It provides a nice introduction to the problems inherent in designing concurrent solutions.
2. It is executable on virtually every machine architecture without additional further software support and is, thus, suitable for micro-controllers, etc.
3. Variants are frequently used in hardware implementations.

However, this approach also suffers from two difficulties:

1. It is very inefficient: machine cycles are expended when executing busy-wait loops.
2. Programming at such a low level is highly prone to error.

96.3.2 Semaphores

Dijkstra [1968] presented the first abstract mechanism for synchronization in concurrent programs. The *semaphore*, so named in direct relation to the semaphores used on railroad lines to control traffic over a single track, is a non-negative integer-valued abstract data type with two operations:

$$P(s) : \text{delay until } s > 0, \text{ then } s := s - 1$$
$$V(s) : s := s + 1$$

When a process delays on a semaphore, it is awakened only when another process executes a V operation on that semaphore. Thus, it uses no machine cycles to check if it can proceed. If more than one process is delaying on a semaphore, only one (which one is implementation dependent) can be awakened by a V operation.

Additionally, the value of s can be set at instance creation via the semaphore declaration; if set to 0, then some process must execute the $V(s)$ operation before any processes first executing the $P(s)$ operation can continue. With this abstract data type, we have a mechanism that handles both interference and synchronization.

Additional notes:

1. These are the *only* two synchronization operations defined; in particular, the value of s is not determinable.
2. Implementation of these operations must be either in the hardware or in the (non-interruptible) system kernel.
3. By sleeping while waiting for a semaphore (the delay in $P(s)$), a process does not waste machine cycles by repeated checking.
4. The operation names (P and V) come from the Dutch words *passeren* (to pass) and *vrygeven* (to release); sometimes, *signal* and *wait* are used in place of P and V , respectively.
5. Each of the P and V operations proceeds atomically; that is, it may not be interrupted by another process.

The use of the semaphore in concurrent programming relates directly to the railroad analogy. Each critical section looks like the following:

```
global var s : semaphore := 1

# entry protocol
P(s)
# critical region
...
# exit protocol
V(s)
```

The initialization of s to 1 ensures that the first process executing $P(s)$ will continue. (Deadlock arises if s were initialized to 0.) Only the first process to reach its $P(s)$ statement is allowed to proceed, as subsequent processes find $s = 0$ and delay. When the first process finishes its critical region, it executes $V(s)$, which sets s to 1. One of the waiting processes is awakened, finds $s > 0$, decrements s , and proceeds. Note the importance that these operations are atomic; this ensures that two processes cannot wake up and each find $s > 0$.

96.3.2.1 Semaphores and Producer-Consumer

The Producer-Consumer problem arises whenever one process is creating values to be used by another process. Examples are Conway's problem and buffers of various kinds, etc. Here we first look at the multi-element buffer version of this problem and then add multiple producers and consumers as a refinement.

```
# define the buffer
const N := ...           # size
var buf[N] : int        # buffer
    front := 1          # pointers
    rear := 1
semaphore empty := N    # counts the number of empty slots
                        # in the buffer
                        full := 0    # counts the number of items
                        # in the buffer

process producer
var x : int
while true do ->
    # produce x
    ...
    P(empty)            # delay until there is space in the buffer
    buf[rear] := x     # place value in the buffer
    V(full)             # signal that the buffer is non-empty
    rear := rear mod N + 1 # update buffer pointer
end producer

process consumer
var x : int
while true do ->
    P(full)             # delay until a value is in the buffer
    x := buf[front]    # obtain value
    V(empty)           # signal that the buffer is not full
    front := front mod N + 1 # update buffer pointer
    # consume x
    ...
end consumer
```

The buffer processing is conventional; only the actual buffer access must be placed into a critical region because there is no possibility of interference between the assignments to `rear` and `front`. Note also the use of two semaphores: `empty` to signal that the producer can proceed because there is at least one empty slot in the buffer and `full` to signal that the consumer can proceed because there is at least one item in the buffer. Although it is possible to solve this problem with one semaphore, less concurrency results. Note that the `empty` semaphore is initialized to `N`, the size of the buffer. The producer process can run up to `N` steps ahead of the consumer process.

To allow multiple producers and/or consumers, we must protect the actual buffer operations with additional semaphores to prevent, for example, two producers from accessing `rear` simultaneously with read and assignment operations. These semaphores, `mutexR` and `mutexF`, guarantee mutual exclusion of access to the `rear` and `front` pointers, respectively. It is not sufficient to use `empty` here because up to `N` producers will be able to continue through the `P(empty)` statement.

```
# define the buffer as previously
semaphore empty := N, full := 0
```

```

semaphore mutexR := 1      # mutual exclusion on rear pointer
       mutexF := 1      # mutual exclusion on front pointer

process pi                # one for each producer
var x : int
while true do ->
  # produce x
  ...
  P(empty)                # delay until there is space in the buffer
  P(mutexR)               # delay until rear pointer is not in use
  # place value in the buffer and modify pointer
  buf[rear] := x; rear := rear mod N + 1
  V(mutexR)               # release rear pointer
  V(full)                  # signal that the buffer is non-empty
end pi

process ci                # one for each consumer
var x : int
while true do ->
  P(full)                  # delay until a value is in the buffer
  P(mutexF)               # delay until front pointer is not in use
  # access the value in the buffer and modify pointer
  x := buf[front]; front := front mod N + 1
  P(mutexF)               # release front pointer
  V(empty)                 # signal that there is space in the buffer
  # consume x
  ...
end ci

```

96.3.2.2 Semaphores and Readers-Writers

The Readers-Writers model captures the fundamental actions of a database; i.e.,

- No exclusion between readers
- Exclusion between readers and a writer
- Exclusion between writers

In other words, the software must guarantee only one update of a database record at a time, and no reading of that record while it is being updated.

The simplest semaphore solution is to wait only for the first reader; subsequent readers need not check because no writer can be writing if there is already a reader reading (here, nr and nw are the numbers of active readers and writers, respectively):

```

...
nr := nr + 1
if nr = 1 -> P(rw)      # if no one is presently reading,
                       # then ensure no one is writing
                       # before proceeding

# access database
...
nr := nr - 1
if nr = 0 -> V(rw)      # if no more are reading, possibly wake up
                       # writer, or prepare for next reader

```

```

...
P(rw)          # delay until no readers or writers
# access database
...
V(rw)          # wake up delayed reader or writer, or prepare
# for next reader or writer

```

This solution gives readers preference over writers: new readers continually freeze out waiting writers. Extending this solution to other kinds of preferences, such as writer preference or first-come-first-served preference is cumbersome.

A more general approach is known as “passing the baton”; it is easily extended to other kinds of preferences because control is explicitly handed from process to process. Although a careful explanation of the approach is not given here, the concept is easily summarized. A process must check to ensure that it can legally proceed before doing so; if it cannot proceed, the process waits upon a semaphore assigned to it. For example, a writer process checks to see if no readers or writers are executing on the database before it proceeds; if they are executing on the database, then the writer process sleeps, waiting upon the semaphore assigned to it. When a process is finished accessing the database, it checks the conditions and wakes up (via signaling on the appropriate semaphore) one of the processes waiting upon the condition. This last operation essentially “passes the baton” from one process to another. The key is that first a check is made to ensure that it is legal for the other process to wake up. The strength of the “passing the baton” approach emerges when its flexibility is used to develop more general solutions. Details may be found in Andrews [1991].

