The carry select adder divides the words to be added into blocks and forms two sums for each block in parallel (one with a carry in of 0 and the other with a carry in of 1). As shown for a 16-bit carry select adder in Figure 22.6, the carryout from the previous block controls a multiplexer that selects the appropriate sum. The carryout is computed using Equation 22.13, because the group propagate signal is the carryout of an adder with a carry input of 1 and the group generate signal is the carryout of an adder with a carry input of 0.

If a constant block width of k is used, there will be $\lceil n/k \rceil$ blocks and the delay to generate the sum is $2k + 3$ gate delays to form the carryout of the first block, 2 gate delays for each of the $\lceil n/k \rceil - 2$ intermediate

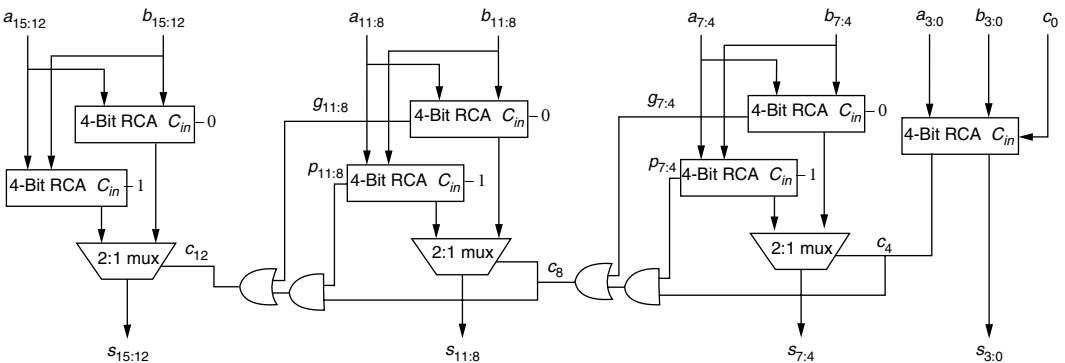

FIGURE 22.6 16-bit carry select adder.

blocks, and 3 gate delays (for the multiplexer) in the final block. To simplify the analysis, the ceiling function in the count of intermediate blocks is ignored. Thus, the total delay is

$$\text{DELAY}_{C\text{-SEL}} = 2k + 2\frac{n}{k} + 2 \quad (22.21)$$

The optimum block size is determined by taking the derivative of $\text{DELAY}_{\text{SEL}}$ with respect to k , setting it to zero, and solving for k . The results are:

$$k = \sqrt{n} \quad (22.22)$$

$$\text{DELAY}_{\text{SEL}} = 2 + 4\sqrt{n} \quad (22.23)$$

As for the carry skip adder, better results can be obtained by varying the width of the blocks. In this case, the optimum is to make the two least significant blocks the same size and each successively more significant block 1 bit larger. In this configuration, the delay for each block's most significant sum bit will equal the delay to the multiplexer control signal [Goldberg 1990, p. A-38].

The complexity of the carry select adder is $2n - k$ ripple carry adder stages, the intermediate carry logic and $(\lceil n/k \rceil - 1)$ k -bit-wide 2:1 multiplexers:

$$\begin{aligned} \text{GATES}_{\text{SEL}} &= 9(2n - k) + 2\left(\left\lceil \frac{n}{k} \right\rceil - 2\right) + 3(n - k) + \left\lceil \frac{n}{k} \right\rceil - 1 \\ &= 21n - 12k + 3\left\lceil \frac{n}{k} \right\rceil - 5 \end{aligned} \quad (22.24)$$

This is slightly more than twice the complexity of a ripple carry adder of the same size.

22.3.2 Fixed Point Subtraction

To produce an adder/subtractor, the adder is modified as shown in Figure 22.7 by including EXCLUSIVE-OR gates to complement operand B when performing subtraction. It forms either $A + B$ or $A - B$. In the case of $A + B$, the mode selector is set to logic 0, which causes the EXCLUSIVE-OR gates to pass operand B through unchanged to the ripple carry adder. The carry into the least significant adder stage is also set to ZERO, so standard addition occurs. Subtraction is implemented by setting the mode selector to logic ONE, which causes the EXCLUSIVE-OR gates to complement the bits of B ; formation of the two's complement of B is completed by setting the carry into the least significant adder stage to ONE.

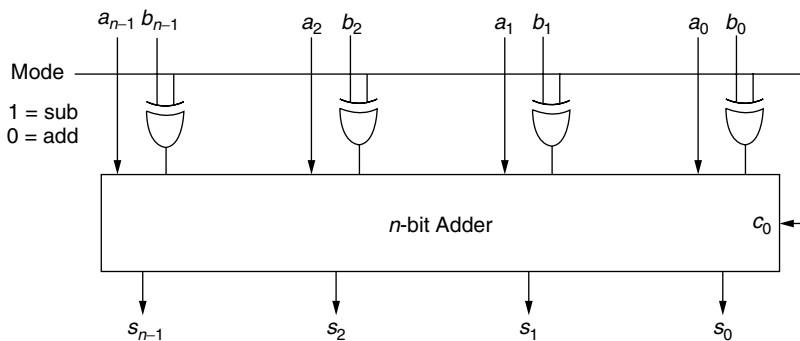

FIGURE 22.7 Adder/subtractor.

22.3.3 Fixed Point Multiplication

Multiplication is generally implemented either via a sequence of addition, subtraction, and shift operations or by direct logic implementations.

22.3.3.1 Sequential Booth Multiplier

The Booth algorithm [Booth 1951] is widely used for two's complement multiplication because it is easy to implement. Earlier two's complement multipliers (e.g., [Shaw 1950]) require data-dependent correction cycles if either operand is negative. In the Booth algorithm, to multiply A times B , the product P is initially set to 0. Then, the bits of the multiplier A are examined in pairs of adjacent bits, starting with the least significant bit (i.e., $a_0 a_{-1}$) and assuming $a_{-1} = 0$:

- If $a_i = a_{i-1}$, $P = P/2$.
- If $a_i = 0$ and $a_{i-1} = 1$, $P = (P + B)/2$.
- If $a_i = 1$ and $a_{i-1} = 0$, $P = (P - B)/2$.

The division by 2 is not performed on the last stage (i.e., when $i = n - 1$). All of the divide by 2 operations are simple arithmetic right shifts (i.e., the word is shifted right one position and the old sign bit is repeated for the new sign bit), and overflows in the addition process are ignored. The algorithm is illustrated in Figure 22.8, in which products for all combinations of $\pm 5/8$ times $\pm 3/4$ are computed for 4-bit operands. The sequential Booth multiplier requires n cycles to form the product for a pair of n -bit

Positive Times Positive			$A = \frac{5}{8} = 0.101$	$B = \frac{3}{4} = 0.110$
i	a_i	a_{i-1}	Operation	Result
0	1	0	$P = (P - B)/2$	1.1010
1	0	1	$P = (P + B)/2$	0.00110
2	1	0	$P = (P - B)/2$	1.101110
3	0	1	$P = P + B$	0.011110
Thus: $P = 0.011110 = \frac{15}{32}$				
Negative Times Positive			$A = -\frac{5}{8} = 1.011$	$B = \frac{3}{4} = 0.110$
i	a_i	a_{i-1}	Operation	Result
0	1	0	$P = (P - B)/2$	1.1010
1	1	1	$P = P/2$	1.11010
2	0	1	$P = (P + B)/2$	0.010010
3	1	0	$P = P - B$	1.100010
Thus: $P = 1.100010 = -\frac{15}{32}$				
Positive Times Negative			$A = \frac{5}{8} = 0.101$	$B = -\frac{3}{4} = 1.010$
i	a_i	a_{i-1}	Operation	Result
0	1	0	$P = (P - B)/2$	0.0110
1	0	1	$P = (P + B)/2$	1.1010
2	1	0	$P = (P - B)/2$	0.010010
3	0	1	$P = P + B$	1.100010
Thus: $P = 1.100010 = -\frac{15}{32}$				
Negative Times Negative			$A = -\frac{5}{8} = 1.011$	$B = -\frac{3}{4} = 1.010$
i	a_i	a_{i-1}	Operation	Result
0	1	0	$P = (P - B)/2$	0.0110
1	1	1	$P = P/2$	0.00110
2	0	1	$P = (P + B)/2$	1.101110
3	1	0	$P = P - B$	0.011110
Thus: $P = 0.011110 = \frac{15}{32}$				

FIGURE 22.8 Example of sequential Booth multiplication.

TABLE 22.3 Operations for the Radix-4 Modified Booth Algorithm

a_{i+1}	a_i	a_{i-1}	Operation
0	0	0	$P = P/4$
0	0	1	$P = (P + B)/4$
0	1	0	$P = (P + B)/4$
0	1	1	$P = (P + 2B)/4$
1	0	0	$P = (P - 2B)/4$
1	0	1	$P = (P - B)/4$
1	1	0	$P = (P - B)/4$
1	1	1	$P = P/4$

numbers, where each cycle consists of either an n -bit addition and a shift, an n -bit subtraction and a shift, or a shift without any other arithmetic operation.

22.3.3.2 Sequential Modified Booth Multiplier

The radix-4 modified Booth multiplier [MacSorley 1961] uses $n/2$ cycles in which each cycle examines three adjacent bits; adds or subtracts 0, B , or $2B$; and shifts 2 bits to the right. Table 22.3 shows the operations as a function of the three bits: a_{i+1} , a_i , and a_{i-1} . The radix-4 modified Booth multiplier requires half as many cycles as the standard (radix-2) Booth multiplier although the operations performed during each cycle are slightly more complex (because it is necessary to select one of five possible addends instead of one of three). Extensions to higher radices that examine more than 3 bits are possible but generally are not attractive because the addition/subtraction operations involve multiples of B that are not powers of two (such as 3, 5, etc.), which raises the complexity.

22.3.3.3 Array Multipliers

An alternative approach to multiplication involves the combinational generation of all bit products and their summation with an array of full adders. The block diagram for an 8-by-8 array multiplier is shown in Figure 22.9. It uses an 8-by-8 array of AND gates to form the bit products (some of the AND gates are denoted G in Figure 22.9 and the remainder are contained within the FA and HA blocks) and an 8-by-7 array of adders [48 full adders (denoted FA in Figure 22.9) and 8 half-adders (denoted HA in Figure 22.9)] to sum the 64-bit products. Summing the bits requires 14 adder delays.

Modification of the array multiplier to multiply two's complement numbers requires inverting most of the signals in the most significant row and column and also adding a few correction terms [Baugh and Wooley 1973, Blankenship 1974]. Array multipliers are easily laid out in a cellular fashion, making them suitable for very large scale integrated (VLSI) implementation, where minimizing the design effort may be more important than maximizing the speed of the multiplier.

22.3.3.4 Wallace Tree/Dadda Fast Multiplier

A method for fast multiplication was developed by Wallace [1964] and refined by Dadda [1965]. With this method, a three-step process is used to multiply two numbers: (1) the bit products are formed; (2) the bit product matrix is reduced to a two-row matrix in which the sum of the rows equals the sum of the bit products; and (3) the two numbers are summed using a fast adder to produce the product. Although this may seem to be a complex process, it yields multipliers with delay proportional to the logarithm of the operand word size, which is faster than the Booth multiplier, the modified Booth multiplier, or array multipliers, all of which have delays proportional to the word size.

The second step in the fast multiplication process is shown for an 8-by-8 Dadda multiplier in Figure 22.10. An input 8-by-8 matrix of dots (each dot represents a bit product) is shown as Matrix 0. Columns having more than six dots (or that will grow to more than six dots due to carries) are reduced by the use of half-adders (each half-adder takes in two dots and outputs one in the same column and one in the next

FIGURE 22.9 Unsigned 8-by-8 array multiplier.

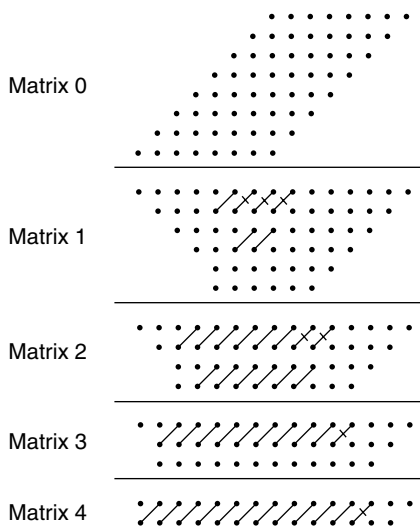

FIGURE 22.10 Unsigned 8-by-8 Dadda multiplier.

more significant column) and full adders (each full adder takes in three dots and outputs one in the same column and one in the next more significant column) so that no column in Matrix 1 will have more than six dots. Half-adders are shown by two dots connected with a crossed line in the succeeding matrix and full adders are shown by two dots connected with a line in the succeeding matrix. In each case, the rightmost dot of the pair connected by a line is in the column from which the inputs were taken for the adder. In the succeeding steps, reduction to Matrix 2 with no more than four dots per column, Matrix 3 with no more than three dots per column, and finally Matrix 4 with no more than two dots per column is performed. The height of the matrices is determined by working back from the final (two-row) matrix and limiting the height of each matrix to the largest integer that is no more than 1.5 times the height of its successor. Each matrix is produced from its predecessor in one adder delay. Because the number of matrices is logarithmically related to the number of bits in the words to be multiplied, the delay of the matrix reduction process is proportional to $\log n$. Because the adder that reduces the final two-row matrix can be implemented as a carry lookahead adder (which also has logarithmic delay), the total delay for this multiplier is proportional to the logarithm of the word size.

22.3.4 Fixed Point Division

Division is traditionally implemented as a digit recurrence requiring a sequence of shift, subtract, and compare operations, in contrast to the shift and add approach employed for multiplication. The comparison operation is significant. It results in a serial process, which is not amenable to parallel implementation. There are several digit recurrence-based division algorithms, including binary restoring, nonrestoring, nonrestoring, and Sweeney, Robertson, and Tocher (SRT) division algorithms for a variety of radices [Ercegovac and Lang 1994].

22.3.4.1 Nonrestoring Divider

Traditional nonrestoring division is based on selecting digits of the quotient Q (where $Q = N/D$) to satisfy the following equation:

$$P_{k+1} = r P_k - q_{n-k-1} D \quad \text{for } k = 1, 2, \dots, n-1 \quad (22.25)$$

where P_k is the partial remainder after the selection of the k th quotient digit, $P_0 = N$ (subject to the constraint $|P_0| < |D|$), r is the radix ($r = 2$ for binary nonrestoring division), q_{n-k-1} is the k th quotient digit to the right of the binary point, and D is the divisor. In this section, it is assumed that both N and D are positive; see Ercegovac and Lang [1994] for details on handling the general case.

In nonrestoring division, the quotient digits are constrained to be ± 1 (i.e., q_k is selected from $\{1, \bar{1}\}$). The digit selection and resulting partial remainder are given for the k th iteration by the following relations:

$$\text{If } P_k \geq 0, \quad q_{n-k-1} = 1 \quad \text{and} \quad P_{k+1} = r P_k - D \quad (22.26)$$

$$\text{If } P_k < 0, \quad q_{n-k-1} = \bar{1} \quad \text{and} \quad P_{k+1} = r P_k + D \quad (22.27)$$

This process continues either for a set number of iterations or until the partial remainder is smaller than a specified error criterion. The k th most significant bit of the quotient is a 1 if P_k is 0 or positive and is a $\bar{1}$ (-1) if P_k is negative. The algorithm is illustrated in Figure 22.11, where $\frac{5}{16}$ is divided by $\frac{3}{8}$. The result ($\frac{13}{16}$) is the closest 4-bit fraction to the correct result of $\frac{5}{6}$.