96.3.2.3 Difficulties with Semaphores in Software Design

While the use of semaphores does provide a complete solution to the interference problem, the correctness of the solution directly depends on the correct usage of the semaphore operations, which are fairly low-level and unstructured. Semaphores and shared variables are global to all processes and, like any global data structure, their correct usage requires considerable discipline by the programmer. Additionally, if a large system is to be built, any one implementor is likely responsible for only a portion of the semaphore usage so that correct pairing of Ps and Vs may be difficult. Despite this difficulty, semaphores are a widely used construct for concurrency.

96.3.3 Monitors

A more structured approach is to encapsulate the shared data/resources and their operations into a single module called a *monitor*. A monitor can contain non-externally accessible data and procedures that handle the state of resources. External access is strictly controlled through procedure calls to the monitor; mutual exclusion is ensured because procedure execution within the monitor is not concurrent.

Monitors have the traditional advantages of abstract data types, but they must also deal with two issues rising from their use by concurrently executing processes: avoiding interference and providing synchronization. This section illustrates some sample applications of monitors and how they internally handle concurrency.

Returning to the Producer-Consumer problem, we implement a monitor for handling shared access to the buffer. The monitor requires a synchronization mechanism to ensure that the Producer cannot overfill the buffer and that the Consumer cannot retrieve from an empty buffer. Monitors implement *condition variables*, the values of which are queues of processes delayed upon the corresponding conditions. Two standard operations defined on conditional variable *cv* are:

1. `wait(cv)`: causes the executing process to delay and to be placed at the end of *cv*'s queue; in order to allow eventual awakening of the process, the process must relinquish exclusive access to the monitor when it executes a `wait`.
2. `signal(cv)`: causes the process at the head of *cv*'s queue to be awakened; if the queue is empty, there is no effect.

Although these operations mirror those of semaphores, there is a key difference: the `signal` operation has no memory.

96.3.3.1 Monitors and Producer-Consumer

The buffer monitor can be defined as follows:

```
monitor Buffer
  # define the buffer
  const N := ..           # size of the buffer
  var buf[N] : int       # buffer
      front := 1         # buffer pointers
      rear := 1
  # define the condition variables
  var not_full,          # signaled when count < N
      not_empty : cv    # signaled when count > 0
  procedure deposit(data : int)
    if count = N        # check for space
      then wait(not_full) # delay if no space
    buf[rear] := data
    rear := (rear mod N) + 1
    N := N + 1
    signal(not_empty)  # signal non-empty
  end
  procedure fetch(var data : int)
    if count = 0        # check for not empty
      then wait(not_empty) # delay if empty
    data := buf[front]
    front := (front mod N) + 1
    N := N - 1
    signal(not_full)   # signal not full
  end Buffer
```

Using this monitor, the producer and consumer tasks can be redone as follows:

```
process Producer
  var x : int
  while true do ->
    # produce x
    ...
    deposit(x)
  end Producer

process Consumer
  var x : int
  while true do ->
    fetch(x)
    # consume x
    ...
  end Consumer
```

Now it is clear that programming (outside of the monitor) can now be done at a more abstract level, which will lead to more reliable software.

96.3.3.2 Difficulties with Monitors

There are difficulties with monitors as well. Consider the case where we have two consumers, C1 and C2. If the buffer is empty when C1 executes `fetch`, then C1 will delay on `not_empty`. If the producer then executes `deposit` (note that `deposit` and `fetch` cannot be executed concurrently), it will eventually `signal(not_empty)`, which will awaken C1. But if C2 executes `fetch` before C1 continues execution and its call to `fetch` proceeds, then C1 will access an empty buffer. Hence, the `signal` operation must be considered to be a *hint* that proceeding with execution is possible, but not that it is correct. The following two approaches are used to solve this problem:

1. Replace the check on the condition variable with a check inside a loop to ensure that the condition is true before execution proceeds. For example:

```
procedure deposit(data : int)
  while count = N do ->    # check for space
    then wait(not_full)   # delay if no space
  buf[rear] := data
  rear := (rear mod N) + 1
  N := N + 1
  signal(not_empty)      # signal non-empty
end
```

2. Give the highest priority to awakening processes so that intervening access to the monitor is not possible; this also requires that the `signal` operation be the last operation executed in any procedure in which it occurs (to ensure that two processes will not be executing within the monitor).

Monitors form the basis for concurrent programming in a number of systems and provide an efficient, high-level synchronization mechanism. They have the further advantage, as do other abstract data types or objects, of allowing for local modification and tuning without affecting the remainder of the system.

96.3.4 Message Passing

Consider a hardware architecture with multiple independent computers. Creating a semaphore to be efficiently accessed by processes running on separate computers is a difficult problem. We need a new abstraction for this case: message passing in which a sending process outputs a message to a *channel* and a receiving process inputs the message from this same channel. There are a large number of variations of this basic concept, depending on the semantics of the operations and the channels.

The basic primitives are:

1. Channel declaration
2. `send <channel> <message>`
3. `receive <channel> <variable>`

If both sending and receiving processes block upon reaching their corresponding message-passing operation, we have *synchronous* communication; if the sending process can send a message and continue without waiting for receipt, the system is *asynchronous*. Analogies are telephone communication and the postal system. The synchronous approach allows for ready synchronization of processes (at the instant of message passing we know where both are in their execution). This was the approach chosen by Hoare [1985] for his communicating sequential processes model and its subsequent implementation in the *occam* language [Jones and Goldsmith, 1988]. If we desire asynchronicity, we can add intermediate buffer processes to the synchronous approach. An advantage of synchronous message passing is that it often simplifies analysis of an algorithm because it is known where the sending and receiving processes are in their execution at the moment the message is passed.

Further variations arise, depending on whether channels are one process-to-one process or one-to-many, statically instantiated at load time or dynamically created during execution, bi-directional or

uni-directional, whether the receiving process must be named by the sending process, etc. However, the basic concept is the same in all cases; ease of use and efficiency of implementation vary.

Further variations include *remote procedure call* (RPC), which is the core of many distributed systems, and *rendezvous*, the approach used in Ada. We further explore these approaches after looking more closely at simple message passing.

Note that, in the message-passing approach, there are no shared variables so interference is not an issue. The critical section issue does not arise because there is no way for concurrent processes to interfere with each other. This is one of the major motivating factors for the use of message-passing software architectures.

96.3.4.1 Message Passing and Producer-Consumer

If the message-passing system is asynchronous, as demonstrated below, we can rely on the system itself to buffer values:

```
channel P2C

process Producer
  int x
  while true do ->
    # produce x
    send P2C x
  end Producer

process Consumer
  int x
  while true do ->
    receive P2C x
    # consume x
  end Consumer
```

Using this approach, the `Producer` sends a message over channel `P2C` and continues producing and sending (up to channel capacity at which point the system blocks), while the `Consumer` blocks at the receive statement if no messages are available.

If our system is synchronous, then as shown below, we create a separate buffer process:

```
channel P2B, B2C

process Buffer
  # create the buffer
  const N := ..
  var buffer[N] : int
      front := 1
      rear := 1
      count := 0          # number of items in the buffer
  while true do ->
    if
      # there is room and the producer is sending
      count < n and receive P2B buffer[rear] ->
        count++; rear := rear mod n + 1
    else
      # there are items and the consumer is receiving
      count > 0 and send B2C buffer[front] ->
        count--; front := front mod n + 1
    end Buffer
```

```

process Producer
var x : int
while true do ->
  # produce x
  ...
  send P2B x
end Producer

```

```

process Consumer
var x : int
while true do ->
  receive B2C x
  # consume x
end Consumer

```

Above the if statement is nondeterministic; that is, any true clause can be selected. The Boolean conditions in the clauses are called *guards*. The clauses are:

- If there is room and the producer wishes to send a character
- If there are items to retrieve and the consumer wishes to receive a character

For implementation efficiency reasons, actual programming languages do not allow guards for both input and output statements, so we must modify our solution; for example, as shown below, we can modify the buffer and consumer processes to eliminate the output guard:

```

channel P2B, B2C, C2B

process Buffer
# define the buffer
var buffer[n] : int
var front := 1
    rear := 1
    count := 0
while true do - >
  if
    # there is room and the producer is sending
    count < n and receive P2B buffer[rear] ->
      count++; rear := rear mod n + 1
  else
    # there are items and the consumer is requesting
    count > 0 and receive C2b buffer[front] ->
      send B2C buffer[front]
      count--; front := front mod n + 1
  end Buffer

process Producer
var x : int
while true do ->
  # produce x

```

```

...
send P2B x
end Producer

process Consumer
var int : x
while true do ->
    send C2B NIL          # announce ready for input
    receive B2C x
    # consume x
    ...
end Consumer

```

Above, the Consumer process first announces its intention to receive a value from the Buffer process (`send C2B NIL`; the `NIL` signifying that no message need be actually exchanged) and then actually receives the value (`receive B2C x`).

This program is an example of *client/server* programming. The Consumer process is a client of the Buffer process; that is, it requests service from the buffer, which provides it. Client/server programming is widely used to provide services across a network and is based on the message-passing paradigm.

96.3.4.2 Message Passing and Readers-Writers

The message-passing approach to Readers-Writers is straightforward: do not accept a message from a reader or writer if a writer is writing; do not accept a message from a writer if a reader is reading. The solution, shown below, is simple if we adopt synchronous message passing and the notion of the database as a server:

```

channel Rrequests, Rreceives, Wsends

Reader
send Rrequests <request message>
receive Rreceives <data>

Writer
send Wsends <write message>

Server
if
    # there are no writers, accept reader requests
    nw = 0 ->
        receive Rrequests <request message>
        # access the database
        ...
        send Rreceives <data>
    # there are no readers or writers, accept writer
    requests
    nr = 0 and nw = 0 ->
        receive Wsends <write message>
        # modify the database
        ...

```

96.3.4.3 Message Passing and Semaphore Simulation

Of course, as we show next, message passing can simulate a semaphore (and vice versa if need be):

```
channels P, V, initSemaphore

process Semaphore
var s : int
receive initSemaphore i
s := i
while true do ->
  if
    # semaphore is non-zero accept P operation
    s > 0 and receive P NIL->
    s--
    # always accept V operation
    receive V NIL ->
    s++
end Semaphore
```

96.3.4.4 The Remote Procedure Call and Rendezvous Abstractions

The remote procedure call, or RPC, abstraction is widely used to provide client/server services in a distributed system. Revisiting the client/server examples above, it is clear that the client executes a `send-receive` pair while the server executes a `receive-send` pair. Using the standard procedure model to capture the server's actions, a call statement to capture the client's actions and parameters to capture the messages being sent, we have:

```
Client
...
call Server(args)
...

Server(formal args)
...
return
```

which mirrors traditional procedure calls. The difference is that the `Server` procedure can be on a machine remote to the `Client` process. Indeed, the `Server` is implemented as a process that is always delayed until a `Client` executes a call. If multiple `Clients` concurrently execute calls to a `Server`, the `Server` must be re-entrant or must provide protection for shared information. The RPC approach forms the basis for distributed systems programs on a wide variety of platforms; its relationship to monitors should be clear.

The calling process and procedure are not truly concurrent in the sense used throughout this chapter, in that the calling process delays once the call is made, the procedure does not execute until called, the procedure delays when the return is executed, and the calling process resumes execution only upon the return from the procedure. The model is similar to that of synchronous message passing if the execution of the procedure is viewed as a component of the message-passing process (essentially, the procedure creates the return message).

We can increase the power of this approach if we modify the procedure into a process and have both processes executing concurrently. When a call is made, execution of the calling process delays while execution of the called process continues until it is ready to accept the call (via a special statement). The called process continues execution, performing actions or calculating values for the return message. The return message is sent back to the caller, the called process continues executing, and the calling process

resumes execution once the message is received. Because there is an extended time period during which the two processes are synchronized (from called accept through called return), this model of concurrency is termed *rendezvous*. It is the basis for the model of concurrency used in the Ada language. The Ada model is not symmetric: the calling process must know the name of the process it is calling, but the called process need not know its caller. Accept statements may have guards, as discussed above for message passing, in order to control acceptance of calls. The complexity of these guards, and their priority, must be carefully followed during program implementation.

There are several advantages to this approach, all based on the possibility of the called routine using multiple accept statements:

1. The called routine can provide different responses to the calling process at different stages of its execution.
2. The called routine can respond differently to different calling processes.
3. The called routine chooses when it will receive a call.
4. Different accept statements can be used to provide different services in a clear fashion (rather than through parameter values).

96.3.4.5 Difficulties with Message Passing

Message-passing systems are frequently inefficient during execution unless the algorithm is developed carefully. This is because messages take time to propagate, and this time is essentially overhead. For example, a single element buffer version of Conway's problem spends significantly more time exchanging messages than any other operation.

96.4 Distributed Systems

In addition to the difficulties inherent in developing and understanding concurrent solutions, distributed systems contain the fundamental problem of identifying global state. For example, how do we determine if a program has terminated? In the sequential case, this is obvious, we execute the `exit` or `end` statement. In the concurrent case, we must ensure that all processes are ready to terminate. In the multiprogramming case, we can do this by checking the ready queue; if it is empty, then there are no processes waiting to run, which ensures that no process will ever be added to the ready queues (if no process can run, then there can be no changes to create another ready process). But if we are in a distributed system, there is no single ready queue to examine. If a process is in the suspended queue on its processor, it may be made ready by a message from a process on a different processor.

Similarly, we may still require mutual exclusion on a system resource — how do we ensure access across processors? The solution is to develop a method of determining global state; see, for example, Ben-Ari [1990].

While a true “distributed” paradigm has not yet emerged in the programming paradigms domain, it will most likely evolve in the area of operating systems; for more information on distributed computing, readers are encouraged to look at [Chapter 108](#) in this *Handbook*.

96.5 Formal Approaches

We argued above that software verification in concurrent programming must take into account the enormous number of possible interactions between concurrent processes. Obviously, traditional testing only demonstrates the presence of “good” execution histories and is not a mechanism to verify any solution — sequential or concurrent. The use of a trace routine to generate execution histories is a standard sequential technique that becomes infeasible in the concurrent domain. Consider, for example, that n processes each executing m atomic actions generates $(n * m)! / (m!)^n$ histories. For three processes, each executing only two actions, this is a total of 90 possible histories!

The alternative is to use a formal, mathematically rigorous method to develop a solution and/or to verify a complete solution. Two approaches have been applied to verifying concurrent software:

1. Axiomatic or assertional
2. Process algebraic

The axiomatic approach develops assertions in the predicate logic that characterize the possible states of a computation. The actions of a program are viewed as predicate transformers that move the computation from one state to another. The beginning state is specified by the pre-condition of the computation, and the final state is characterized by the post-condition. This approach has been exploited for some time in the sequential paradigm; see Schneider [1997] for a comprehensive introduction to the field in the context of concurrency.