The signed digit number (comprising ± 1 digits) can be converted into a conventional binary number by subtracting n , the number formed by the negative digits (with 0s where there are 1s in Q and 1s where

Nonrestoring division

$$N = \frac{5}{16} = 0.0101$$

$$D = \frac{3}{8} = 0.0110$$

$$P_{(0)} = N$$

$$\begin{array}{l} \text{Since } P_{(0)} \geq 0, q_3 = 1 \text{ and } P_{(1)} = 2P_{(0)} - D \\ \begin{array}{r} 2P_{(0)} = 0.1010 \\ -D \quad 1.1010 \\ \hline P_{(1)} = 0.0100 \end{array} \end{array}$$

$$\begin{array}{l} \text{Since } P_{(1)} \geq 0, q_2 = 1 \text{ and } P_{(2)} = 2P_{(1)} - D \\ \begin{array}{r} 2P_{(1)} = 0.1000 \\ -D \quad 1.1010 \\ \hline P_{(2)} = 0.0010 \end{array} \end{array}$$

$$\begin{array}{l} \text{Since } P_{(2)} \geq 0, q_1 = 1 \text{ and } P_{(3)} = 2P_{(2)} - D \\ \begin{array}{r} 2P_{(2)} = 0.0100 \\ -D \quad 1.1010 \\ \hline P_{(3)} = 1.1110 \end{array} \end{array}$$

$$\begin{array}{l} \text{Since } P_{(3)} < 0, q_0 = \bar{1} \text{ and } P_{(4)} = 2P_{(3)} + D \\ \begin{array}{r} 2P_{(3)} = 1.1100 \\ +D \quad 0.0110 \\ \hline P_{(4)} = 0.0010 \end{array} \end{array}$$

$$Q = 0.111\bar{1} = 0.1101 = \frac{13}{16}$$

FIGURE 22.11 Example of nonrestoring division.

there are $\bar{1}$ s in Q), from p , the number formed by the positive digits (with 0s where there are $\bar{1}$ s in Q and 1s where there are 1s in Q). For the example of Figure 22.11:

$$\begin{aligned} Q &= 0.111\bar{1} \\ n &= 0.0001 \\ p &= 0.1110 \\ p - n &= 0.1110 - 0.0001 \\ &= 0.1110 + 1.1111 \\ &= 0.1101 \end{aligned}$$

Other digit recurrence division algorithms include the restoring algorithm and the SRT algorithms [Robertson 1958]. The restoring algorithm is similar to the nonrestoring algorithm presented here except that either subtract and shift or shift and shift are permitted for each iteration instead of subtract and shift or add and shift as in Equations 22.26 and 22.27. Restoring division forms the quotient from the digits 0 and 1 so that no signed digit to binary conversion is required (as it is for nonrestoring division). For all of the digit recurrence algorithms, the number of steps is proportional to the number of quotient digits.

The more advanced SRT division process for radix-2 and higher radices is similar to nonrestoring division in that the recurrence of Equation 22.25 is used, but the set of allowable quotient digits is increased. The process of quotient digit selection is sufficiently complex that a research monograph has been devoted to SRT division [Ercegovac and Lang 1994].

22.3.4.2 Newton–Raphson Divider

A second division algorithm uses a form of Newton–Raphson iteration to derive a quadratically convergent approximation to the reciprocal of the divisor, which is then multiplied by the dividend to produce the quotient. In systems that include a fast multiplier, this process is often faster than conventional division [Ferrari 1967].

$$\begin{aligned}
N &= 0.625 \\
D &= 0.75 \\
R_{(0)} &= 2.915 - 2 \cdot D && 1 \text{ Shift, 1 Subtract} \\
&= 2.915 - 2 \cdot .75 \\
R_{(0)} &= 1.415 \\
R_{(1)} &= R_{(0)} (2 - D \cdot R_{(0)}) && 2 \text{ Multiplies, 1 Subtract} \\
&= 1.415 (2 - .75 \cdot 1.415) \\
&= 1.415 \cdot .93875 \\
R_{(1)} &= 1.32833125 \\
R_{(2)} &= R_{(1)} (2 - D \cdot R_{(1)}) && 2 \text{ Multiplies, 1 Subtract} \\
&= 1.32833125 (2 - .75 \cdot 1.32833125) \\
&= 1.32833125 \cdot 1.00375156 \\
R_{(2)} &= 1.3333145677 \\
R_{(3)} &= R_{(2)} (2 - D \cdot R_{(2)}) && 2 \text{ Multiplies, 1 Subtract} \\
&= 1.3333145677 (2 - .75 \cdot 1.3333145677) \\
&= 1.3333145677 \cdot 1.00001407 \\
R_{(3)} &= 1.3333333331 \\
Q &= N \cdot R_{(3)} && 1 \text{ Multiply} \\
&= 0.625 \cdot 1.3333333331 \\
Q &= 0.83333333319
\end{aligned}$$

FIGURE 22.12 Example of Newton–Raphson division.

The Newton–Raphson division algorithm to compute $Q = N/D$ consists of three basic steps:

1. Calculate a starting estimate of the reciprocal of the divisor $R_{(0)}$. If the divisor D is normalized (i.e., $\frac{1}{2} \leq D < 1$), then $R_{(0)} = 3 - 2D$ exactly computes $1/D$ at $D = 0.5$ and $D = 1$ and exhibits maximum error (of approximately 0.17) at $D = \sqrt{\frac{1}{2}}$. Adjusting $R_{(0)}$ downward to by half the maximum error gives:

$$R_{(0)} = 2.915 - 2D \quad (22.28)$$

This produces an initial estimate that is within about 0.087 of the correct value for all points in the interval $\frac{1}{2} \leq D < 1$.

2. Compute successively more accurate estimates of the reciprocal by the following iterative procedure:

$$R_{(i+1)} = R_{(i)}(2 - DR_{(i)}) \quad \text{for } i = 0, 1, \dots, k \quad (22.29)$$

3. Compute the quotient by multiplying the dividend times the reciprocal of the divisor,

$$Q = NR_{(k)} \quad (22.30)$$

where i is the iteration count and N is the numerator. Figure 22.12 illustrates the operation of the Newton–Raphson algorithm. For this example, three iterations (one shift, four subtractions, and seven multiplications) produce an answer accurate to nine decimal digits (approximately 30 bits).

With this algorithm, the error decreases quadratically, so that the number of correct bits in each approximation is roughly twice the number of correct bits on the previous iteration. Thus, from a $3\frac{1}{2}$ -bit initial approximation, two iterations produce a reciprocal estimate accurate to 14 bits, four iterations produce a

reciprocal estimate accurate to 56 bits, etc. The number of iterations is proportional to the logarithm of the number of accurate quotient digits.

The efficiency of this process is dependent on the availability of a fast multiplier, since each iteration of Equation 22.29 requires two multiplications and a subtraction. The complete process for the initial estimate, three iterations, and the final quotient determination requires a shift, four subtractions, and seven multiplications to produce a 16-bit quotient. This is faster than a conventional nonrestoring divider if multiplication is roughly as fast as addition, a condition that is usually satisfied for systems that include hardware multipliers.

22.4 Floating Point Arithmetic

Advances in VLSI have increased the feasibility of hardware implementations of floating point arithmetic units. The main advantage of floating point arithmetic is that its wide dynamic range virtually eliminates overflow for most applications.

22.4.1 Floating Point Number Systems

A floating point number, A , consists of a signed significand, S_a , and an exponent, E_a . The value of a number, A , is given by the equation

$$A = S_a r^{E_a} \quad (22.31)$$

where r is the radix (or base) of the number system. The significand is generally normalized by requiring that the most significant digit be nonzero. Use of the binary radix (i.e., $r = 2$) gives maximum accuracy but may require more frequent normalization than higher radices.

The IEEE Standard 754 single precision (32-bit) floating point format, which is widely implemented, has an 8-bit biased integer exponent, which ranges from 0 to 255 [IEEE 1985]. The exponent is expressed in excess 127 code, which means that its effective value is determined by subtracting 127 from the stored value. Thus, the range of effective values of the exponent is -126 to 127 , corresponding to stored values of 1 to 254, respectively. A stored exponent value of 0 (E_{\min}) (effective value = -127) serves as a flag for 0 (if the significand is 0) and for denormalized numbers (if the significand is nonzero). A stored exponent value of 255 (E_{\max}) (effective value = 128) serves as a flag for infinity (if the significand is 0) and for “Not A Number” (NAN) (if the significand is nonzero). The significand is a 25-bit sign magnitude mixed number (the binary point is to the right of the most significant bit, which is always a 1 except for denormalized numbers). More details on floating point formats and on the various considerations that arise in the implementation of floating point arithmetic units are given in Gosling [1980], Goldberg [1990], Parhami [2000], Flynn and Oberman [2001], and Koren [2002].

22.4.1.1 Floating Point Addition

A flowchart for a floating point addition algorithm is shown in [Figure 22.13](#). For this flowchart (and those that follow for multiplication and division), the significands are assumed to have magnitudes in the range $[1, 2)$.

On the flowchart, the operands are (E_a, S_a) and (E_b, S_b) , and the result is (E_s, S_s) . In step 1, the operand exponents are compared; if they are unequal, the significand of the number with the smaller exponent is shifted right in either step 3 or step 4 by the difference in the exponents to properly align the significands. For example, to add 0.867×10^5 and 0.512×10^4 , the latter would be shifted right and 0.867 added to 0.0512 to give a sum of 0.9182×10^5 . The addition of the significands is performed in step 5. Steps 6 through 8 test for overflow and correct if necessary by shifting the significand one position to the right and incrementing the exponent. Step 9 tests for a zero significand. The loop of steps 10 and 11 scales unnormalized (but non-0) significands upward to normalize the significand. Step 12 tests for underflow.

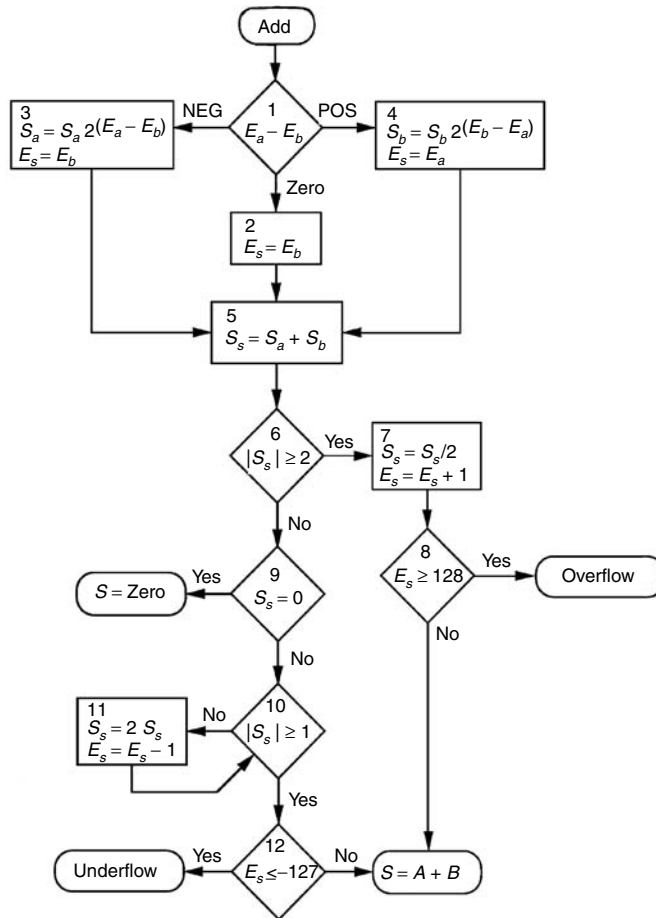

FIGURE 22.13 Floating point addition.

Floating point subtraction is implemented with a similar algorithm. Many refinements are possible to improve the speed of the addition and subtraction algorithms, but floating point addition will, in general, be much slower than fixed point addition as a result of the need for preaddition alignment and postaddition normalization.

22.4.1.2 Floating Point Multiplication

The algorithm for floating point multiplication is shown in the flowchart of Figure 22.14. In step 1, the product of the operand significands and the sum of the operand exponents are computed. Steps 2 and 3 normalize the significand if necessary. For radix-2 floating point numbers, if the operands are normalized, at most a single shift is required to normalize the product. Step 4 tests the exponent for overflow. Finally, step 5 tests for underflow.

22.4.1.3 Floating Point Division

The floating point division algorithm is shown in the flowchart of Figure 22.15. The quotient of the significands and the difference of the exponents are computed in step 1. The quotient is normalized (if necessary) in steps 2 and 3 by shifting the quotient significand while the quotient exponent is adjusted appropriately. For radix-2, if the operands are normalized, only a single shift is required to normalize the quotient. The computed exponent is tested for underflow in step 4. Finally, the fifth step tests for overflow.

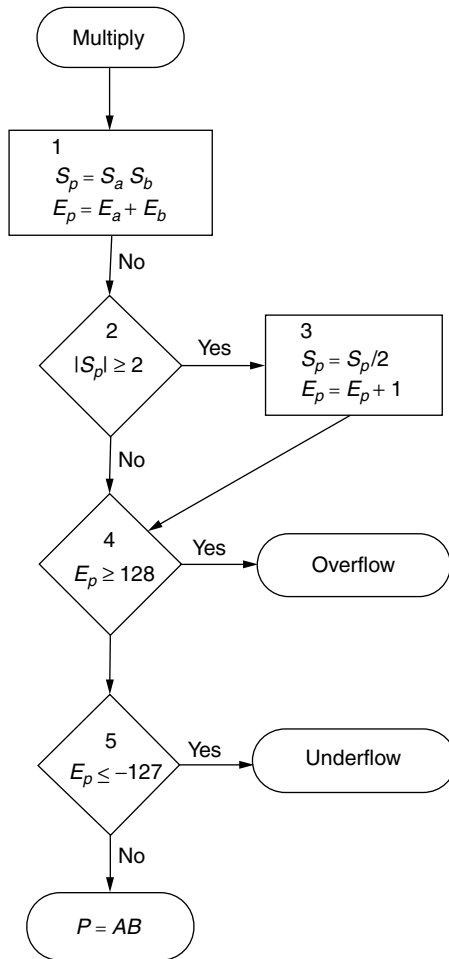

FIGURE 22.14 Floating point multiplication.

22.4.1.4 Floating Point Rounding

All floating point algorithms may require rounding to produce a result in the correct format. A variety of alternative rounding schemes have been developed for specific applications. Round to nearest, round toward ∞ , round toward $-\infty$, and round toward 0 are all available in implementations of the IEEE floating point standard.

22.5 Conclusion

This chapter has presented an overview of binary number systems, algorithms for the basic integer arithmetic operations, and a brief introduction to floating point operations. When implementing arithmetic units there is often an opportunity to optimize both the performance and the area for the requirements of the specific application. In general, faster algorithms require either more area or more complex control: it is often useful to use the fastest algorithm that will fit the available area.

23.1 Introduction

Parallel or concurrent operation has many different forms within a computer system. Multiple computers can be executing pieces of the same program in parallel, or a single computer can be executing multiple instructions in parallel, or some combination of the two. Parallelism can arise at a number of levels: task level, instruction level, or some lower machine level. The parallelism may be exhibited in space with multiple independently functioning units, or in time, where a single function unit is many times faster than several instruction-issuing units. This chapter attempts to remove some of the complexity regarding parallel architectures (unfortunately, there is no hope of removing the complexity of programming some of these architectures, but that is another matter).

With all the possible kinds of parallelism, a framework is needed to describe particular instances of parallel architectures. One of the oldest and simplest such structures is the stream approach [Flynn 1966] that is used here as a basis for describing developments in parallel architecture. Using the stream model, different architectures will be described and the defining characteristics for each architecture will be presented. These characteristics provide a qualitative feel for the architecture for high-level comparisons between different processors — they do not attempt to characterize subtle or quantitative differences that, while important, do not provide a significant benefit in a larger view of an architecture.