The process algebraic approach was pioneered by Hoare [1985], who also pioneered the coarse-grained model of concurrency. The concept is that the interactions between a system and its environment (which are all that is ultimately observable) can be modeled via a mathematical abstraction called a process (this is the abstraction of the computing process as used above). Processes can be combined via algebraic laws to form systems. Communication between processes is an example of this interaction. By building up a system through these mathematical laws and then transforming the abstract mathematics into an implementable language, one arrives at a correct solution. The *occam* language was designed to match the algebraic laws devised by Hoare; transformations exist between these laws and *occam* programming constructs (but the transformations are not perfect due to practicalities of implementation) [Hinchey and Jarvis, 1995]. A number of subsequent efforts developed process algebras with varying properties [Milner, 1989]; see Magee and Kramer [1999] for the use of a process algebra in the development of Java programs.

Although both approaches are in active use, they are not typically applied in the concurrent paradigm with any greater frequency than they are in the sequential paradigm, and they remain primarily research tools. The fundamental difficulty is that theoreticians search for the “fundamental particles” of computing to develop mathematical laws enabling formal reasoning. Practical languages are (inherently) extremely complex mixtures of these fundamental particles and laws in order to have sufficient power to solve real-world problems. Theoretical tools do not yet scale to these large, complex problems.

96.6 Existing Languages with Concurrency Features

A large number of languages have been developed to use the concurrency paradigm; most have remained in the laboratory environment. If the underlying operating system provides the requisite support, then semaphores can be implemented in any language via system calls. Higher-level concurrency control structures require modification of the underlying sequential language; for example, Concurrent Pascal [Brinch Hansen, 1975] uses monitors while Concurrent C [Gehani and Roome, 1986] is based on the rendezvous. By beginning with a widely used sequential programming language, a designer has a large community from which to draw users to the new language. The Ada (concurrency based upon the rendezvous) and SR (which includes structures for all of the approaches discussed in this chapter and is therefore particularly useful for exploring concurrent programming) [Andrews and Olsson, 1993; see Hartley, 1995, for extensive examples] languages are examples of sequential languages with concurrent structures included from the initial stages of development.

Object-oriented languages have similarly had concurrency features added. For example, Smalltalk has the Process and Semaphore classes to provide for the dynamic creation of independent processes and their interaction using the semaphore approach [Goldberg and Robson, 1989].

Languages based on an inherently concurrent model include Linda (more a language-independent philosophy than a language) [Ahuja et al., 1986] and *occam* (synchronous message passing) [Jones and Goldsmith, 1988].

A different approach is to provide a standardized interface (an application program interface or API) that is language independent. A language implementation then provides a set of library routines to implement this API. Thus, programmers can use a language of their choice while being assured that their

program will function correctly. Currently, the two main paradigms that are the basis for writing parallel programs are message passing and shared memory. A hybrid paradigm is used in systems comprised of shared-memory multiprocessor nodes that communicate via message passing. For writing message-passing programs, MPI (Message Passing Interface) [<http://www-unix.mcs.anl.gov/mpi/index.html>] is a widely used standard; many variants of MPI exist, including MPICH, CH for Chameleon, which is a complete, freely-available implementation of the MPI specification, targeted at high performance [<http://www-unix.mcs.anl.gov/mpi/mpich/>].

MPI's interface includes features of a number of message-passing systems and attempts to provide portability and ease-of-use. The MPI programming model is an MPMD (multiple program multiple data) model, in which every MPI process can execute a different program. A computation is envisioned as one or more processes that communicate by calling library routines to send and receive messages to other processes. In general, a fixed set of processes, one for each processor, is created at program initialization (versions of MPI that will support dynamic creation and termination of processes are anticipated). Local and global communication (e.g., broadcast and summation) is provided by point-to-point and collective communication operations, respectively. The former is used to send messages from one named process to another, while the latter is used to provide message passing among a group of processes. Most parallel algorithms are readily implemented using MPI. If an algorithm creates just one task per processor, it can be implemented directly with point-to-point or collective communication routines that meet its communication requirements. In contrast, if tasks are created dynamically or if several tasks are executed concurrently on a processor, the algorithm must be refined to permit an MPI implementation.

The OpenMP API is becoming a standard that supports multi-platform shared-memory parallel programming in C/C++ and Fortran on all architectures, including Unix and Windows NT platforms. OpenMP is a portable, scalable model that gives shared-memory parallel programmers a simple and flexible interface for developing parallel applications for platforms ranging from the desktop to the super-computer [<http://www.openmp.org/>]. This API is jointly defined by a group of major computer hardware and software vendors. OpenMP can be used to explicitly direct multi-threaded, shared memory parallelism. It is comprised of three primary API components: compiler directives, runtime library routines, and environment variables. Using the fork/join model of parallel execution, an OpenMP program begins as a single master thread. The master thread creates or forks a set of parallel threads, which concurrently execute a parallel region construct. On completion, the threads parallel threads join (i.e., synchronize and terminate), leaving only the master thread. The API supports nested parallelism and dynamic threads, that is, dynamic alternation of the number of active threads. Variable scoping, for example, declaration of private and shared data, parallelism, and synchronization are specified through the use of compiler directives. By itself, OpenMP is not meant for distributed memory parallel systems. For example, for high-performance cluster architectures such as the IBM SP, where intranode communication is accomplished via shared memory and internode communication is performed via message passing, OpenMP is used within a node while MPI is used between nodes.

There are many parallel programming tools available that help the user parallelize her/his application and then easily port it to a parallel machine. These machines can be shared-memory machines or a network of workstations.

96.7 Research Issues

While it is clear that concurrency is a necessary technique for the solution of many problems, it also is clear that progress must be made in order to ensure its effective application. That this is still a research issue is clear whenever an operating system crashes due to system processes that interfere with each other or we discover someone in our airplane seat due to concurrent access to the airline's database. This required progress falls into three categories:

1. Theoretical advances must be made to develop formal techniques that scale to real-world applications. For example, process interference checkers exist, but operate essentially by checking all

possible interactions between processes to check for deadlock, etc. This approach rapidly develops combinatorial explosion.

2. Design tools that provide development support for concurrent solutions. For example, debuggers that capture the concurrent computation without overwhelming the user with information.
3. Languages with powerful structures to support the correct application of concurrency. For example, the development of concurrent object-oriented languages appears straight-forward: simply allow each object to run concurrently because each object is logically autonomous. However, there are a number of issues that need resolution, including:
 - a. Not all objects need to run concurrently because the majority of computation will still be sequential (thereby incurring no scheduler overhead).
 - b. If we consider multiple concurrent objects attempting to communicate with the same object:
 - i. Acceptance of a message must delay all other messages in order to correctly preserve the internal state of the object.
 - ii. Ordering of message acceptance must be synchronized to ensure computations are correct.
 - iii. Acceptance of messages must occur only at appropriate points in the object's execution.
 - c. Inheritance through the class hierarchy creates problems because it will mix this synchronization with object behavior.

96.8 Summary

The single outstanding problem with concurrency is the development of correct solutions (as it is in all software systems): the state of development of both formal methods and software engineering tools for concurrent solutions lags behind the sequential world in this regard and well behind hardware advances.

Defining Terms

Asynchronous message passing: The message-sending process allows messages to be buffered and the sending process may continue after the send is initiated; the receiving process blocks if the message queue is empty.

Channel: The data structure, which may be realized in hardware, over which processes send messages.

Client/server: The software architecture in which clients are able to request services of processes executing on remote machines.

Condition variables: A variable used within a monitor to delay an executing process.

Critical regions: A section of code that must appear to be executed indivisibly.

Deadlock: The state in which processes are waiting for events that can never occur; that is, the processes cannot progress.

Distributed processing: The use of multiple processors that are remote from each other.

Fairness: Processes will eventually be able to progress, that is, enter their critical regions.

Message passing: A technique for providing mutual exclusion, communication, and synchronization among concurrent processes via sending messages between processes.

Monitor: An encapsulation of a resource and the operations on that resource that serve to ensure mutual exclusion.

Multiprocessing: The use of multiple processors.

Multiprogramming: Simulating concurrency by interleaving instruction execution from multiple programs; time sharing or time slicing.

Mutual exclusion: The property ensuring that a critical region is executed indivisibly by one process or thread at a time.

Race: Nondeterministic behavior caused by incorrectly synchronized concurrent processes.

Remote procedure call: The message-passing architecture in which processes request services of processes executing procedures on remote machines.

Rendezvous: The message-passing construct used in the Ada language.

Semaphore: A nonnegative integer-valued variable on which two operations are defined: P and V to signal intent to enter and exit, respectively, a critical region.

Synchronous message passing: The message-sending process requires both sender and receiver to synchronize at the moment of message transmission.

97.1 Introduction

The fundamental purpose of a **type system** is to prevent the occurrence of *execution errors* during the running of a program. This informal statement motivates the study of type systems, but requires clarification. Its accuracy depends, first of all, on the rather subtle issue of what constitutes an execution error, which we will discuss in detail. Even when that is settled, the absence of execution errors is a nontrivial property. When such a property holds for all the program runs that can be expressed within a programming language, we say that the language is **type sound**. It turns out that a fair amount of careful analysis is required to avoid false and embarrassing claims of type soundness for programming languages. As a consequence, the classification, description, and study of type systems has emerged as a formal discipline.

The formalization of type systems requires the development of precise notations and definitions, and the detailed proof of formal properties that give confidence in the appropriateness of the definitions. Sometimes the discipline becomes rather abstract. One should always remember, however, that the basic motivation is pragmatic: the abstractions have arisen out of necessity and can usually be related directly to concrete intuitions. Moreover, formal techniques need not be applied in full in order to be useful and influential. A knowledge of the main principles of type systems can help in avoiding obvious and not-so-obvious pitfalls, and can inspire regularity and orthogonality in language design.

When properly developed, type systems provide conceptual tools with which to judge the adequacy of important aspects of language definitions. Informal language descriptions often fail to specify the type

structure of a language in sufficient detail to allow unambiguous implementation. It often happens that different compilers for the same language implement slightly different type systems. Moreover, many language definitions have been found to be type unsound, allowing a program to crash even though it is judged acceptable by a **typechecker**. Ideally, formal type systems should be part of the definition of all typed programming languages. This way, typechecking algorithms could be measured unambiguously against precise specifications and, if at all possible and feasible, whole languages could be shown to be type sound.

In this introductory section we present an informal nomenclature for typing, execution errors, and related concepts. We discuss the expected properties and benefits of type systems, and we review how type systems can be formalized. The terminology used in the introduction is not completely standard; this is due to the inherent inconsistency of standard terminology arising from various sources. In general, we avoid the words *type* and *typing* when referring to runtime concepts; for example, we replace dynamic typing with dynamic checking and avoid common but ambiguous terms such as strong typing. The terminology is summarized in the “Defining Terms” section.

In [Section 97.2](#) we explain the notation commonly used for describing type systems. We review **judgments**, which are formal assertions about the typing of programs; **type rules**, which are implications between judgments; and **derivations**, which are deductions based on type rules. In [Section 97.3](#) we review a broad spectrum of simple types, the analog of which can be found in common languages, and we detail their type rules. In [Section 97.4](#) we present the type rules for a simple but complete imperative language. In [Section 97.5](#) we discuss the type rules for some advanced type constructions: *polymorphism* and *data abstraction*. In [Section 97.6](#) we explain how type systems can be extended with a notion of *subtyping*. [Section 97.7](#) is a brief commentary on some important topics that we have glossed over. In [Section 97.8](#) we discuss the *type inference* problem and present type inference algorithms for the main type systems that we have considered. Finally, [Section 97.9](#) presents a summary of achievements and future directions.

97.1.1 Execution Errors

The most obvious symptom of an execution error is the occurrence of an unexpected software fault, such as an illegal instruction fault or an illegal memory reference fault.

There are, however, more subtle kinds of execution errors that result in data corruption without any immediate symptoms. Moreover, there are software faults, such as divide by zero and dereferencing *nil*, that are not normally prevented by type systems. Finally, there are languages lacking type systems where, nonetheless, software faults do not occur. Therefore, we need to define our terminology carefully, beginning with what is a type.

97.1.1.1 Typed and Untyped Languages

A program variable can assume a range of values during the execution of a program. An upper bound of such a range is called a **type** of the variable. For example, a variable x of type *Boolean* is supposed to assume only Boolean values during every run of a program. If x has type *Boolean*, then the Boolean expression *not* (x) has a sensible meaning in every run of the program. Languages for which variables can be given (nontrivial) types are called **typed languages**.

Languages that do not restrict the range of variables are called **untyped languages**; they do not have types or, equivalently, have a single universal type that contains all values. In these languages, operations may be applied to inappropriate arguments; the result may be a fixed arbitrary value, a fault, an exception, or an unspecified effect. The pure λ -calculus is an extreme case of an untyped language where no fault ever occurs; the only operation is function application and, because all values are functions, that operation never fails.

A type system is that component of a typed language that keeps track of the types of variables and, in general, of the types of all expressions in a program. Type systems are used to determine whether programs are **well behaved** (as discussed subsequently). Only program sources that comply with a type system should be considered real programs of a typed language; the other sources should be discarded before they are run.

A language is typed by virtue of the existence of a type system for it, whether or not types actually appear in the syntax of programs. Typed languages are **explicitly typed** if types are part of the syntax, and

implicitly typed otherwise. No mainstream language is purely implicitly typed, but languages such as ML and Haskell support writing large program fragments where type information is omitted; the type systems of those languages automatically assign types to such program fragments.

97.1.1.2 Execution Errors and Safety

It is useful to distinguish between two kinds of execution errors: the ones that cause the computation to stop immediately, and the ones that go unnoticed (for awhile) and later cause arbitrary behavior. The former are called **trapped errors**, whereas the latter are **untrapped errors**.

An example of an untrapped error is improperly accessing a legal address, for example, accessing data past the end of an array in absence of runtime bounds checks. Another untrapped error that may go unnoticed for an arbitrary length of time is jumping to the wrong address; memory there may or may not represent an instruction stream. Examples of trapped errors are division by zero and accessing an illegal address: the computation stops immediately (on many computer architectures).

A program fragment is *safe* if it does not cause untrapped errors to occur. Languages for which all program fragments are safe are called **safe languages**. Therefore, safe languages rule out the most insidious form of execution errors: the ones that may go unnoticed. Untyped languages may enforce **safety** by performing runtime checks. Typed languages may enforce safety by statically rejecting all programs that are potentially unsafe. Typed languages may also use a mixture of runtime and **static checks**.

Although safety is a crucial property of programs, it is rare for a typed language to be concerned exclusively with the elimination of untrapped errors. Typed languages usually aim to rule out also large classes of trapped errors, along with the untrapped ones. We discuss these issues next.