23.2 The Stream Model

A parallel architecture has, or at least appears to have, multiple interconnected **processor elements** (PE in [Figure 23.1](#)) that operate concurrently, solving a single overall problem. Initially, the various parallel architectures can be described using the *stream* concept. A stream is simply a sequence of objects or

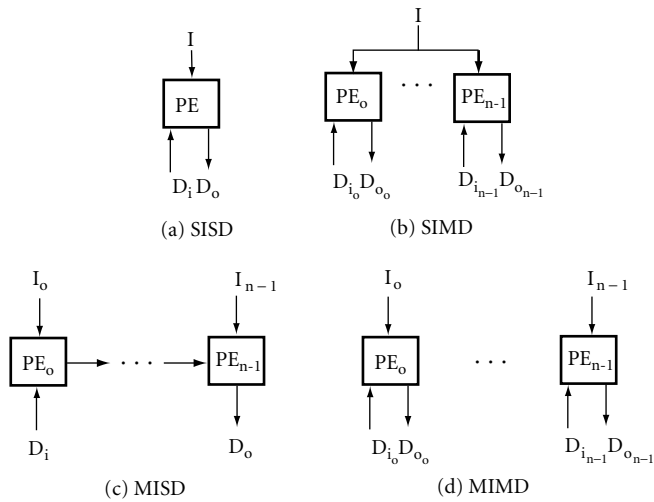

FIGURE 23.1 The stream model.

actions. Since there are both instruction streams and data streams (I and D in Figure 23.1), there are four combinations that describe most familiar parallel architectures:

1. SISD — single instruction, single data stream. This is the traditional uniprocessor [Figure 23.1a].
2. SIMD — single instruction, multiple data stream. This includes vector processors as well as massively parallel processors [Figure 23.1b].
3. MISD — multiple instruction, single data stream. These are typically systolic arrays [Figure 23.1c].
4. MIMD — multiple instruction, multiple data stream. This includes traditional multiprocessors as well as newer work in the area of networks of workstations [Figure 23.1d].

The stream description of architectures uses as its reference point the programmer’s view of the machine. If the processor architecture allows for parallel processing of one sort or another, then this information must be visible to the programmer at some level for this reference point to be useful.

An additional limitation of the stream categorization is that, while it serves as a useful shorthand, it ignores many subtleties of an architecture or an implementation. Even an SISD processor can be highly parallel in its execution of operations. This parallelism is typically not visible to the programmer even at the assembly language level, but it becomes visible at execution time with improved performance.

There are many factors that determine the overall effectiveness of a parallel processor organization, and hence its eventual speedup when implemented. Some of these, including networks of interconnected streams, will be touched upon in the remainder of this chapter. The characterizations of both processors and networks are complementary to the stream model and, when coupled with the stream model, enhance the qualitative understanding of a given processor configuration.

23.3 SISD

The SISD class of processor architectures is the most familiar class — it can be found in video games, home computers, engineering workstations, and mainframe computers. From the reference point of the assembly language programmer there is no parallelism in an SISD organization, yet a good deal of concurrency can be present. **Pipelining** is an early technique that is used in almost all current processor implementations. Other techniques aggressively exploit parallelism in executing code whether it is declared statically or determined dynamically from an analysis of the code stream.

FIGURE 23.2 Canonical pipeline.

FIGURE 23.3 Instruction issue for superscalar processors.

Pipelining is a straightforward approach to exploiting parallelism that is based on concurrently performing different phases of processing an instruction. These phases often include fetching an **instruction** from memory, decoding an instruction to determine its **operation** and **operands**, accessing its operands, performing the computation specified by the operation, and storing the computed value (IF, DE, RF, EX, and WB, respectively, in Figure 23.2). Pipelining assumes that these phases are independent between different operations and can be overlapped — when this condition does not hold, the processor stalls the downstream phases to enforce the dependency. Thus multiple operations can be processed simultaneously with each operation at a different phase of its processing. For a simple pipelined machine, only one operation is in each phase at any given time — thus one operation is being fetched, one operation is being decoded, one operation is accessing operands, one operation is executing, and one operation is storing results. With this scheme, assuming that each phase takes a single cycle to complete (which is not always the case), a pipelined processor could achieve a speedup of five over a traditional nonpipelined processor design.

Unfortunately, it can be argued that pipelining does not achieve true concurrency but that it only eliminates (in the limit) the overhead associated with instruction processing. With this viewpoint, the only phase of instruction processing that is not overhead is the evaluation of the result — everything else just supports this evaluation. Even so, there is still a speedup of five over a nonpipelined processor, but this speedup serves only to bring the maximum execution rate up from one operation every five cycles to one operation every cycle (for the pipeline just described). This is the best performance that can be achieved by a processor without true parallel execution.

While pipelining does not necessarily lead to achieving true concurrency, there are other techniques that do. These techniques use some combination of static scheduling and dynamic analysis to perform concurrently the actual evaluation phase of several different operations — potentially yielding an execution rate of greater than one operation every cycle. This kind of parallelism exploits concurrency at the computation level (in contrast to pipelining, which exploits concurrency at the overhead level). Since historically most instructions consist of only a single operation (and thus a single computation), this kind of parallelism has been named *instruction-level parallelism* (ILP).

Two architectures that exploit ILP — **superscalar** and **VLIW** (very long instruction word) — use radically different techniques to achieve more than one operation per cycle. A superscalar processor dynamically examines the instruction stream to determine which operations are independent and can be executed concurrently. Figure 23.3a shows the issue of ready instructions from a window of available instructions and the routing of these instructions to the appropriate function units (FU). A VLIW processor depends on the compiler to analyze the available operations (OP) and to schedule independent operations into wide instruction words; it then executes these operations in parallel with no further analysis. Figure 23.3b shows the issue of

TABLE 23.1 Typical Scalar Processors

Processor	Year of Introduction	Number of Function Units	Issue Width	Scheduling	Issue/Complete Order
Intel x86	1978	2	1	Dynamic	In-order/In-order
Stanford MIPS-X	1981	1	1	Dynamic	In-order/In-order
Berkeley RISC-I	1981	1	1	Dynamic	In-order/In-order
Sun SPARC	1987	2	1	Dynamic	In-order/In-order
MIPS R3000	1988	2	1	Dynamic	In-order/In-order
MIPS R4000	1992	2	1	Dynamic	In-order/In-order
HP PA-RISC 1.1	1992	1	1	Dynamic	In-order/In-order

operations from a wide instruction word to all function units in parallel. In the superscalar processor, even if two operations have been determined to be independent by the compiler and are scheduled properly for the current processor, at execution time the dependency analysis must still be performed to ensure that the proper ordering is maintained. In the VLIW processor, since the compiler is depended upon to ensure the proper scheduling of operations, any operations that are improperly scheduled result in indeterminate (and probably bad!) results. Considering the programmer's reference point, the kind of parallelism that superscalar processors exploit is invisible, while the kind of parallelism that VLIW processors exploit is visible only at the assembly level where the explicit packing of multiple operations into instructions is visible — the high-level language programmer in both cases is isolated from the machine-exploited ILP. Actually, these statements are true only in the general sense; for the superscalar processor, the assembly language programmer may be aware of the organization and characteristics of the machine and be able to schedule instructions so that they can be executed in parallel by the processor (this scheduling is usually performed by the compiler, although there are assemblers which perform minor scheduling transformations). For the VLIW processor, the assembly language programmer must be aware of the specific characteristics of the machine to ensure the proper scheduling of operations (the assembler could perform the analysis and scheduling although this is typically not desired by the programmer). For both processors, even at the high-level language level there are ways of writing programs that make it easy for the compiler to find the latent parallelism.

Both superscalar and VLIW use the same compiler techniques to achieve their superscalar performance. However, a superscalar processor is able to execute code scheduled for any instruction-compatible processor while a VLIW processor can only execute code that was specifically scheduled for execution on that particular processor.* This flexibility is not for free. While a superscalar processor does execute inappropriately scheduled code, the achieved performance can be significantly worse than if it were appropriately scheduled. Nevertheless, the flexibility is an important feature in a marketplace with a significant investment in software where binary compatibility is more important than raw performance.

A SISD processor has four defining characteristics. The first characteristic is whether or not the processor is capable of executing multiple operations concurrently. The second characteristic is the mechanism by which operations are scheduled for execution — statically at compile time, dynamically at execution, or possibly both. The third characteristic is the order in which operations are issued and retired relative to the original program order — these can be in order or out of order. The fourth characteristic is the manner in which exceptions are handled by the processor — precise, imprecise, or a combination. This last characteristic is not of immediate concern to the applications programmer, although it is certainly important to the compiler writer or operating system programmer, who must be able to properly handle exceptional conditions. Most processors implement precise exceptions, although a few high-performance architectures allow imprecise floating-point exceptions (with the ability to select between precise and imprecise exceptions).

Tables 23.1, 23.2, and 23.3 present some representative (pipelined) scalar and super-scalar (both superscalar and VLIW) processor families. As Table 23.1 and Table 23.2 show, the trend has been from a scalar

*This does not have to be true — although past VLIW processors have had this restriction, this has been due to engineering decisions in the implementation and not to anything inherent in the specification. For two variant approaches to providing support for dynamic scheduling in VLIW processors see Rau [1993] and Rudd [1994].

TABLE 23.2 Typical Superscalar Processors

Processor	Year of Introduction	Number of Function Units	Issue Width	Scheduling	Issue/Complete Order
DEC 21064	1992	4	2	Dynamic	In-order/In-order
Sun UltraSPARC	1992	9	4	Dynamic	In-order/Out-of-order
MIPS R8000	1994	6	4	Dynamic	In-order/In-order
DEC 21164	1994	4	2	Dynamic	In-order/In-order
Motorola PowerPC 620	1995	6	4	Dynamic	In-order/Out-of-order
HP PA-RISC 8000	1995	10	4	Dynamic	Out-of-order/Out-of-order
MIPS R10000	1995	5	5	Dynamic	Out-of-order/Out-of-order
Intel Pentium Pro	1996	5	3	Dynamic	In-order x86 Out-of-order uops/Out-of-order
AMD K5	1996	6	4	Dynamic	In-order x86 Out-of-order ROPs/Out-of-order

TABLE 23.3 Typical VLIW Processors

Processor	Year of Introduction	Number of Function Units	Issue Width	Scheduling	Issue/Complete Order
Multiflow Trace 7/200	1987	7	7	Static	In-order/In-order
Multiflow Trace 28/200	1987	28	28	Static	In-order/In-order
Cydrome Cydra 5	1987	7	7	Static	In-order/In-order
Philips TM-1	1996	27	5	Static	In-order/In-order

to a compatible superscalar processor (except for the DEC Alpha and the IBM/Motorola/Apple PowerPC processors, which were designed from the ground up to be capable of superscalar performance). There have been very few VLIW processors to date, although advances in compiler technology may cause this to change. Philips has explored VLIW processors internally for years, and the TM-1 is the first of a planned series of processors. After the demise of both Multiflow and Cydrome, HP acquired both the technology and some of the staff of these companies and has continued research in VLIW processors.

23.4 SIMD

The SIMD class of processor architectures includes both array and vector processors. The SIMD processor is a natural response to the use of certain regular data structures, such as vectors and matrices. From the reference point of an assembly language programmer, programming an SIMD architecture appears to be very similar to programming a simple SISD processor except that some operations perform computations on aggregate data. Since these regular structures are widely used in scientific programming, the SIMD processor has been very successful in these environments.

Two types of SIMD processor will be considered: the **array processor** and the **vector processor**. They differ both in their implementations and in their data organizations. An array processor consists of many interconnected processor elements that each have their own local memory space. A vector processor consists of a single processor that references a single global memory space and has special function units that operate specifically on vectors.

23.4.1 Array Processors

The array processor is a set of parallel processor elements (typically hundreds to tens of thousands) connected via one or more networks (possibly including local and global interelement data and control communications). Processor elements operate in lockstep in response to a single broadcast instruction

TABLE 23.4 Typical Array Processors

Processor	Year of Introduction	Memory Model	Processor Element	Number of Processors
Burroughs BSP	1979	Shared	General purpose	16
Thinking Machines CM-1	1985	Distributed	Bit-serial	Up to 65,536
Thinking Machines CM-2	1987	Distributed	Bit-serial	4,096–65,536
MasPar MP-1	1990	Distributed	Bit-serial	1,024–16,384

from a control processor. Each processor element has its own private memory, and data are distributed across the elements in a regular fashion that is dependent on both the actual structure of the data and also the computations to be performed on the data. Direct access to global memory or another processor element's local memory is expensive (although scalar values can be broadcast along with the instruction), so intermediate values are propagated through the array through local interelement connections. This requires that the data are distributed carefully so that the routing required to propagate these values is simple and regular. It is sometimes easier to duplicate data values and computations than it is to effect a complex or irregular routing of data between processor elements.

Since instructions are broadcast, there is no means local to a processor element of altering the flow of the instruction stream; however, individual processor elements can conditionally disable instructions based on local status information — these processor elements are idle when this condition occurs. The actual instruction stream consists of more than a fixed stream of operations — an array processor is typically coupled to a general-purpose control processor that provides both scalar operations (that operate locally within the control processor) as well as array operations (that are broadcast to all processor elements in the array). The control processor performs the scalar sections of the application, interfaces with the outside world, and controls the flow of execution; the array processor performs the array sections of the application as directed by the control processor.

A suitable application for use on an array processor has several key characteristics: a significant amount of data which has a regular structure; computations on the data which are uniformly applied to many or all elements of the data set; simple and regular patterns relating the computations and the data. An example of an application that has these characteristics is the solution of the Navier–Stokes equations, although any application that has significant matrix computations is likely to benefit from the concurrent capabilities of an array processor.

The programmer's reference point for an array processor is typically the high-level language level — the programmer is concerned with describing the relationships between the data and the computations, but is not directly concerned with the details of scalar and array instruction scheduling or the details of the interprocessor distribution of data within the processor. In fact, in many cases the programmer is not even concerned with size of the array processor. In general, the programmer specifies the size and any specific distribution information for the data, and the compiler maps the implied virtual processor array onto the physical processor elements that are available and generates code to perform the required computations. Thus, while the size of the processor is an important factor in determining the performance that the array processor can achieve, it is not a defining characteristic of an array processor.

The primary defining characteristic of a SIMD processor is whether the memory model is shared or distributed. In this chapter, only processors using a distributed memory model are described, since this is the configuration used by SIMD processors today and the cost of scaling a shared-memory SIMD processor to a large number of processor elements would be prohibitive. Processor element and network characteristics are also important in characterizing a SIMD processor, and these are described in [Section 23.2](#) and [Section 23.6](#).

There have not been a significant number of SIMD architectures developed, due to a limited application base and market requirement. Table 23.4 shows several representative architectures.

23.4.2 Vector Processors

A vector processor is a single processor that resembles a traditional SISD processor except that some of the function units (and registers) operate on vectors — sequences of data values that are seemingly operated

on as a single entity. These function units are deeply pipelined and have a high clock rate; while the vector pipelines have as long or longer latency than a normal scalar function unit, their high clock rate and the rapid delivery of the input vector data elements results in a significant throughput that cannot be matched by scalar function units.

Early vector processors processed vectors directly from memory. The primary advantage of this approach was that the vectors could be of arbitrary lengths and were not limited by processor resources; however, the high startup cost, limited memory system bandwidth, and memory system contention proved to be significant limitations. Modern vector processors require that vectors be explicitly loaded into special vector registers and stored back into memory — the same course that modern scalar processors have taken for similar reasons. However, since vector registers can rapidly produce values for or collect results from the vector function units and have low startup costs, modern register-based vector processors achieve significantly higher performance than the earlier memory-based vector processors for the same implementation technology.

Modern processors have several features that enable them to achieve high performance. One feature is the ability to concurrently load and store values between the vector register file and main memory while performing computations on values in the vector register file. This is an important feature, since the limited length of vector registers requires that vectors that are longer than the registers be processed in segments — a technique called strip mining. Not being able to overlap memory accesses and computations would pose a significant performance bottleneck.