97.1.1.3 Execution Errors and Well-Behaved Programs

For any given language, we can designate a subset of the possible execution errors as **forbidden errors**. The forbidden errors should include all the untrapped errors, plus a subset of the trapped errors. A program fragment is said to have **good behavior**, or equivalently to be well behaved, if it does not cause any forbidden error to occur. (The contrary is to have *bad behavior*, or equivalently to be *ill behaved*.) In particular, a well-behaved fragment is safe. A language in which all the (legal) programs have good behavior is called **strongly checked**.

Thus, with respect to a given type system, the following holds for a strongly checked language:

- No untrapped errors occur (safety guarantee).
- None of the trapped errors designated as forbidden errors occur.
- Other trapped errors may occur; it is the programmer's responsibility to avoid them.

Typed languages can enforce good behavior (including safety) by performing static (i.e., compile time) checks to prevent unsafe and ill-behaved programs from ever running. These languages are **statically checked**; the checking process is called **typechecking**, and the algorithm that performs this checking is called the **typechecker**. A program that passes the typechecker is said to be **well typed**; otherwise, it is **ill typed**, which may mean that it is actually ill behaved, or simply that it could not be guaranteed to be well behaved. Examples of statically checked languages are ML, Java, and Pascal (with the caveat that Pascal has some unsafe features).

Untyped languages can enforce good behavior (including safety) in a different way, by performing sufficiently detailed runtime checks to rule out all forbidden errors. (For example, they may check all array bounds, and all division operations, generating recoverable exceptions when forbidden errors would happen.) The checking process in these languages is called **dynamic checking**; LISP is an example of such a **dynamically checked language**. These languages are strongly checked although they have neither static checking nor a type system.

Even statically checked languages usually need to perform tests at runtime to achieve safety. For example, array bounds must in general be tested dynamically. The fact that a language is statically checked does not necessarily mean that execution can proceed entirely blindly.

TABLE 97.1 Safety

	Typed	Untyped
Safe	ML, Java	LISP
Unsafe	C	Assembler

Several languages take advantage of their static type structures to perform sophisticated dynamic tests. For example, Simula67's INSPECT, Modula-3's TYPECASE, and Java's instanceof constructs discriminate on the runtime type of an object. These languages are still (slightly improperly) considered statically checked, partially because the dynamic type tests are defined on the basis of the static type system. That is, the dynamic tests for type equality are compatible with the algorithm that the typechecker uses to determine type equality at compile time.

97.1.2 Lack of Safety

By our definitions, a well-behaved program is safe. Safety is a more primitive and perhaps more important property than good behavior. The primary goal of a type system is to ensure language safety by ruling out *all* untrapped errors in all program runs. However, most type systems are designed to ensure the more general good-behavior property and, implicitly, safety. Thus, the declared goal of a type system is usually to ensure good behavior of all programs, by distinguishing between well-typed and ill-typed programs.

In reality, certain statically checked languages do not ensure safety. That is, their set of forbidden errors does not include all untrapped errors. These languages can be euphemistically called weakly checked (or *weakly typed*, in the literature), meaning that some unsafe operations are detected statically and some are not detected. Languages in this class vary widely in the extent of their weakness. For example, Pascal is unsafe only when untagged variant types and function parameters are used, whereas C has many unsafe and widely used features, such as pointer arithmetic and casting. It is interesting to notice that the first five of the ten commandments for C programmers [Spencer] are directed at compensating for the weak-checking aspects of C. Some of the problems caused by weak checking in C have been alleviated in C++, and even more have been addressed in Java, confirming a trend away from weak checking. Modula-3 supports unsafe features, but only in modules that are explicitly marked as unsafe, and prevents safe modules from importing unsafe interfaces.

Most untyped languages are, by necessity, completely safe (e.g., LISP). Otherwise, programming would be too frustrating in the absence of both compile time and runtime checks to protect against corruption. Assembly languages belong to the unpleasant category of untyped unsafe languages (see Table 97.1).

97.1.3 Should Languages Be Safe?

Some languages, like C, are deliberately unsafe because of performance considerations: the runtime checks needed to achieve safety are sometimes considered too expensive. Safety has a cost even in languages that do extensive static analysis: tests such as array bounds checks cannot be, in general, completely eliminated at compile time.

Still, there have been many efforts to design safe subsets of C, and to produce development tools that try to execute C programs safely by introducing a variety of (relatively expensive) runtime checks. These efforts are due to two main reasons: (1) the widespread use of C in applications that are not largely performance critical, and (2) the security problems introduced by unsafe C programs. The security problems include buffer overflows and underflows caused by pointer arithmetic, and lack of array bounds checks that can lead to overwriting areas of memory and that can be exploited for attacks.

Safety is cost-effective according to different measures than just pure performance. Safety produces fail-stop behavior in case of execution errors, reducing debugging time. Safety guarantees the integrity of runtime structures, and therefore enables garbage collection. In turn, garbage collection considerably reduces code size and code development time, at the price of some performance. Finally, safety

has emerged as a necessary foundation for system security, particularly for systems (such as operating system kernels and Web browsers) that load and run foreign code. System security is becoming one of the most expensive aspects of program development and maintenance, and safety can reduce these costs.

Thus, the choice between a safe and unsafe language may be ultimately related to a trade-off between development and maintenance time, and execution time. Although safe languages have been around for many decades, it is only recently that they have become mainstream, uniquely because of security concerns.

97.1.4 Should Languages Be Typed?

The issue of whether programming languages should have types is still subject to some debate. There is little doubt that production code written in untyped languages can be maintained only with great difficulty. From the point of view of maintainability, even weakly checked unsafe languages are superior to safe but untyped languages (e.g., C vs. LISP). Following are the arguments that have been put forward in favor of typed languages, from an engineering point of view:

- *Economy of execution.* Type information was first introduced in programming to improve code generation and runtime efficiency for numerical computations, for example, in FORTRAN. In ML, accurate type information eliminates the need for *nil*-checking on pointer dereferencing. In general, accurate type information at compile time leads to the application of the appropriate operations at runtime without the need for expensive tests.
- *Economy of small-scale development.* When a type system is well designed, typechecking can capture a large fraction of routine programming errors, thus eliminating lengthy debugging sessions. The errors that do occur are easier to debug, simply because large classes of other errors have been ruled out. Moreover, experienced programmers adopt a coding style that causes some logical errors to show up as typechecking errors: they use the typechecker as a development tool. (For example, by changing the name of a field when its invariants change even though its type remains the same, so as to get error reports on all its old uses.)
- *Economy of compilation.* Type information can be organized into *interfaces* for program modules, for example, as in Modula-2 and Ada. Modules can then be compiled independently of each other, with each module depending only on the interfaces of the others. Compilation of large systems is made more efficient because, at least when interfaces are stable, changes to a module do not cause other modules to be recompiled.
- *Economy of large-scale development.* Interfaces and modules have methodological advantages for code development. Large teams of programmers can negotiate the interfaces to be implemented, and then proceed separately to implement the corresponding pieces of code. Dependencies between pieces of code are minimized, and code can be locally rearranged without fear of global effects. (These benefits can also be achieved by informal interface specifications; but in practice, typechecking helps enormously in verifying adherence to the specifications.)
- *Economy of development and maintenance in security areas.* Although safety is necessary to eliminate security breaches such as buffer overflows, typing is necessary to eliminate other catastrophic security breaches, such as the following. If there is any way at all, no matter how convoluted, to cast an integer into a value of pointer type (or object type), the entire system is compromised. If that is possible, attackers can access any data anywhere in the system, even within the confines of an otherwise typed language, using any type they choose to view the data. Another helpful technique is to convert a given typed pointer into an integer, and then into a pointer of different type as above. The most cost-effective way to eliminate these security problems, in terms of maintenance and execution efficiency, is to employ typed languages. Still, security is a problem at all levels of a system; typed languages provide an excellent foundation, but not a complete solution.