Just like their SISD cousins, vector processors support a form of result bypassing — in this case called chaining — which allows a follow-on computation to commence as soon as the first value is available from the preceding computation. Thus, instead of waiting for the entire vector to be processed, the follow-on computation can be significantly overlapped with the preceding computation that it is dependent on. Sequential computations can be efficiently compounded and behave as if they were a single operation with a total latency equal to the latency of the first operation with the pipeline and chaining latencies of the remaining operations but none of the startup overhead that would be incurred without chaining. For example, division could be synthesized by chaining a reciprocal with a multiply operation. Chaining typically works for the results of load operations as well as normal computations. Most vector processors implement some form of chaining.

A typical vector processor configuration might have a vector register file, one vector addition unit, one vector multiplication unit, and one vector reciprocal unit (used in conjunction with the vector multiplication unit to perform division); the vector register file contains multiple vector registers (eight registers with 64 double-precision floating-point values is typical). In addition to the vector registers there are also a number of auxiliary and control registers, the most important of which is the vector length register. The vector length register contains the length of the vector (or the loaded subvector if the full vector length is longer than the vector register itself) and is used to control the number of elements processed by vector operations — there is no reason to perform computations on nondata that are useless or could cause an exception.

As with the array processor, the programmer's reference point for a vector machine is the high-level language. In most cases, the programmer sees a traditional SISD machine; however, since vector machines excel on vectorizable loops, the programmer can often improve the performance of the application by carefully coding the application — in some cases explicitly writing the code to perform strip mining — and by providing hints to the compiler that help to locate the vectorizable sections of the code. This situation is purely an artifact of the fact that the programming languages are scalar-oriented and do not support the treatment of vectors as an aggregate data type but only as a collection of individual values. As languages are defined (such as Fortran 90 or High Performance Fortran) that make vectors a fundamental data type, then the programmer is exposed less to the details of the machine and to its SIMD nature.

The vector processor has one primary characteristic. This characteristic is the location of the vectors — vectors can be memory- or register-based. There are many features that vector processors have that are not included here due to their number and many variations. These include variations on chaining, masked vector operations based on a Boolean mask vector, indirectly addressed vector operations (scatter/gather), compressed/expanded vector operations, reconfigurable register files, multiprocessor support, etc.

TABLE 23.5 Typical Vector Processors

Processor	Year of Introduction	Memory-or Register-Based	Number of Processor Units	Maximum Vector Length	Number of Vector Units
Cray 1	1976	Register	1	64	7
CDC Cyber 205	1981	Memory	1	65,535	3–5
Cray X-MP	1982	Register	1–4	64	8
Hitachi HITAC S-810	1984	Register	1		4–8

NEC SX-4	1994	Register	1–512		4–8
Cray T90	1995		1–32		2

^aSold as the Amdahl VP1100/VP1200 in the United States.

Vector processors have developed dramatically from simple memory-based vector processors to modern multiple-processor vector processors that exploit both SIMD vector and MIMD-style processing. Table 23.5 shows some representative vector processors.

23.5 MISD

While it is easy to both envision and design MISD processors, there has been little interest in this type of parallel architecture. The reason, so far anyway, is that there are no ready programming constructs that easily map programs into the MISD organization.

Abstractly, the MISD can be represented as multiple independently executing function units operating on a single stream of data, forwarding results from one function unit to the next. On the microarchitecture level, this is exactly what the vector processor does. However, in the vector pipeline the operations are simply fragments of an assembly-level operation, as distinct from being a complete operation in themselves. Surprisingly, some of the earliest attempts at computers in the 1940s could be seen as the MISD concept. They used plugboards for programs, where data in the form of a punched card were introduced into the first stage of a multistage processor. A sequential series of actions were taken where the intermediate results were forwarded from stage to stage until at the final stage a result was punched into a new card.

There are, however, more interesting uses of the MISD organization. Nakamura [1995] has pointed out the value of an MISD machine called the SHIFT machine. In the SHIFT machine, all data memory is decomposed into shift registers. Various function units are associated with each shift column. Data are initially introduced into the first column and are shifted across the shift-register memory. In the SHIFT-machine concept, data are regularly shifted from memory region to memory region (column to column) for processing by various function units. The purpose behind the SHIFT machine is to reduce memory latency. In a traditional organization, any function unit can access any region of memory and the worst-case delay path for accessing memory must be taken into account. In the SHIFT machine, we must allow for access time only to the worst element in a data column. The memory latency in modern machines is becoming a major problem — the SHIFT machine has a natural appeal for its ability to tolerate this latency.

23.6 MIMD

The MIMD class of parallel architecture brings together multiple processors with some form of interconnection. In this configuration, each processor executes completely independently, although most applications require some form of synchronization during execution to pass information and data between processors.

While there is no requirement that all processor elements be identical, most MIMD configurations are homogeneous with all processor elements being identical. There have been heterogeneous MIMD configurations that use different kinds of processor elements to perform different kinds of tasks, but (with the possible exception of recent work aimed at using networked workstations as a loosely coupled MIMD configuration) these configurations have not lent themselves to general-purpose applications. We limit ourselves to homogeneous MIMD organizations in the remainder of this section.

Up to this point, the MIMD processor with its multiple processor elements interconnected by a network appears to be very similar to a SIMD array processor. This similarity is deceptive, since there is a significant difference between these two configurations of processor elements — in the array processor the instruction stream delivered to each processor element is the same, while in the MIMD processor the instruction stream delivered to each processor element is independent and specific to each processor element. Recall that in the array processor, the instruction stream for each processor element is generated by the control processor and that the processor elements operate in lockstep. In the MIMD processor, the instruction stream for each processor element is generated independently by that processor element as it executes its program. While it is often the case that each processor element is running pieces of the same program, there is no reason that different processor elements could not run different programs.

The interconnection network in both the array processor and the MIMD processor passes data between processor elements; however, in the MIMD processor it is also used to synchronize the independent execution streams between processor elements. When the memory of the processor is distributed across all processors and only the local processor element has access to it, all data sharing is performed explicitly using messages and all synchronization is handled within the message system. When the memory of the processor is shared across all processor elements, synchronization is more of a problem — certainly messages can be used through the memory system to pass data and information between processor elements, but this is not necessarily the most effective use of the system.

When communications between processor elements is performed through a shared memory address space — either global or distributed between processor elements (called distributed shared memory to distinguish it from distributed memory) — there are two significant problems that arise. The first is maintaining **memory consistency** — the programmer-visible ordering effects of memory references both within a processor element and between different processor elements. The second is **cache coherency** — the programmer-invisible mechanism to ensure that all processor elements see the same value for a given memory location. Neither of these problems is significant in SISD or SIMD array processors. In a SISD processor, there is only one instruction stream and the amount of reordering is limited, so the hardware can easily guarantee the effects of perfect memory reference ordering and thus there is no consistency problem; since a SISD processor has only one processor element, cache coherency is not applicable. In a SIMD array processor (assuming distributed memory), there is still only one instruction stream and typically no instruction reordering; since all interprocessor element communication is via messages, there is neither a consistency problem nor a coherency problem.

The memory consistency problem is usually solved through a combination of hardware and software techniques. At the processor element level, the appearance of perfect memory consistency is usually guaranteed for local memory references only — this is usually a feature of the processor element itself. At the MIMD processor level, memory consistency is often guaranteed only through explicit synchronization between processors. In this case, all nonlocal references are only ordered relative to these synchronization points (such as fences or acquire/release points). While the programmer must be aware of the limitations imposed by the ordering scheme, the added performance achieved using nonsequential ordering can be significant. [Table 23.6](#) shows the common memory consistency schemes and a brief description of their basic characteristics (\checkmark indicates that the given feature exists, and $\sim \checkmark$ indicates that a restricted form of the feature exists).

The cache coherency problem is usually solved exclusively through hardware techniques. This problem is significant because of the possibility that multiple processor elements will have copies of data in their local caches and these copies could have differing values. There are two primary techniques to maintain cache coherency. The first technique is to ensure that all processor elements are informed of any change

TABLE 23.6 Simple Categorization of Consistency Models

Model ^a	Relaxation: ^b W → R Order	W → W Order	W → RW Order	Read Other's Write Early	Read Own Write Early	Explicit Synchronization ^c
SC					✓	
TSO, PC	✓			~ ✓	✓	RMW
PSO	✓	✓			✓	RMW, fence
WO	✓	✓	✓		✓	Fence
RC	✓	✓	✓	~ ✓	✓	Release, acquire, nsync, RMW

^aSC = sequential consistency, TSO = total store order, PC = processor consistency, PSO = partial store order, WO = weak order, RC = release consistency.

^b $x \rightarrow y$ represents the relaxation of the logical ordering between the reference x and a following reference y ; R = read reference, W = write reference, RW = read or write reference.

^cRMW is an atomic read–modify–write operation. Fetch-and-add is a common example of the general Fetch-and- Φ operation. (Source: Based on information in Adve and Gharachorloo [1995] and used with their permission.)

TABLE 23.7 Cache Coherency Summary

Coherency Model	Protocol Type	Modification Policy	Exclusive Use State	Exclusive Write State
Write once	Invalidate	Copyback on first write		
Synapse $N + 1$	Invalidate	Copyback	✓	
Berkeley	Invalidate	Copyback		✓
Illinois	Invalidate	Copyback	✓	
Firefly	Broadcast	Copyback private, writethrough shared	✓	

to the shared memory state — these changes are broadcast throughout the MIMD processor, and each processor element monitors these changes (commonly referred to as “snooping”). The second technique is to keep track of all users of a memory address or block in a directory structure and to specifically inform each user when there is a change made to the shared memory state. In either case the result of a change can be one of two things — either the new value is provided and the local value is updated, or all other copies of the value are invalidated.

As the number of processor elements in a system increases, a directory-based system becomes significantly better, since the amount of communications required to maintain coherency is limited to only those processors holding copies of the data. Snooping is frequently used within a small cluster of processor elements to track local changes — here the local interconnection can support the extra traffic used to maintain coherency since each cluster has only a few (typically two to eight) processor elements in it. Table 23.7 shows the common cache coherency schemes and a brief description of their basic characteristics (✓ indicates that the given state exists).

The primary characteristic of a MIMD processor is the nature of the memory address space — it is either separate or shared for all processor elements. The interconnection network is also important in characterizing a MIMD processor and is described in the next section. With a separate address space (distributed memory), the only means of communications between processor elements is through messages, and thus these processors force the programmer to use a message-passing paradigm. With a shared address space (shared memory), communication between processor elements is through the memory system — depending on the application needs or programmer preference, either a shared-memory or a message-passing paradigm can be used.

The implementation of a distributed-memory machine is far easier than the implementation of a shared-memory machine when memory consistency and cache coherency are taken into account. However, programming a distributed-memory processor can be much more difficult, since the applications must be written to exploit and not be limited by the use of message passing as the only form of communications between processor elements. On the other hand, despite the problems associated with maintaining

TABLE 23.8 Typical MIMD Systems

System	Year of Introduction	Processor Element	Number of Processors	Memory Distribution	Programming Paradigm	Interconnection Type
Alliant FX/2800	1990	Intel i860	4–28	Central	Shared memory	Bus + crossbar

consistency and coherency, programming a shared-memory processor can take advantage of whatever communications paradigm is appropriate for a given communications requirement and can be much easier to program. Both distributed and shared-memory processors can be extremely scalable and neither approach is significantly more difficult to scale than the other. Some typical MIMD systems are described in Table 23.8.

23.7 Network Interconnections

Both SIMD array processors and MIMD processors rely on networks for the transfer of data between processor elements or processors. A bus is a simple kind of network — it serves to interconnect all devices that are plugged into it — but is not commonly referred to as a network. We discuss here only the aspects of networks that are of interest in characterizing a processor — particularly the SIMD array processors and MIMD processors — and present some network characteristics that provide a qualitative sense that is useful for understanding the basic nature of a multiprocessor interconnect.

There are three primary characteristics of networks. The first is the method used to transfer the information through the network — either using packet routing or circuit switching. The second characteristic is the mechanism that connects source and destination nodes — either the connections are static and fixed or they are dynamic and reconfigurable. The third characteristic is whether the network is a single-level or a multiple-level network. While these characteristics leave out a significant amount of detail about the actual network, they qualitatively describe the network connections and how information is routed between processor elements.

Packet routing is efficient for small random packets, but it has the drawback that neither the latency nor the bandwidth is necessarily deterministic and thus packets may not be delivered in the same order that they were sent; circuit switching achieves high bandwidth for a given connection between processor nodes and guarantees uniform latency and proper receipt ordering, but it has the drawback that the latency for small packets becomes the latency for setting up and breaking down the connection.

Dynamic networks allow network reconfiguration so that there are essentially direct connections between nodes across the network, producing high bandwidth and low latency but limiting the scalability of the system; static networks improve the scalability, since connections are node to node and any two nodes can be connected either directly or through intermediate nodes, resulting in longer latency and lower-bandwidth connections. Use of multilevel networks, which use clusters of processor elements at each network node, increases the complexity of the system but reduces congestion on the global interconnect and leads to a more scalable system — intracluster communications are performed on a local interconnect that is much faster and does not leave the cluster. Single-level networks are more general but

less scalable, since all communications must use the global interconnect, and traffic can be much higher for the same number of processor elements.

23.8 Afterword

In this chapter we have reviewed a number of different parallel architectures organized by the stream model. We have described some general characteristics that offer some insight into the qualitative differences between different parallel architectures but, in the general case, provide little quantitative information about the architectures themselves — this would be a much more significant task, although there is no reason why a significantly increased level of detail could not be described. Just as the stream model is incomplete and overlapping (consider that a vector processor can be considered to be a SIMD, MISD, or SISD processor depending on the particular categorization desired), so the characteristics for each class of architecture are also incomplete and overlapping. However, the general insight gained from considering these general characteristics leads to an understanding of the qualitative differences between gross classes of computer architectures, so the characteristics that we have described provide similar benefits and liabilities.

In a sense, the characterizations that we have provided for each architectural class of processor can be considered as specializations on the stream model. Thus a superscalar processor could be described as a SISD processor which supports concurrent execution of multiple operations that are scheduled dynamically, performs issue and retire out of order, and provides precise interrupts. A similar superscalar processor that does not provide precise interrupts would be described almost identically, but the description would provide an insight into one significant difference between these two processors — the first superscalar processor would be more complicated to design and might run more slowly than the second superscalar processor, but it would support more efficient exception recovery. While this comparison does not, in all likelihood, provide sufficient information to make a design choice in many cases, it does provide a basis for processor comparison.

For a MIMD or a SIMD processor, although the primary characteristic is the characterization of the memory address space, the system can be more completely described by including the description of both the processor element (most likely a SISD processor) along with a description of any networks that are included in the processor. This results in a description of the processor that provides a more complete understanding of the system as a whole but now including much more information about the remainder of the system.

This is not meant to imply that the aggregate of the stream model along with the relevant characteristics is a complete and formal extension to the original taxonomy — far from it. There are still a wide range of processors that are problematic to describe well in this (and likely in any) framework. The example was given earlier concerning the appropriate placement of a vector processor. Another example is the proper placement of an architecture that is designed to support multiple threads on a single processor element. These processor elements could be considered to be just SISD processors which have a specialized operating system that provides this support (albeit requiring hardware support as well), but there is some reason to believe that multiple threads are a significant feature, especially in the case of the Tera MTA architecture [Alverson et al. 1990], where the threads are interleaved through the execution units on a cycle-by-cycle basis — clearly a distinct difference beyond simply performing efficient task switches.

Whatever the problems with classifying and characterizing a given architecture, processor architectures, particularly multiprocessor architectures, are developing rapidly. Much of this growth is the result of significant improvements in compiler technology that allow the unique capabilities of an architecture to be efficiently exploited. In many cases, the design of a system is based on the ability of a compiler to produce code for it. It may be that a feature is unable to be utilized if a compiler cannot exploit it and thus the feature is wasted (although perhaps the inclusion of such a feature would spur compiler development). It may also be that an architectural feature is added specifically to support a capability that a compiler readily supports and thus performance is improved. Compiler development is clearly an integral part of system design and architectural effectiveness is no longer limited only to concerns for the processor itself.

Defining Terms

- Array processor:** An array of processor elements operating in lockstep in response to a single instruction and performing computations on data that are distributed across the processor elements.
- Cache coherency:** The programmer-invisible mechanism that ensures that all caches within a computer system have the same value for the same shared-memory address.
- Instruction:** Specification of a collection of operations that may be treated as an atomic entity with a guarantee of no dependencies between these operations. A typical processor uses an instruction containing one operation.
- Memory consistency:** The programmer-visible mechanism that guarantees that multiple processor elements in a computer system receive the same value on a request to the same shared-memory address.
- Operand:** Specification of a storage location — typically either a register or a memory location — that provides data to or receives data from the results of an operation.
- Operation:** Specification of one or a set of computations on the specified source operands placing the results in the specified destination operands.
- Pipelining:** The technique used to overlap stages of instruction execution in a processor so that processor resources are more efficiently used.
- Processor element:** The element of a computer system that is able to process a data stream (sequence) based on the content of an instruction stream (sequence). A processor element may or may not be capable of operating as a stand-alone processor.
- Superscalar processor:** A popular term to describe a processor that dynamically analyzes the instruction stream and attempts to execute multiple ready operations independently of their ordering within the instruction stream.
- Vector processor:** A computer architecture with specialized function units designed to operate very efficiently on vectors represented as streams of data.
- VLIW processor:** A popular term to describe a processor that performs no dynamic analysis on the instruction stream and executes operations precisely as ordered in the instruction stream.

Further Information

There are many good sources of information on different aspects of parallel architectures. The references for this chapter provide a selection of texts that cover a wide range of issues in this field. There are many professional journals that cover different aspects of this area either specifically or as part of a wider coverage of related areas. Some of these are:

IEEE Transactions on Computers, Transactions on Parallel and Distributed Systems, Computer, Micro.
ACM Transactions on Computer Systems, Computer Surveys.
Journal of Supercomputing.
Journal of Parallel and Distributed Computing.

There are also a number of conferences that deal with various aspects of parallel processing. The proceedings from these conferences provide a current view of research on the topic. Some of these are:

International Symposium on Computer Architecture (ISCA).
Supercomputing.
International Symposium on Microarchitecture (MICRO).
International Conference on Parallel Processing (ICPP).
International Symposium on High Performance Computer Architecture (HPCA).
Symposium on the Frontiers of Massively Parallel Computation.

24.1 Introduction

The word “architecture,” as it applies to computer networks, can be interpreted in at least two different ways. The overall design of a network (analogous to an architect’s blueprint of a building) — including the interconnection pattern, communication media, choice of protocols, placement of network management resources, and other design decisions — is generally referred to as the network’s architecture. However, we can also speak of the hardware and the hardware-specific protocols used to implement the various pieces of the network (much as we would speak of the beams, pipes, bricks, and mortar that comprise a building).

The goal of this overview is to concentrate on architectures of networks in both senses of the word, but with emphasis on the second, showing how established and relatively stable design technologies, such as multiplexing and signal modulation, are integrated with an array of hardware devices, such as routers and modems, into a physically realized network. More specifically, this chapter presents representative technologies whose general characteristics will remain applicable even as the hardware state of the art advances.

The organizing principle used in this study is the notion of a network protocol stack, defined in the next section, which provides a hierarchy of communication models that abstract away from the physical details of the network. Each of the network technologies considered in this survey is best explained in relation to a particular abstraction level in this hierarchy. At times, this classification scheme may be relaxed a bit for terminological reasons; for example, voice modems are most relevant to layer 1 of the protocol stack,

whereas cable modems are really layer 2 devices, but these modems are all discussed in the same section of the chapter. On the other hand, in a few cases, the classification is difficult to apply. The word “switch” can be applied to network hubs and telephone switches (normally associated with layer 1) or to LAN (local area network) switches (normally thought of as layer 2 devices), or to routers (implementing layer 3 functionality). Unavoidably, the discussion of switching will overlap different layers.

Other chapters of this *Handbook* deal in greater depth with architecture in its first sense. [Chapter 72](#) deals with topics such as network topologies and differences between local area and wide area networks; [Chapter 73](#) discusses the important subject of routing in networks.

For the most part, the technologies presented in this chapter represent standards that are recognized worldwide. Several organizations provide standards for networking hardware and software. The International Telecommunication Union (which replaced the International Telegraph and Telephone Consultative Committee, or CCITT) has a sector (ITU-T) devoted to telecommunication standards. The ITU-T has recommended standards for modems (the “V” series of recommendations) and data networks and open system communication (the “X” series, including the well-known X.25 recommendation for virtual circuit connections in packet-switching networks), multiplexing standards, and many others, some of which are described in greater detail below. The International Organization for Standardization (ISO), formerly the International Standards Organization, has produced a huge number of standards documents in many areas, including information technology. (Their recommendation for the Open Systems Interconnection (OSI) reference model is described briefly in the next section.) The Institute for Electrical and Electronics Engineers (IEEE) is responsible for the “802” series of LAN standards, most of which have been adopted by the ISO. The American National Standards Institute (ANSI) is one of the founding members of the ISO and the originator of many networking standards. Gallo and Hancock [2002] provide a concise summary of most of the important regional, national, international, and industry, trade, and professional standards organizations.

24.2 Underlying Principles

We adopt Tanenbaum’s definition of a computer network as an interconnected collection of autonomous computers [Tanenbaum, 1996]. We will refer to these as hosts or stations in the following discussion. Although this definition fails to take into account many network-like structures, from “networks-on-a-chip” [Benini and De Micheli, 2002] to interconnected “information appliances” such as Web-enabled cellular telephones and portable digital assistants, it is sufficient for an introductory look at the architectures of networks.

24.2.1 LANs, WANs, MANs, and Topologies

We will often make references to local area networks (LANs) and wide area networks (WANs). The phrases are fairly self-explanatory. LANs normally connect machines in a geographical area not much larger than a building or a small cluster of buildings, while WANs could connect machines separated by tens of thousands of kilometers. The higher-level architecture of LANs and WANs is described in more detail in [Chapter 72](#). Another category, the metropolitan area network (MAN), is often mentioned in the literature. MANs lie in between LANs and WANs, perhaps joining machines distributed over the area of a large city. Classifications such as “personal area network” (PAN), “system area network” (SAN), “desk area network” (DAN), and others have been proposed, but their meanings are not yet well-established.

Many of the most popular LAN architectures represent broadcast networks: the host machines comprising the network share a common transmission medium (such as a wire in an Ethernet LAN or a block of the electromagnetic spectrum in a wireless LAN). Each host on the network sees every transmission (whether or not it is the intended recipient), and each must contend with the others for access to this medium when it wishes to transmit. The details of such multiple access methods can influence, for example, the manner in which the physical signal is encoded (for instance, code-division multiple access

methods require each host to have a unique code word that is used to represent the bits transmitted by that host).

In some instances, particularly in the area of LAN networks, our discussion of networking devices will depend upon the network topology (the interconnection pattern of the hosts comprising the network). For example, a LAN may be organized using a bus topology (such as a single Ethernet cable), a star topology (several Ethernet lines joined at a central point), or a ring topology (such as an FDDI network). Repeaters may be needed to extend a bus further than the limits imposed by the physical properties of the medium. A hub might be used to join machines into a star configuration. Rings require some sort of switching mechanism to restore the ring topology when part of the network is damaged.

Topology is less of a concern with WANs, which present an entirely different set of equipment issues. Most wide area networks are comprised of a combination of media, ranging from copper twisted-pair wires to high-bandwidth fiber optic cables to terrestrial microwave or satellite transmission. Devices are needed to deal with the interfaces between these media and to perform routing and switching.

24.2.2 Circuit Switching and Packet Switching

Data transmission in networks can generally be classified into one of two categories. If data is conveyed as a bit stream by means of a dedicated “line” (in the form of optical fiber, copper wire, or reserved bandwidth along a transmission path), it is said to be **circuit-switched**. However, if it is subdivided into smaller units, each of which finds its way more or less independently from source to destination, it is said to be **packet-switched**. At the lowest layer of the protocol stack, where we deal only with streams of bits, we are usually not concerned with this distinction; however, at higher levels, devices such as switches must be designed according to which of the two methods is used. A technique known as **virtual circuits** combines features of both of these switching categories. In a virtual circuit, a path is set up in advance, after which data is relayed along the path using packet-switching methods. Virtual circuits can be either permanent or switched; in the latter case, each virtual circuit is preceded by a set-up phase that builds the virtual circuit and is followed by a tear-down phase.

In general, packets can vary in size (for example, IP packets can be anywhere from 20 to 65,536 bytes in length). A technology known as Asynchronous Transfer Mode (ATM) uses fixed-size packets of 53 bytes, which are usually referred to as cells. The term “packet-switching” is customarily used to describe packet-switching methods other than ATM. ATM is described in greater detail in [Chapter 72](#); however, we will discuss some of the details of ATM switching in later sections.

24.2.3 Protocol Stacks

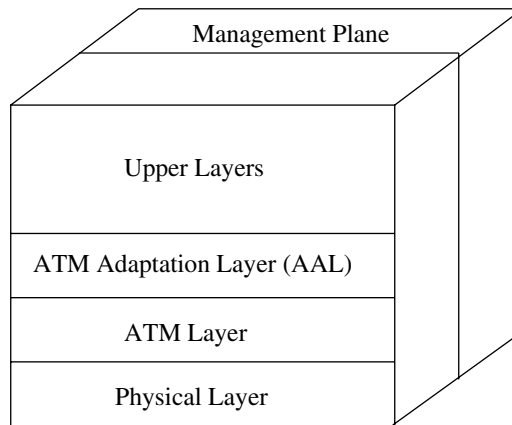

A **communication protocol** is a set of conventions and procedures agreed upon by two communicating parties. Protocols are usually grouped together into layers (a protocol stack); the actions required to implement a protocol at the $(i + 1)$ st layer of the stack require the services of the protocols at the i th layer.

This layered approach to network design has been used in many network implementations, dating back at least to the initial proposed three-layer protocol stack for the ARPA network [Meyer 1970]. In 1983, the International Standards Organization (ISO) proposed the seven-layer Open Systems Interconnection (OSI) Reference Model for network protocol stacks. Although there have been criticisms of this model, some of which are summarized by Tanenbaum [1996], it has served as a convenient framework for discussion and comparison of protocol architectures. A summary of the ISO/OSI Reference Model sufficient for the purposes of this discussion is given in [Table 24.1](#).

Protocols in the upper layers are classified as “end-to-end” because they provide abstractions that deal only with the source and destination nodes of a network communication; they are usually more concerned with details that are global in nature, such as establishing a connection to a remote host or determining how to proceed when data is damaged or lost in transit. Details about routing, encoding, contention for network resources, etc., are reserved for layers 3 and lower, which are termed “point-to-point” because they mediate communication between adjacent nodes in the network.

TABLE 24.1 The ISO-OSI Reference Model

**FIGURE 24.1** ATM reference model (simplified).

The protocol stack used in the Internet is often called the TCP/IP reference model, although technically it is not a model but an actual architecture. Our interest in this chapter is primarily with the lower levels of the protocol stack, and at these levels the distinctions between these two models are not critical to the discussion.

The ATM reference model is organized in a slightly different fashion, not completely analogous to the OSI stack. Figure 24.1 gives a simplified view. In addition to a vertical organization of protocols into layers, ATM specifies different *planes* that cut across the layers. The full specification includes a user plane and a control plane (not shown in the figure). The physical layer roughly corresponds to layer 1 in the OSI model, but the relationship between the ATM and AAL layers and the layers in OSI is not clear-cut. Certainly, layer 2 functionality is included in these two layers, and for the purposes of this chapter it is not necessary to make any finer distinctions.

The OSI seven-layer model does not represent the final level of granularity; most technology standards divide the OSI levels into two or more sublayers. To give just one example, the IEEE 802.3 standard for CSMA/CD networks [IEEE, 2002] subdivides the physical layer into four sublayers: PLS (physical layer signaling), AUI (attachment unit interface), MAU (medium attachment unit), and MDI (medium-dependent interface). Forouzan gives a very readable description of these sublayers [Forouzan, 2003]. In what follows, we limit ourselves to distinguishing between the logical link control and medium access control sublayers of the data-link layer and leave the remaining fine structure of this and other layers for further reading.

It is worth noting that alternatives to the layered network architecture approach have been proposed (see, for example, Braden et al. [2002]); however, this approach appears to be firmly established and unlikely to change.

24.2.4 Data Representation: Baseband Methods

There are many ways of physically representing, or keying, binary digits for transmission along some medium. To take the simplest example, consider a copper wire. We can use, for example, a voltage v_0 to represent a binary 0 and a different voltage v_1 to represent a binary 1. Although this is the most straightforward and obvious method, it suffers from several problems, most notably issues of synchronization and signal detection (a very long string of 0s or 1s, for example, would be represented as a steady voltage, making it difficult to count the bits and, if some drift in the signal value is possible, perhaps leading to the mistaken assumption that no signal is present at all). To correct this, we could use, not the voltage values themselves, but transitions between voltages (a transition from v_0 to v_1 or v_1 to v_0) to indicate bit values. This is the method used in Manchester encoding, which is the signaling method for Ethernet local area networks. Manchester encoding can be thought of as a phase modulation of a square-wave signal; phase modulation is discussed below. This encoding suffers from a different problem, namely that the transmitted signal must change values twice as fast as the bit rate, because two different voltages (low/high or high/low) are needed for each bit.

We need not restrict ourselves to just two values. If the sender and receiver are capable of distinguishing among a larger set of voltages, we could use, say, eight different voltages v_0, \dots, v_7 to encode any of the eight 3-bit strings 000, 001, \dots , 111. The limits of this approach are dictated by the amount of noise in the transmission medium and the sensitivity of the receiver. If just three voltages are available, say $v_0 < 0$, 0 , and $v_1 > 0$, we can require the signal to return to the zero value after each bit (RZ schemes), or we can use a “non-return-to-zero” scheme (NRZ) that uses only the positive and negative values.

Some encoding schemes assume the existence of a clock that divides the signal into discrete time intervals; others, such as the Manchester scheme, are self-clocking because every time interval contains a transition. A compromise between these two is a block encoding scheme in which extra bits are inserted at regular intervals to provide a synchronization mechanism. One such method, called 4B5B, transmits 5 bits for every 4 bits of data; each combination of 4 bits has a corresponding 5-bit code. Fiber Distributed Data Interface (FDDI) uses a combination of 4B5B and NRZ.

Six examples of encoding schemes are shown in [Figure 24.2](#). The straightforward binary encoding (a) would require a clocking mechanism for synchronization to deal with long constant bit strings. This can be avoided using three signal values and a return-to-zero encoding (b). The Manchester encoding (c) is an NRZ scheme because the zero is not used. A low-to-high transition signifies a binary zero; a high-to-low transition signifies a binary 1. The differential Manchester encoding (d) uses, not transitions of a particular type, but *changes* in the transition type to indicate bits — if a low-to-high transition is followed by a high-to-low transition (or vice versa), a 1 bit is indicated; but if two successive transitions are of the same type, a 0 bit is indicated. Bipolar alternate mark inversion, or AMI (e), uses alternating positive and negative values to represent the “1” bits in the signal. It, too, is subject to synchronization problems (long strings of zeros hold the signal constant, although long strings of ones are no longer a problem). Several variations of bipolar AMI counteract this effect. For example, in B8ZS, strings of eight consecutive zeros are replaced by the string “00011011,” but in such a way that the encoding of the spurious “1”s violates the rule of sign alternation. NRZ-I (f) uses the occurrence of a signal change to indicate a 1 bit; it requires a clock or must be used in conjunction with a coding method such as 4B5B that guarantees regular changes in the signal value.

These are examples of baseband signaling — the digital signal (or an analog signal that closely approximates it) is the only thing sent. An alternative to baseband signaling is to use a carrier wave modulated by the digital signal. This process is explained in more detail below.