- *Economy of language features.* Type constructions are naturally composed in orthogonal ways. For example, in Pascal, an array of arrays models two-dimensional arrays; in ML, a procedure with a single argument that is a tuple of n parameters models a procedure of n arguments. Thus, type systems promote orthogonality of language features, question the utility of artificial restrictions, and thus tend to reduce the complexity of programming languages.

97.1.5 Expected Properties of Type Systems

In the remainder of this chapter we proceed under the assumption that languages should be both safe and typed, and therefore that type systems should be employed. In the study of type systems, we neither distinguish between trapped and untrapped errors, nor between safety and good behavior; we concentrate on good behavior, and we take safety as an implied property.

Types, as normally intended in programming languages, have pragmatic characteristics that distinguish them from other kinds of program annotations. In general, annotations about the behavior of programs can range from informal comments to formal specifications subject to theorem proving. Types sit in the middle of this spectrum: they are more precise than program comments, and more easily mechanizable than formal specifications. Here are the basic properties expected of any type system:

- Type systems should be *decidably verifiable*: there should be an algorithm (called a typechecking algorithm) that can ensure that a program is well behaved. The purpose of a type system is not simply to state programmer intentions, but to actively capture execution errors before they happen. (Arbitrary formal specifications do not have these properties.)
- Type systems should be *transparent*: a programmer should be able to predict easily whether a program will typecheck. If it fails to typecheck, the reason for the failure should be self-evident. (Automatic theorem proving does not have these properties.)
- Type systems should be *enforceable*: type declarations should be statically checked as much as possible, and otherwise dynamically checked. The consistency between type declarations and their associated programs should be routinely verified. (Program comments and conventions do not have these properties.)

97.1.6 How Type Systems Are Formalized

As we have discussed, type systems are used to define the notion of well typing, which is itself a static approximation of good behavior (including safety). Safety facilitates debugging because of fail-stop behavior, and enables garbage collection by protecting runtime structures. Well typing further facilitates program development by trapping execution errors before runtime.

But how can we guarantee that well-typed programs are really well behaved? That is, how can we be sure that the type rules of a language do not accidentally allow ill-behaved programs to slip through?

Formal type systems are the mathematical characterizations of the informal type systems that are described in programming language manuals. Once a type system is formalized, we can attempt to prove a *type soundness* theorem stating that *well-typed programs are well behaved*. If such a soundness theorem holds, we say that the type system is sound. (Good behavior of all programs of a typed language and soundness of its type system mean the same thing.)

To formalize a type system and prove a soundness theorem, we must in essence formalize the whole language in question, as we now sketch.

The first step in formalizing a programming language is to describe its syntax. For most languages of interest, this reduces to describing the syntax of types and *terms*. Types express static knowledge about programs, whereas terms (statements, expressions, and other program fragments) express the algorithmic behavior.

The next step is to define the *scoping* rules of the language, which unambiguously associate occurrences of identifiers to their binding locations (the locations where the identifiers are declared). The scoping needed for typed languages is invariably *static*, in the sense that the binding locations of identifiers must

be determined before runtime. Binding locations can often be determined purely from the syntax of a language, without any further analysis; static scoping is then called *lexical scoping*. The lack of static scoping is called *dynamic scoping*.

Scoping can be formally specified by defining the set of *free variables* of a program fragment (which involves specifying how variables are bound by declarations). The associated notion of *substitution* of types or terms for free variables can then be defined.

When this much is settled, one can proceed to define the type rules of the language. These describe a relation *has-type* of the form $M : A$ between terms M and types A . Some languages also require a relation *subtype-of* of the form $A <: B$ between types, and often a relation *equal-type* of the form $A = B$ of type equivalence. The collection of type rules of a language forms its type system. A language that has a type system is called a typed language.

The type rules cannot be formalized without first introducing another fundamental ingredient that is not reflected in the syntax of the language: *static typing environments*. These are used to record the types of free variables during the processing of program fragments; they correspond closely to the symbol table of a compiler during the typechecking phase. The type rules are always formulated with respect to a static environment for the fragment being typechecked. For example, the has-type relation $M : A$ is associated with a static typing environment Γ that contains information about the free variables of M and A . The relation is written in full as $\Gamma \vdash M : A$, meaning that M has type A in environment Γ .

The final step in formalizing a language is to define its semantics as a relation *has-value* between terms and a collection of *results*. The form of this relation depends strongly on the style of semantics that is adopted. In any case, the semantics and the type system of a language are interconnected: the types of a term and of its result should be the same (or appropriately related); this is the essence of the soundness theorem.

The fundamental notions of type system are applicable to virtually all computing paradigms (functional, imperative, concurrent, etc.). Individual type rules can often be adopted unchanged for different paradigms. For example, the basic type rules for functions are the same whether the semantics are call-by-name or call-by-value or, orthogonally, functional or imperative.

In this chapter we discuss type systems independently of semantics. It should be understood, however, that ultimately a type system must be related to a semantics, and that soundness should hold for those semantics. Suffice it to say that the techniques of structural operational semantics deal uniformly with a large collection of programming paradigms, and fit very well with the treatment found in this chapter.

97.1.7 Type Equivalence

As mentioned above, most nontrivial type systems require the definition of a relation *equal type* of type equivalence. This is an important issue when defining a programming language: when are separately written type expressions equivalent? Consider, for example, two distinct type names that have been associated with similar types:

$$\text{type } X = \text{Bool}$$
$$\text{type } Y = \text{Bool}$$

If the type names X and Y match by virtue of being associated with similar types, we have *structural equivalence*. If they fail to match by virtue of being distinct type names (without looking at the associated types), we have *by-name equivalence*.

In practice, a mixture of structural and by-name equivalence is used in most languages. Pure structural equivalence can be easily and precisely defined by means of type rules, while by-name equivalence is more difficult to pin down, and often has an algorithmic flavor. Structural equivalence has unique advantages when typed data must be stored or transmitted over a network; in contrast, by-name equivalence cannot deal easily with interacting programs that have been developed and compiled separately in time or space.

We assume structural equivalence in what follows (although this issue does not arise often). Satisfactory emulation of by-name equivalence can be obtained within structural equivalence, as demonstrated by the Modula-3 *branding* mechanism.

97.2 The Language of Type Systems

A type system specifies the type rules of a programming language independently of particular typechecking algorithms. This is analogous to describing the syntax of a programming language by a formal grammar, independently of particular parsing algorithms.

It is both convenient and useful to decouple type systems from typechecking algorithms: type systems belong to language definitions, while algorithms belong to compilers. It is easier to explain the typing aspects of a language by a type system, rather than by the algorithm used by a given compiler. Moreover, different compilers may use different typechecking algorithms for the same type system.

As a minor problem, it is technically possible to define type systems that admit only unfeasible typechecking algorithms, or no algorithms at all. The usual intent, however, is to allow for efficient typechecking algorithms.