24.2.5 Data Representation: Modulation

In modulation, an underlying signal, for example, a sine wave, is used as a carrier and modifications to its amplitude, frequency, and phase are used to encode the digital information. [Figure 24.3](#) gives a simplified view of this process, showing the same digital signal encoded three different ways: by amplitude modulation, by frequency modulation, and by phase modulation.

(a)

The 8-bit binary signal 01101001

(b)

Return-to-zero (RZ) encoding

(c)

Manchester encoding — 0 is a “low-to-high” transition, 1 is a “high-to-low”

(d)

Differential Manchester encoding — 1 is represented by a change in the transition direction

(e)

Bipolar AMI encoding — successive 1s alternate between positive and negative

(f)

NRZ-I encoding — a 1 toggles the signal value

FIGURE 24.2 Six baseband signaling methods.

FIGURE 24.3 Modulation of a signal by amplitude, frequency, and phase.

It is possible to combine several types of modulation in the same signal. Furthermore, there is no reason to limit the set of possible values to simple binary choices. Using a variety of amplitudes and phases, it is possible to encode several bits in one signaling time unit (e.g., with four phases and two amplitudes, we can encode eight distinct values, or 3 bits, in one signal). This technique is called quadrature amplitude modulation, or QAM.

24.2.5.1 Multiplexing

It is often the case that many signals must be sent over a single transmission path. For a variety of reasons it makes sense to **multiplex** these signals — to merge them together before placing them on the transmission medium and separate them at the other end (the separation process is called demultiplexing). One way to do this is called time division multiplexing. Each signal is divided into segments and each segment is

allocated a certain amount of time, much as time-sharing in an operating system permits several processes to share a single processor. Another way to achieve it is to use frequency division multiplexing — different signals are allocated different frequency bands from the available bandwidth. (Standard signal processing techniques permit the receiver to discriminate among the various frequency bands used.) Wavelength division multiplexing or WDM (sometimes called *dense* WDM or DWDM) is a form of frequency division multiplexing used in optical communication and assigns different colors of the light spectrum to different signals.

Several multiplexing standards exist to facilitate connecting telephone and data networks to one another. **T-carriers** were defined by AT&T and are the standard in North America and (with slight discrepancies) Japan (where they are sometimes called J-carriers). A T1 carrier uses time-division methods to multiplex 24 voice channels together, each 8 bits wide; the data rate is 1.544 Mbps. A T2 carrier multiplexes four T1 carriers (6.312 Mbps), a T3 carrier multiplexes six T2 carriers (44.736 Mbps), and a T4 carrier multiplexes seven T3 carriers (274.176 Mbps). However, a conflicting standard, the **E-carrier**, is used in Europe and the rest of the world [ITU, 1998]. An E-1 carrier multiplexes 32 8-bit channels together and has a rate of 2.048 Mbps. E-2 and higher carriers each increase the number of channels by an additional factor of four; thus, an E-2 carrier has 120 channels (8.448 Mbps), E-3 has 480 channels (34.368 Mbps), etc.

With the increasing use of optical fiber, another set of multiplexing standards has been adopted. SONET (Synchronous Optical Network), ANSI standard T.105, and SDH (Synchronous Digital Hierarchy), developed by the ITU, are very similar and are often referred to as SONET/SDH. The basic building block, called STS-1 (for Synchronous Transport Signal), defines a synchronized sequence of 810-bit frames and a basic data rate of 51.84 Mbps. The corresponding optical carrier signal is called OC-1. STS-*n* (OC-*n*) corresponds to *n* multiplexed STS-1 signals (thus, STS-3/OC-3 corresponds to three multiplexed STS-1 signals and has a data rate of 155.52 Mbps).

Signals are sometimes multiplexed when several hosts try to simultaneously access a shared medium. In code division multiple access (CDMA), which is used in some wireless networks such as the IEEE 802.11b standard [IEEE, 1999b], each host is assigned a unique binary code word, also called a chip code or chipping code. Each 1 bit is transmitted using this code word, while a 0 bit uses the complementary bit sequence (the word “chip” suggests a fraction of a bit). If the codes satisfy certain orthogonality properties, a combination of statistical techniques and a process very similar to Fourier analysis can be used to extract a particular signal from the sum of several such signals. Chipping codes are used in Direct Sequence Spread Spectrum (DSSS) transmission; Tanenbaum [1996] and Kurose and Ross [2003] provide good introductions to CDMA.

SDMA (Spatial Division Multiple Access) is used in satellite communications. It allows two different signals to be broadcast along the same frequency but in different directions. If the recipients are sufficiently separated in space, each will receive only the intended signal.

Some wireless technologies, such as IEEE 802.11a [IEEE, 1999a] and the newly approved 54-Mbps 802.11g standard [Lawson, 2003], use a technique called OFDM (Orthogonal Frequency Division Multiplexing). Rather than combining signals from several transmitters, this variation of FDM is used for sending a single message by means of modulating multiple carriers to overcome effects such as multipath fading (in which a signal is canceled out by interference with delayed copies of itself).

24.3 Best Practices: Physical Layer Examples

24.3.1 Media

The lowest layer of the protocol stack concerns itself with simply delivering bits from one machine to another, regardless of any meaning that may be attached to the bits. Communicating a stream of bits between two computers requires a transmission medium and one or more protocols specifying the way in which the bits are represented and their rate of transmission. Typical media in modern networks include ordinary copper, usually in the form of “twisted pairs” of wires, fiber-optic cable, and wireless transmission via radio, microwave, or infrared waves. A detailed description of the physical properties of each of these

would require a separate chapter; therefore, only brief descriptions of some of the more common media are given.

Ordinary copper wire remains one of the most common and most versatile media. Occurring in the form of twisted pairs of wires or coaxial cable, copper wiring occurs in telephone wiring (particular the “last mile” connection between homes and local telephone switching offices), many local area networks such as Ethernet and ATM LANs, and other places where an inexpensive and versatile short-haul transmission medium is needed.

Optical fiber is much more expensive but has the benefits of large bandwidth and low noise, permitting larger data transfer rates over much longer distances than copper. Fiber can be either glass or plastic and transmits data in the form of light beams, generally in the low infrared region. Multi-mode fiber permits simultaneous transmission of light beams of many different wavelengths; single-mode fiber allows transmission of just one wavelength.

Wireless transmission can be at any of a number of electromagnetic frequencies, such as radio, microwave, or infrared. This overview deals primarily with guided media.

At the physical layer, among the many challenges facing network designers are signal detection, attenuation, corruption due to noise, signal drift, synchronization, and multipath fading. Standard signal processing techniques handle many of these problems; Stein [2000] gives an overview of these techniques from a computer science point of view. Some of the more interesting problems deal with interfacing transmission media (particularly issues dealing with digital vs. analog representation) and maximizing the bandwidth usage of various media. Several representative technologies for dealing with these concerns are presented in this section.

24.3.2 Repeaters and Regenerators

A repeater is essentially just a signal amplifier; the term predates computer networks, originally referring to radio signal repeaters. The term “regenerator” is sometimes used to describe a device that amplifies a binary (as opposed to an analog) signal. Repeaters are used where the transmission medium (e.g., twisted pair copper wire or microwaves) has an inherent physical range limit beyond which the signal becomes too attenuated to use. Microwave antennas serve the function of repeaters in terrestrial microwave networks; communication satellites can be thought of as repeaters that amplify electromagnetic signals and retransmit them back to the ground. Optical repeaters, used with fiber-optic cable, sometimes have additional functionality, such as converting between single-mode and multimode fiber transmission. Because repeaters are relatively simple, they introduce very little delay in the signal. Repeaters are sometimes incorporated into more sophisticated devices, such as hubs connecting several local area networks; hubs are discussed in more detail in a later section.

An amplifier will amplify noise just as well as data. More sophisticated technologies are required to ensure the integrity of the bit stream. In the particular case of a digital signal regenerator, much of the noise can be eliminated using fairly standard techniques that involve synchronizing the data signal with a clock signal and using threshold methods; see, for example, Anttalainen’s [1999] discussion of regenerative repeaters.

With the growth in popularity of wireless networks, new kinds of repeater mechanisms are coming into play; for example, “smart antennas” can selectively amplify some signals and inhibit others [Liberti and Rappaport, 1999].

24.3.3 Voice Modems

Modems are used when a digital signal must be encoded in analog fashion using modulation. This is often the case when home subscribers to an Internet service provider must use the analog lines of the public switched telephone network (PSTN) to go online. The word “modem” is a shortened form of modulator/demodulator.

Some manufacturers make a distinction between **hard modems**, which contain all of the necessary digital signal processing functions on the modem board, and the less-expensive **soft modems**, which off-load some of the signal processing responsibility to software on the host machine.

Modems designed for data transmission over telephone lines, also called voice-grade modems or simply telephone modems, use a combination of modulation techniques. QAM is used in all modems that adhere to ITU-T modem standards V.32 and higher.

The most recent ITU voice-grade modem recommendations as of this writing are V.90 and V.92, which specify an asymmetric data connection in which one direction (called “upstream”) is analog and the other (“downstream”) is digital. The maximum data rates for these are 33,000 to 48,000 bits per second for upstream and about 56,000 bits per second for downstream, respectively.

The difference in the upstream and downstream rates for V.90/V.92 modems is due to the fact that the digital-to-analog conversion used in the upstream connection incurs a penalty (the so-called “quantization noise”). The upstream data rate is nearly at the “Shannon limit” of roughly 38,000 bits per second, a theoretical upper bound on the achievable bit rate based on estimates of the best signal-to-noise ratio for analog telephone lines [Tanenbaum, 1996]. (Compression techniques used in V.92 permit some improvement here.) Lower signal-to-noise ratios result in slower data transfer rates. However, disregarding noise, both rates are limited to about 56,000 bits per second (56 Kbps) by the inherent properties of telephone voice transmission, which uses a very narrow bandwidth (about 3000 Hertz [3 kHz]), and a technique called pulse code modulation (PCM), which involves sampling the analog signal 8000 times per second. Each sample yields 8 bits, 7 of which contain data and 1 of which is used for control.

In the United States, the 56-Kbps downstream rate has, until recently, been unachievable owing to a Federal Communications Commission (FCC) restriction on power usage that effectively reduced the limit to 53K. In 2002, the FCC granted power to set such standards to a private industry committee, the Administrative Council for Terminal Attachments, which adopted new power limits permitting the 56-Kbps data rate for V.90 and V.92 modems [FCC, 2002; ACTA, 2002].

24.3.4 Cable Modems

The word “modem,” once used almost exclusively to refer to voice-grade communication over telephone lines, has more recently been applied to other interfacing devices. A cable modem interfaces a computer to the cable television infrastructure, allowing digital signals to share bandwidth with the audio and visual broadcast content. Cable modem systems generally use coaxial cable or a combination of coaxial cable and fiber-optic cable (the latter are called hybrid fiber-coaxial, or HFC, networks). The much larger bandwidth of the cable TV connection permits faster data rates than telephone modems. As was the case with V.90 modems, the upstream and downstream data rates differ. With a cable modem, upstream data transfer rates can be millions of bits per second (Mbps), and downstream data rates can be in the tens of millions. The discrepancy between upstream and downstream rates is due, in part, to the fact that cable television systems were originally designed only for downstream data transfer from the cable provider to the television owner. A small portion of the bandwidth must be allocated for the upstream signal. (Cable companies offering cable modem service must upgrade their equipment by adding amplifiers for the upstream signal.)

Unlike telephone modem connections, which are dedicated point-to-point connections, cable modem connections are part of a broadcast network consisting of all the cable modem users in a particular neighborhood. When demand is high, the portion of bandwidth available to each user diminishes and data transfer rates decrease. In fact, a cable modem should be considered more as a layer 2, or data-link layer, device because it actually links a client computer to a local area network of cable modem users.

24.3.5 DSL

Sometimes, the word “modem” is used in a rather loose sense. For example, digital subscriber lines (DSL) use existing copper telephone wires and also require so-called digital modems. Technically, a digital modem is not a “modulator/demodulator,” but the term has become standard. DSL exploits the fact that much more bandwidth is available than the narrow range (between about 300 and 3300 Hz) used for voice transmission. A portion of this bandwidth is reserved for ordinary voice transmission; the rest is divided into upstream and downstream bandwidth and uses digital rather than analog techniques. DSL comes in

several varieties, the most common of which is asymmetric DSL, or ADSL. In ADSL, the upstream data rate is generally no more than about 600 Kbps, and the downstream rate is generally no more than about 8 Mbps.

There are several other varieties of DSL — rate-adaptive DSL (RADSL), high bit-rate DSL (HDSL), very high bit-rate DSL (VDSL), etc. Peden and Young [2001] describe the various flavors of DSL and provide an overview of how DSL modems have evolved from voice-grade modems.

24.3.6 Hubs and Other LAN Switching Devices

The commonplace meaning of switch, a device for making and breaking connections in a circuit, encompasses a great many components in networks at several levels of the protocol stack: hubs, telephone switches (part of the communication infrastructure supporting wide area networks), bridges (devices for connecting local area networks to other networks), routers (devices used to direct packets along an appropriate path), and others.

The word “switch” is sometimes specialized to a particular class of devices normally associated with layer 2 of the OSI stack, in order to distinguish them from less-intelligent devices such as hubs. Although they clearly must communicate via the physical layer, they possess additional capabilities to do data-link-layer processing such as interpreting physical device addresses. When the word “switch” is used in the sequel, it will always be more precisely qualified.

A *hub* is used to connect several data lines into a single local area network; it simply takes incoming bits and broadcasts them to all the other lines to which it is connected. Such a hub is sometimes called a repeating hub. Early hubs did not even perform the amplification needed to regenerate the signal. These “passive hubs” were equivalent to wiring concentrators that are used to gather wires together into a central location; hubs are still sometimes referred to as concentrators.

Most LANs are broadcast networks; that is, all messages sent across the LAN are seen by all hosts in the network. As the number of hosts in a network grows, it becomes inefficient to force every host machine to see every message (more formally, we say that these hosts all share the same **collision domain** because two messages are said to collide if they are broadcast at the same time). Better segmentation is achieved using the protocols of the data-link layer and more sophisticated devices called **bridges**, which are discussed in the next section. Commercial vendors are increasingly using phrases such as “intelligent hub” to describe more bridge-like, even router-like, devices.

Some physical layer switching devices are specialized to particular situations. FDDI (Fiber Distributed Data Interface) networks consist of a number of hosts connected to two counter-rotating rings of fiber-optic cable (i.e., one ring transmits data clockwise, the other transmits it counterclockwise). One of these rings is designated the primary ring and is normally used for all data transfer; the secondary ring is idle. However, from time to time, one of the network hosts will fail, or one of the fibers may become damaged. In this case, a switch called a dual attachment concentrator “wraps” the primary and secondary rings together to form a single ring. A second type of switch, called an optical bypass switch, can also be used to handle host outages. Unlike the concentrator, the bypass switch optically “splices” each of the rings across the broken section, retaining the dual ring structure. (It is worth mentioning here that physically splicing fiber is an extremely precise operation; the optical switch uses mirrors to achieve the effect of an actual splice operation.) Downes et al. [1998] provide a good introduction to FDDI and its associated protocols.