97.2.1 Judgments

Type systems are described by a particular formalism, which we now introduce. The description of a type system starts with the description of a collection of formal utterances called *judgments*. A typical judgment has the form:

$$\Gamma \vdash \mathfrak{J} \quad \text{where } \mathfrak{J} \text{ is an assertion; the free variables of } \mathfrak{J} \text{ are declared in } \Gamma.$$

We say that Γ *entails* \mathfrak{J} . Here, Γ is a static typing environment; for example, an ordered list of distinct variables and their types, of the form $\emptyset, x_1 : A_1, \dots, x_n : A_n$. The empty environment is denoted by \emptyset , and the collection of variables $x_1 \cdots x_n$ declared in Γ is indicated by $\text{dom}(\Gamma)$, the domain of Γ . The form of the *assertion* \mathfrak{J} varies from judgment to judgment, but all the free variables of \mathfrak{J} must be declared in Γ .

The most important judgment, for our present purposes, is the *typing judgment*, which asserts that a term M has a type A with respect to a static typing environment for the free variables of M . It has the form:

$$\Gamma \vdash M : A \quad M \text{ has type } A \text{ in } \Gamma$$

Examples.

$$\begin{array}{ll} \emptyset \vdash \text{true} : \text{Bool} & \text{true has type Bool} \\ \emptyset, x : \text{Nat} \vdash x + 1 : \text{Nat} & x + 1 \text{ has type Nat, provided that } x \text{ has type Nat} \end{array}$$

Other judgment forms are often necessary; a common one asserts simply that an environment is **well formed**:

$$\Gamma \vdash \diamond \quad \Gamma \text{ is well-formed (i.e., it has been properly constructed)}$$

Any given judgment can be regarded as *valid* (e.g., $\Gamma \vdash \text{true} : \text{Bool}$) or *invalid* (e.g., $\Gamma \vdash \text{true} : \text{Nat}$). Validity formalizes the notion of well-typed programs. The distinction between valid and invalid judgments could be expressed in a number of ways; however, a highly stylized way of presenting the set of valid judgments has emerged. This presentation style, based on type rules, facilitates stating and proving technical lemmas and theorems about type systems. Moreover, type rules are highly modular: rules for different constructs can be written separately (in contrast to a monolithic typechecking algorithm). Therefore, type rules are comparatively easy to read and understand.

97.2.1.1 Type Rules

Type rules assert the validity of certain judgments on the basis of other judgments that are already known to be valid. The process gets off the ground by some intrinsically valid judgment (usually: $\emptyset \vdash \diamond$, stating that the empty environment is well formed).

The general form of a type rule is:

$$\frac{\text{(Rule name) (Annotations)} \quad \Gamma_1 \vdash \mathfrak{J}_1 \dots \Gamma_n \vdash \mathfrak{J}_n \text{ (Annotations)}}{\Gamma \vdash \mathfrak{J}}$$

Each type rule is written as a number of *premise* judgments $\Gamma_i \vdash \mathfrak{J}_i$ above a horizontal line, with a single *conclusion* judgment $\Gamma \vdash \mathfrak{J}$ below the line. When all the premises are satisfied, the conclusion must hold; the number of premises may be zero. Each rule has a name. (By convention, the first word of the name is determined by the conclusion judgment; for example, rule names of the form “(Val . . .)” are for rules whose conclusion is a value typing judgment.) When needed, conditions restricting the applicability of a rule, as well as abbreviations used within the rule, are annotated next to the rule name or the premises.

For example, the first of the following two rules states that any numeral is an expression of type *Nat*, in any well-formed environment Γ . The second rule states that two expressions M and N denoting natural numbers can be combined into a larger expression $M + N$, which also denotes a natural number. Moreover, the environment Γ for M and N , which declares the types of any free variable of M and N , carries over to $M + N$.

$$\begin{array}{c} \text{(Val } n) \text{ (} n = 0, 1, \dots \text{)} \\ \hline \Gamma \vdash \diamond \\ \hline \Gamma \vdash n : \text{Nat} \end{array} \qquad \begin{array}{c} \text{(Val } +) \\ \hline \Gamma \vdash M : \text{Nat} \quad \Gamma \vdash N : \text{Nat} \\ \hline \Gamma \vdash M + N : \text{Nat} \end{array}$$

A fundamental rule states that the empty environment is well formed, with no assumptions:

$$\begin{array}{c} \text{(Env } \emptyset) \\ \hline \emptyset \vdash \diamond \end{array}$$

A collection of type rules is called a (*formal*) *type system*. Technically, type systems fit into the general framework of *formal proof systems*: collections of rules used to carry out step-by-step deductions. The deductions carried out in type systems concern the typing of programs.

97.2.1.2 Type Derivations

A derivation in a given type system is a tree of judgments with leaves at the top and a root at the bottom, where each judgment is obtained from the ones immediately above it by some rule of the system. A fundamental requirement on type systems is that it must be possible to check whether or not a derivation is properly constructed.

A **valid judgment** is one that can be obtained as the root of a derivation in a given type system. That is, a valid judgment is one that can be obtained by correctly applying the type rules. For example, using the three rules given previously, we can build the following derivation, which establishes that $\emptyset \vdash 1 + 2 : \text{Nat}$ is a valid judgment. The rule applied at each step is displayed to the right of each conclusion:

$$\begin{array}{c} \frac{}{\emptyset \vdash \diamond} \quad \text{by (Env } \emptyset) \quad \frac{}{\emptyset \vdash \diamond} \quad \text{by (Env } \emptyset) \\ \hline \frac{\emptyset \vdash 1 : \text{Nat} \quad \emptyset \vdash 2 : \text{Nat}}{\emptyset \vdash 1 + 2 : \text{Nat}} \quad \text{by (Val } +) \end{array}$$

97.2.2 Well Typing and Type Inference

In a given type system, a term M is well typed for an environment Γ if there is a type A such that $\Gamma \vdash M : A$ is a valid judgment; that is, if the term M can be given some type.

The discovery of a derivation (and hence of a type) for a term is called the **type inference** problem. In the simple type system consisting of the rules (Env \emptyset), (Val n), and (Val $+$), a type can be *inferred* for the term $1 + 2$ in the empty environment. This type is *Nat*, by the preceding derivation.

Suppose we now add a type rule with premise $\Gamma \vdash \diamond$ and conclusion $\Gamma \vdash \text{true} : \text{Bool}$. In the resulting type system, we cannot infer any type for the term $1 + \text{true}$ because there is no rule for summing a natural number with a Boolean. Because of the absence of any derivations for $1 + \text{true}$, we say that $1 + \text{true}$ is *not typeable*, or that it is ill typed, or that it has a **typing error**.

We could further add a type rule with premises $\Gamma \vdash M : \text{Nat}$ and $\Gamma \vdash N : \text{Bool}$, and with conclusion $\Gamma \vdash M + N : \text{Nat}$ (e.g., with the intent of interpreting *true* as 1). In such a type system, a type could be inferred for the term $1 + \text{true}$, which would now be well typed.

Thus, the type inference problem for a given term is very sensitive to the type system in question. An algorithm for type inference may be very easy, very difficult, or impossible to find, depending on the type system. If found, the best algorithm may be very efficient, or hopelessly slow. Although type systems are expressed and often designed in the abstract, their practical utility depends on the availability of good type inference algorithms.

The type inference problem for explicitly typed procedural languages such as Pascal is fairly easily solved; we treat it in [Section 97.8](#). The type inference problem for implicitly typed languages such as ML is much more subtle, and we do not treat it here. The basic algorithm is well understood (several descriptions of it appear in the literature) and is widely used. However, the versions of the algorithm that are used in practice are complex and are still being investigated.