Telephone switching has, of course, resulted in the design of many kinds of switches. One of the earliest types of switch, the **crossbar switch** (so named because the original electromechanical implementation actually used two layers of bars with each bar in one layer crossing every bar in the other), contains connection points for every combination of communication endpoints. Thus, if n ports are involved, there are n^2 switching points, of which only n can be closed at any given time (or $n/2$ if we remove the symmetry and use only the upper triangle of the connection point grid). Despite this quadratic growth, the simplicity of the crossbar design has made it a popular choice for switching, even in high-performance networks. For example, Stanford University’s Tiny Tera packet switch uses a 32-port crossbar [Gupta and

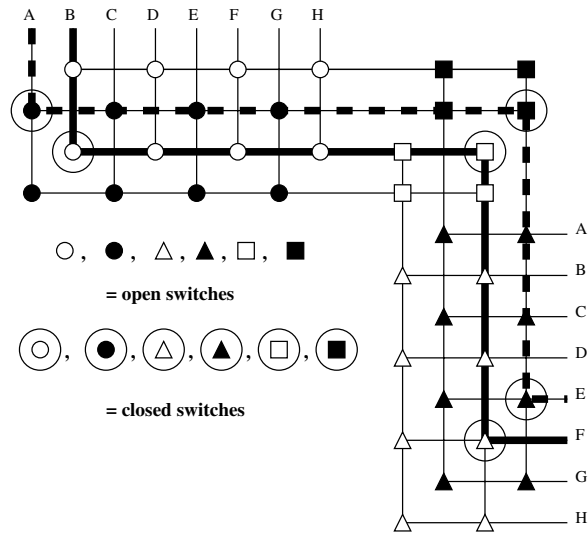

FIGURE 24.4 Space division switching.

McKeown, 1999]. Abel et al. [2003] describe a 256-port crossbar switch operating at data rates up to 4 terabits per second.

A necessary property of any switch is the ability to connect any pair of ports to one another. A desirable property is to permit a large number of simultaneous connections. A crossbar switch allows the maximum number of simultaneous connections, but in many cases it can be shown that fewer than the maximum will be required based on normal network traffic behavior. In such cases, it is possible to use small crossbar switches as modules for building larger multistage switches that allow any port pairs to be connected. This is called *space division switching*. Because there are fewer switches, some attempts to connect ports may “block” (blocking occurs when both endpoints are free but every path between them is unavailable due to conflicts with other connections). Figure 24.4 illustrates this. Any of the eight ports A, . . . , H can be connected to any other port. While a crossbar switch would require 64 connection points, this design uses a combination of four 4-by-2 crossbars (indicated by white and black circles and triangles) and two 2-by-2 crossbars (indicated by white and black rectangles) and has only 40 connection points. Connections are shown between A and E, and between B and F. Ports C and G are currently free, but it is not possible to connect them to each other because the wires needed to join them are already in use by other connections; an attempt to connect C to G would be blocked. In a full crossbar, this connection could be made.

One alternative to space division switching is time division switching. For this we use time division multiplexing to select one of the n input ports during each time slot, in round-robin fashion. Each input slice is placed into a buffer corresponding to its output port, so that after n time slices, all n buffers will be filled. On the output side, buffers are emptied in round-robin fashion and the contents of the i th buffer are sent to output port i . However, it requires n cycles to process one slice from each input port, so timing considerations come into play: the rate at which buffers are filled and emptied must be at least n times faster than the data rate for each port.

All the switching mechanisms described thus far have assumed a one-to-one pairing of input and output ports, an appropriate assumption when telephone conversations are being discussed. For data transfer, however, we often have multiple data streams directed to a single common destination. Switching now becomes just one component (the “switching fabric”) of more complicated devices capable of dealing with such routing issues. These will be taken up once again when we describe switching functions in the higher layers of the protocol stack.

24.4 Best Practices: Data-Link Layer Examples

The data-link layer is sometimes divided into two sublayers. The higher of these is often called the logical link control layer (LLC); the lower sublayer is called the media access layer (MAC). The LLC is responsible for grouping bits together into units called frames and for handling things like flow and error control, while the MAC handles media-specific issues.

24.4.1 Network Interface Cards

Any networked device requires an interface to attach it to the network. A network interface card (NIC), also called an adapter, serves this function. It carries out the layer 2 protocols (framing, flow control, encoding/decoding, etc.) and the layer 1 protocols (transmitting a bit stream onto the network medium). There are two popular driver architectures for network adapters: 3Com/Microsoft's NDIS (Network Device Interface Specification) and Novell's ODI (Open Datalink Interface).

24.4.2 An Example: Ethernet NIC

Due to the many different data-link layer protocols in existence, it would be impractical to try to describe every variation in network adapter behavior. As an example of the type of processing required of an NIC, we describe the main features of the carrier-sense multiple-access protocol with collision detection (CSMA/CD) as described in IEEE [2002] and implemented by a traditional 10-Mbps Ethernet LAN. (Strictly speaking, Ethernet is not identical to IEEE 802.3; but we ignore the differences in what follows.)

Every Ethernet NIC has a 6-byte address, called its MAC address or Ethernet address, that uniquely distinguishes it from every other Ethernet adapter (IEEE controls the allocation of MAC addresses and enforces this uniqueness). Data packets received from the upper layers of the protocol stack are packaged by the data-link layer into frames of sizes ranging from 64 to 1518 bytes. These include the data (which might have been padded with extra bits in order to achieve minimum frame size), the MAC addresses of the sender and the intended recipient, and several other fields. The physical layer prepends an 8-byte preamble used for synchronization and timing purposes, and then transmits the resulting frame using the Manchester encoding described in a previous section.

When a host is ready to transmit, it sets a counter k to zero (this counter keeps track of the number of re-tries made by the sender). It then senses the wire to see if anyone else is transmitting. When the line is free, it waits an additional 96 bit-times (the time needed to transmit 1 bit) — about 9.6 microseconds for 10-Mbps Ethernet — and starts sending data. If, during the transmission, another host were also to begin transmitting, the resulting collision will be detectable by both senders. At this point, the CSMA/CD protocol requires both hosts to stop transmitting and to emit a 32-bit “jam signal.” The sender then increments k and chooses a random number r in the range 0 through 2^{k-1} and waits $512 \times r$ bit-times before trying to retransmit. This is called *exponential backoff*.

The reason for requiring a minimum frame size has to do with collision detection. In the slowest Ethernet environment, 10 Mbps, a signal can travel no more than 2500 meters (the maximum allowed by the Ethernet standard). In this environment, conservatively assuming a propagation speed of one third the speed of light, or 10^8 meters per second (propagation in copper wire is usually twice this amount), a single bit could require as many as 25 microseconds ($25 \mu\text{s}$) to reach any host. If a signal were to travel this far just as a distant host began transmitting, it would take another $25 \mu\text{s}$ for news of the collision to return to the sender of the initial transmission. Therefore, a host might need to wait at least $50 \mu\text{s}$ to learn of a collision. It is important that the transmission last at least this long so that it can be terminated and restarted. About 500 bits (over 60 bytes) can be sent during this time at a speed of 10 Mbps, so 64 bytes is a conservative lower bound to enforce on the size of an Ethernet frame.

The IEEE 802 standards specify similarly precise behaviors for interfacing to Token Ring LANs, wireless LANs (in this case, the NIC is a wireless transceiver, often in the form of a PC card), and others. Most of these are described in nearly any published standard introduction to networks.

24.4.3 Bridges and Other Data-Link Layer Switches

A bridge connects several networks, forwarding data based upon the physical device addresses of the destination host as encoded in the headers added by the link layer protocol (unlike hubs, which indiscriminately forward bits to everyone, and unlike routers, which use logical addresses, such as IP addresses, rather than physical addresses). The word “switch” is sometimes used interchangeably with “bridge,” but the primary difference between them is that LAN switches implement the switching function in hardware, while a bridge implements the switching function in software. For this reason, layer 2 switches can handle more traffic at higher data rates.

Some LAN switches have an additional capability; they are capable of switching a data stream immediately after determining the physical address of the destination (rather than waiting for the entire packet to arrive before forwarding it). These are called **cut-through switches**.

Bridges and switches are described in greater detail in [Chapter 73](#); an excellent treatment of the subject can be found in Perlman’s book [1999].

24.5 Best Practices: Network Layer Examples

Layer 3 of the OSI Reference Model deals mainly with routing. Protocols at this level are responsible for determining where to direct data based upon a *logical address*. In the current incarnation of the Internet protocol, IP version 4 (IPv4), the 32-bit IP address plays this role. However, the proposed IPv6 addressing scheme [Hinden and Deering, 2003] expands the size of IP addresses to 128 bits. For a description of the evolution of IP addressing and the impact of IPv6, see, for example, Kurose and Ross [2003].

The primary technology associated with layer 3 of the OSI stack is the router, which contains protocols from the lowest three layers of the OSI model. Unlike bridges, which use physical addresses to direct data, routers use logical addresses (such as IP addresses) to determine packet destinations. Routers fall into one of two categories: (1) edge routers, which are responsible for routing data between WANs and individual hosts or LANs; and (2) core routers, which perform routing between locations within the WAN.

Chapter 73 deals with routing algorithms (shortest path algorithms, multicast routing, distance vector vs. link state methods, etc.). The discussion here focuses more on the switching process used inside the router.

A router consists of a number of input ports, a number of output ports, and a switching fabric connecting them. We will assume that packets are all the same size (e.g., ATM cells). The small, fixed-size cells used in ATM make switching design much simpler, so a large amount of research has gone into designing high-speed ATM switches. In fact, this is one reason why ATM is a suitable technology for WANs — it lends itself to the design of high-performance switches. Several examples are described here.

Even assuming that all input ports and output ports have the same data rate and that the switching fabric is fast enough to handle all non-conflicting switching requests, it will eventually happen that data packets arriving at two different input ports will be destined for the same output port. The switch must place one or the other packet into a queue.

When queuing occurs at the output ports, there is always a danger of the queue becoming full, in which case routing software must make a decision about which packet to discard. A special kind of crossbar switch, called a *knockout switch* [Yeh, Hluchyj, and Acampora, 1987], uses a series of “competitions” between randomly chosen pairs of packets to eliminate some of them from entering the queue. For descriptions of more sophisticated switching fabrics, see Oie et al. [1990] and Robertazzi [1998].

An alternative to queuing the packet at the output port is to wait until the destination is free before forwarding the second data item. In this case, queuing occurs at the input ports. It is possible that a packet waiting in the input queue for its destination port, which is blocked, may prevent a packet further back in line, whose destination port is available, from being transmitted. This is called *head-of-the-line blocking*. Most switching fabric designs try to avoid input queuing.

A complete and thorough treatment of switching technologies and the associated scheduling and queuing algorithms is beyond the scope of this chapter. Although it has been in print for over a decade, the

IEEE Computer Society's collection of papers on switching is still a useful source of background information on switching technologies [Dhas, Konangi, and Sreetharan, 1991]. Turner and Yamanaka [1998] provide an overview of large-scale switching technologies (with particular reference to ATM networks). Li [2001] provides a modern mathematical treatment of switches with particular reference to networking applications.

24.6 Research Issues and Summary

The biggest challenges facing the next generation of networking devices appear to be in the areas of infrastructure, multimedia, and wireless networking. Most long-distance data transmission now takes place over fast media such as fiber-optic cable. However, replacing copper wire with fiber at the bottleneck points where most consumers access the Internet — the so-called “last mile” — is expensive and time-consuming. DSL and cable modem technologies provide some measure of broadband access, but they have reached the limits imposed by the copper wire medium. A number of alternatives to fiber have been proposed, most of them involving wireless technologies. In recent years, Multichannel Multipoint Distribution Service (MMDS, also sometimes called Multipoint Microwave Distribution System), originally a one-way microwave broadcast technology for subscription television, has been adopted for use in last-mile Internet connections [Ortiz, 2000]. Free-space optics involving infrared lasers could be used in a network of laser diodes to boost last-mile data rates into the gigabit per second range. Acampora and Krishnamurthy [1999] provide a description of a possible wireless broadband access network; and Acampora [2002] gives a nontechnical introduction to these technologies.

Infrastructure includes not only the hardware but also the protocols. TCP/IP has proven to be remarkably robust, to the embarrassment of experts who have occasionally predicted its collapse [Metcalfe, 1996], but address space considerations alone will soon force the issue of making the transition to IPv6.

Multimedia is one of the driving economic forces in the networking industry; services such as video-on-demand [Ma and Shin, 2002], Voice-over-IP [Rosenberg and Schulzrinne, 2000], and others require not only large amounts of bandwidth, but more attention to issues such as real-time networking, multicasting, and quality-of-service. These, in turn, will influence the design of not only the software protocols, but also the switches and routers that must implement them at the hardware level. *Convergence* is the word often used to describe the goal of integrating voice, data, audio, and video into a single network architecture. B-ISDN and ATM were designed with this in mind, but there are still many hurdles to overcome.

Defining Terms

Bridge: A data-link-layer device that connects LANs (usually of the same type) to one another and performs routing based upon physical addresses.

Circuit switching: A transmission method that uses a dedicated path over which the data bit stream is sent.

Cut-through switch: A switch that bypasses the store-and-forward approach of older packet switches and begins immediately to forward data as soon as the destination port has been determined.

IEEE 802: A collection of local area networking standards developed by the Institute of Electrical and Electronics Engineers, including 802.2 (Token Ring), 802.3 (CSMA/CD), and 802.11 (wireless OFDM and CSMA protocols).

Hub: A device used to join several LANs together; broadcasts all bits arriving from an attached network to every other attached network.

LAN switch: A device much like a bridge, but with switching functions implemented in hardware rather than software.

Modem (modulator/demodulator): A device for converting back and forth between digital data and an analog transmission medium.

Modulation: The use of a signal, usually digital, to modify an underlying carrier signal by varying the carrier's amplitude, frequency, phase, or some combination of these properties.

- Multiplexing:** The process of merging several signals into one; can be done in any of several domains: time, frequency, wavelength, etc. The inverse is called *demultiplexing*.
- Packet switching:** A transmission method involving the segmentation of a message into units called packets, each of which is separately and independently sent.
- Protocol:** A set of conventions and procedures agreed upon by two communicating parties.
- Repeater (regenerator):** A device used to simply retransmit the data that it receives; used to extend the range of transmission medium.
- Router:** A network layer device that forwards packets based upon their logical destination address.
- Virtual circuit:** A transmission method in which packets or cells are transmitted upon a path that has been reserved in advance; may be permanent or switched.

Further Information

A number of recent textbooks provide excellent surveys of the architecture of modern networks. In addition to those already mentioned, the books by Stallings [2000], and Peterson and Davie [2000] are worth examining.

It is nearly impossible to study computer networking without examining the telecommunications industry, because so much of networking, particular wide area networking, depends on the existing communication infrastructure. The book by Anttalainen [1999] gives a good overview of communications technologies, and concludes with chapters on data communication networks. Walrand and Varaiya [2000] also achieve a very smooth integration of networking and communication concepts.

A large number of professional organizations sponsor sites on the World Wide Web devoted to networking technologies. The IEEE's pilot "Get IEEE 802" program makes the 802 LAN standards documents freely available electronically (<http://standards.ieee.org/getieee802/>). In addition, the IEEE's Communications Society publishes a number of useful magazines and journals, including *IEEE Transactions on Communications*, *IEEE/ACM Transactions on Networking*, and *IEEE Transaction on Wireless Communications*.

The ATM Forum (<http://www.atmforum.org>) is a particularly well-organized and useful site, offering free standards documents, tutorials, and White Papers in all areas of Asynchronous Transfer Mode and broadband technology.

25.1 Introduction

Fault tolerance is the ability of a system to continue correct operation after the occurrence of hardware or software failures or operator errors. The intended system application is what determines the system reliability requirement. Since computers are used in a vast variety of applications, reliability requirements differ tremendously. For very low-cost systems, such as digital watches, calculators, games, or cell phones, there are minimal requirements: the products must work initially and should continue to operate for a reasonable time after purchase. Failures of these systems are easily discovered by the user. Any repair may be uneconomical. At the opposite extreme are systems in which errors can cause loss of human life. Examples are nuclear power plants and active control systems for civilian aircraft. The reliability requirement for the computer system on an aircraft is specified to be a probability of error less than 10^{-9} per hour [hissa.nist.gov/chissa/SELFramework/framework_7.html].

More typical reliability requirements are those associated with commercial computer installations. For such systems, the emphasis is on designing system features to permit rapid and easy recovery from failures. Major factors influencing this design philosophy are the reduced cost of commercial off-the-shelf (COTS) hardware and software components, the increasing cost and difficulty of obtaining skilled maintenance personnel, and applications of computers in banking, on-line reservations, networking, and also in harsh environments such as automobiles, industrial environments with noise sources, nuclear power plants, medical facilities, and space applications. For applications such as banking, on-line reservations, or e-commerce, the economic impact of computer system outages is significant. For applications such as space missions or satellites, computer failures can have a huge economic impact and cause missed opportunities

to record valuable data that may be available for only a short period of time. Computer failures in industrial environments, automobiles, and nuclear power plants can cause serious health hazards or loss of human life.

Fault tolerance generally includes detection of a system malfunction followed by identification of the faulty unit or units and recovery of the system from the failure. In some cases, especially applications with very short mission times or real-time applications (e.g., control systems used during aircraft landing), a fault-tolerant system requires correct outputs during the short period of mission time. After the mission is completed, the failed part of the system is identified and the system is repaired. Failures that cause a system to stop or crash are much easier to detect than failures that corrupt the data being processed by the system without any apparent irregularities in the system behavior. Techniques to recover a system from failure include system reboot, reloading the correct system state, and repairing or replacing a faulty module in the system.

This discussion is restricted mainly to techniques to tolerate hardware failures. The applicability of the described techniques to software failures will also be discussed.

25.2 Failures, Errors, and Faults

25.2.1 Failures

Any deviation from the expected behavior is a *failure*. Failures can happen due to incorrect functions of one or more physical components, incorrect hardware or software design, or incorrect human interaction.

Physical failures can be either permanent or temporary. A *permanent failure* is a failure that is always present. Permanent failures are caused by a component that breaks due to a mechanical rupture or some wearout mechanism, such as metal electromigration, oxide defects, corrosion, time-dependent dielectric breakdown, or hot carriers [Ohring 98, Blish 00]. Usually, permanent failures are localized. The occurrence of permanent failures can be minimized by careful design, reliability verification, careful manufacture, and screening tests. They cannot be eliminated completely.

A *temporary failure* is a failure that is not present all the time for all operating conditions. Temporary failures can be either transient or intermittent. Examples of causes of transient failures include externally induced signal perturbation (usually due to electromagnetic interference), power-supply disturbances [Cortes 86], and radiation due to alpha particles from packaging material and neutrons from cosmic rays [Ziegler 96, Blish 00].

An *intermittent failure* causes a part to produce incorrect outputs under certain operating conditions and occurs when there is a weak component in the system. For example, some circuit parameter may degrade so that the resistance of a wire increases or drive capability decreases. Incorrect signals occur when particular patterns occur at internal leads. Intermittent failures are generally sensitive to the temperature, voltage, and frequency at which the part operates. Often, intermittent failures cause the part to produce incorrect outputs at the rated frequency for a particular operating condition but to produce correct outputs when operated at a lower frequency of operation. Not all intermittent failures may be due to inaccuracies in manufacture. Intermittent failures can be caused by design practices leading to incorrect or marginal designs. This category includes cross-talk failures caused by capacitive coupling between signal lines and failures caused by excessive power-supply voltage drop. The occurrence of intermittent failures is minimized by careful design, reliability verification, and stress testing of chips to eliminate weak parts.

Major causes of software failures include incorrect software design (referred to as *design bugs*) and incorrect resource utilization such as references to undefined memory locations in data structures, inappropriate allocation of memory resources and incorrect management of data structures, especially those involving dynamic structures such as pointers. Bugs are also common in hardware designs, and can involve millions of dollars when big semiconductor giants are involved [PC World 99, Bentley 01].

Failures due to human error involve maintenance personnel and operators and are caused by incorrect inputs through operator-machine interfaces [Toy 86]. Incorrect documentation in specification documents and user's manuals, and complex and confusing interfaces are some potential causes of human errors.

25.2.2 Errors

The function of a computing system is to produce data or control signals. An *error* is said to have occurred when incorrect data or control signals are produced. When a failure occurs in a system, the effect may be to cause an error or to make operation of the system impossible. In some cases, the failure may be benign and have no effect on the system operation.

25.2.3 Faults

A *fault model* is the representation of the effect of a failure by means of the change produced in the system signals. The usefulness of a fault model is determined by the following factors:

Effectiveness in detecting failures

Accuracy with which the model represents the effects of failures

Tractability of design tools that use the fault model

Fault models often represent compromises between these frequently conflicting objectives of accuracy and tractability. A variety of models are used. The choice of a model or models depends on the failures expected for the particular technology and the system design; it also depends on design tools available for the various models.

The most common fault model is the *single stuck-at fault*. Exactly one of the signal lines in a circuit described as a network of elementary gates (AND, OR, NAND, NOR, and NOT gates) is assumed to have its value fixed at either a logical 1 or a logical 0, independent of the logical values on the other signal lines. The single stuck-at fault model has gained wide acceptance in connection with manufacturing test. It has been shown that although the single stuck-at fault model is not a very accurate representation of manufacturing defects, test patterns generated using this fault model are very effective in detecting defective chips [McCluskey 00]. Radiation from cosmic rays that cause transient errors on signal lines have effects similar to a transient stuck-at fault which persists for one clock cycle.

Another variation of the stuck-at fault model is the *unidirectional fault model*. In this model, it is assumed that one or more stuck-at faults may be present, but all the stuck signals have the same logical value, either all 0 or all 1. This model is used in connection with storage media whose failures are appropriately represented by such a fault. Special error-detecting codes [Rao 89] are used in such situations.

More complex fault models are the *multiple stuck-at* and *bridging fault* models. In a *bridging fault* model, two or more distinct signal lines in a logic network are unintentionally shorted together to create wired logic [Mei 74]. It is shown in McCluskey [00] that a manufacturing defect can convert a combinational circuit into a sequential circuit. This can happen due to either *stuck-open faults* created by any failure that leaves one or more of the transistors of CMOS logic gates in a nonconducting state, or *feedback bridging faults* in which two signal lines, one dependent on the other, are shorted so that wired logic occurs [Abramovici 90].

The previous fault models all involve signals having incorrect logic values. A different class of fault occurs when a signal does not assume an incorrect value, but instead fails to change value soon enough. These faults are called *delay faults*. Some of the delay fault models are the transition fault model [Eichelberger 91], gate delay fault model [Hsieh 77], and path delay fault model [Shedletsky 78a, Smith 85].

The previously discussed fault models also have the convenient property that their effects are independent of the signals present in the circuit. Not all failure modes are adequately modeled by such faults. For example, *pattern sensitive faults* are used in the context of random-access memory (RAM) testing, in which the effect of a fault depends on the contents of RAM cells in the vicinity of the RAM cell to be tested. Failures occurring due to cross-talk effects also belong to this category [Breuer 96].

The fault models described until now generally involve signal lines or gates in a logic network. Many situations occur in which a less detailed fault model at a higher level of abstraction is the most effective choice. In designing a fault-tolerant system, the most useful fault model may be one in which it is

assumed that any single module can fail in an arbitrary fashion. This is called a *single module fault*. The only restriction placed on the fault is the assumption that at most one module will be bad at any given time.

There have been several attempts to develop fault models for software failures [Siewiorek 98]. However, there is no clear consensus about the effectiveness of any of these models — or even whether fault models can be developed for software failures at all.

25.3 Metrics and Evaluation

25.3.1 Metrics

Several metrics are used to quantify how reliable a system is. These are reliability, availability, safety, maintainability, performability, and testability.

The *reliability* of a system at time t is the probability that the system will produce correct outputs up to time t , provided it was producing correct outputs to start with. The concept of reliability directly applies situations in which the system must produce correct outputs for a given period of time. Examples include aircraft control, fly-by-wire systems, automobiles, nuclear reactors, and military and space applications.

The *availability* of a system at time t is defined as the probability that the system is operational at time t . Unlike a reliable system, a highly available system may not be operational for a very short while but must be quickly repaired so that it becomes operational again very quickly. Examples include servers and mainframes, network equipment, and telephone systems. For telephone networks, the availability requirement is 99.999% [<http://www.iec.org/tutorials/five-nines/topic01.html>], which roughly translates to 3 to 5 minutes of downtime per year.

The *safety* of a system at time t is the probability that the system either will be operating correctly or will fail in a “safe” manner. The way a system can fail in a “safe” manner depends on the actual application. For example, a safe failing state of a traffic light is when it is stays red and keeps blinking.

The *performability* of a system at time t is the probability that the system is operating correctly at full throughput or operating at a reduced throughput greater than or equal to a given value. The concept of performability, first introduced in Beudry [77] in terms of performance-related reliability measures, is useful in the context of systems with graceful degradation. As a simple example, consider a network of computers in which one or more network links or computers may not be working. In that case, some of the links and computers will have more traffic and higher workloads. As a result, the system throughput will be less than the full system throughput with all working network links and computers. Depending on the application, such a performance degradation may or may not be acceptable.

The *maintainability* of a system, denoted by $M(t)$, is the probability that it takes t units of time to restore a failed system to normal operation. Depending on the situation, a simple reload of the system state may be sufficient, or the faulty unit in the system (also referred to as the *field replaceable unit* or *FRU*) must be identified to be replaced or repaired. Maintainability is important; if it takes a long time to bring a failed system back to normal state, then the downtime increases and system availability suffers.

The *testability* of a system is the ease with which the system can be tested — this includes the ease with which test patterns can be generated and applied to the system. Test pattern generation cost depends on either the computer time required to run the test pattern generation program plus the (prorated) capital cost of developing the program, or the number of man-hours required for a person to write the test patterns plus the increase in system development time caused by the time taken to develop tests. Test application cost is determined by the cost of the test equipment plus the time required applying the test (sometimes called *socket time*). Attempts to understand circuit attributes that influence testability have produced the concepts of observability (visibility) and controllability (control). *Observability* refers to the ease with which the state of internal signals can be determined at the circuit outputs. *Controllability* refers to the ease of producing a specific internal signal value by applying signals to the circuit inputs [McCluskey 86].

25.3.2 Evaluation

Suppose that we want to estimate the reliability of a component (which can be a system itself) over time. An experimental approach to measure reliability is to take a large number N of these components and test them continuously. Suppose that at any time t , $G(t)$ is the number of components that are operating correctly up to time t and $F(t)$ is the number of components that failed from the time the experiment started up to time t . Note that $G(t) + F(t) = N$. Thus, the reliability $R(t)$ at time t is estimated to be $(G(t)/N)$, assuming that all components had equal opportunity to fail. The rate at which components fail is $(dF(t)/dt)$. The failure rate per component at time t , $\lambda(t)$, is $(1/G(t))(dF(t)/dt)$. Substituting $F(t) = N - G(t)$ and $R(t) = (G(t)/N)$, we obtain $\lambda(t) = -(1/R(t))(dR(t)/dt)$. When the failure rate is constant over time, represented by a constant failure rate λ , reliability $R(t)$ can be derived to be equal to $e^{-\lambda t}$ by solving the previous differential equation. This model of constant failure rate and exponential relationship between reliability and failure rate is widely used. Several other distributions that are used in the context of evaluation of reliable systems are hypoexponential, hyperexponential, gamma, Weibull, and lognormal distributions [Klinger 90, Trivedi 02].

Another metric very closely related to reliability is the *mean time to failure* (MTTF), which is the expected time that a component will operate correctly before failing. The MTTF is equal to $\int_{-\infty}^{\infty} tR(t)dt$. For a system with constant failure rate λ , the MTTF is equal to $\int_{-\infty}^{\infty} te^{-\lambda t} dt = (1/\lambda)$.

The failure rate is generally estimated from field data. For hardware systems, accelerated life testing is also useful in failure rate estimation [Klinger 90]. Figure 25.1 shows how the failure rate of a system varies with time. To start with, the failure rate is high for integrated circuits (ICs) for the first 20 weeks or so; during this time, weak parts that were not identified as defective during manufacturing testing typically fail in the system. After that, the failure rate stays more or less constant over time (in fact, it decreases a little bit), until the system lifetime is reached. After that, the failure rate increases again due to wearout. This dependence of failure rate on time is often referred to as the *bathtub curve*.

When a system fails, it must be repaired before it can be put into operation again. Depending on the extent of the failure, the time required to repair a system may vary. In general, it is assumed that the repair rate of the system is constant (generally represented by μ) and the *mean time to repair* (MTTR) is equal to $(1/\mu)$. For real situations, the assumption of constant repair rate may not be justified; however, this assumption makes the associated mathematics simple and manageable.

Once we know the system failure rate and the system repair rate, the system availability can be calculated using a simple Markov chain [Trivedi 02]. The average availability over a long period of time is given by $(MTTF/(MTTF + MTTR))$. The *mean time between failures* (MTBF) is equal to $MTTF + MTTR$. In general, MTTR should be very small compared to MTTF so that the average availability is very close to 1.

As a hypothetical example, consider system A, with $MTTF = 10$ hours and $MTTR = 1$ hour, and system B, with $MTTF = 10$ days and $MTTR = 1$ day. The average availability over a long period of time is the same for both systems. While MTTR should be brought down as much as possible, having a system with $MTTF = 10$ hours may not be acceptable because of frequent disruptions and system outage. Thus, average availability does not model all aspects of system availability. Other availability metrics include instantaneous availability and interval availability [Klinger 90].

FIGURE 25.1 Failure rate vs. time: bathtub curve. The numbers on the time axis are relevant for integrated circuits.

Several techniques are used to evaluate the previous metrics for reliable system design [Trivedi 02, Iyer 96]. These include analytical techniques based on combinatorial methods and Markov modeling, simulation of faulty behaviors using fault injection, and experimental evaluation.

25.4 System Failure Response

The major reason for introducing fault tolerance into a computer system is to limit the effects of malfunctions on the system outputs. The various possibilities for system responses to failures are listed in Table 25.1.

25.4.1 Error on Output

With no fault tolerance present, failures can cause system outputs to be in error. For many systems, this is acceptable and the cost of introducing fault tolerance is not justified. Such systems are generally small and are used in noncritical applications such as computer games, word processing, etc. The important reliability attribute of such a system is the MTTF. This is an example of a product for which the best approach to reliability is to design it in such a way that it is highly unlikely that it does not fail — a technique called *fault avoidance*. For hardware systems, fault avoidance techniques include

- Robust design (e.g., special circuit design techniques, radiation hardened designs, shielding, etc.) [Kang 86, Calin 96, Wang 99]
- Design validation verification (e.g., simulation, emulation, fault injection, and formal verification)
- Reliability verification (to evaluate the impact of cross-talk, electromigration, hot carriers, careful manufacturing)
- Thorough production testing [Crouch 99, McClusley 86, Needham 91, Perry 95]

At present, it is not possible to manufacture quantities of ICs that are all free of defects. Defective chips are eliminated by testing all chips during production. Some parts may produce correct outputs only for certain operating conditions but may not be detected because production testing is not perfect. It is not economically feasible to test each part for all operating conditions. In addition, there are weak parts that may produce correct outputs for all specified operating conditions right after manufacture but will fail early in the field (within a few weeks) — much earlier than the other parts. Reliability screens are used to detect these parts. Techniques include burn-in [Jensen 82, Hnatek 87, Ohring 98], very low voltage (VLV) testing [Hao 93], and SHOrt Voltage Elevation (SHOVE) tests [Chang 97], and Iddq testing [Gulati 93]. (The applicability of Iddq testing is questionable for deep-submicron technologies.) The cost of IC testing is a significant portion of the manufacturing cost.

Depending on the application, fault avoidance techniques may be very expensive. For example, radiation hardening of hardware for space applications has a very limited market and is very expensive. Moreover, the radiation hardened designs are usually several generations behind the highest-performance designs.

Fault avoidance techniques for software systems include techniques to ensure correct specifications, validation, and testing. Fault avoidance techniques for human errors include adequate training, proper review of user documents, and development of user-friendly interfaces.

TABLE 25.1 System Output Response to Failure

Error on output	Acceptable in noncritical applications (e.g., games, etc.)
Errors masked	Outputs correct even when fault from specific class occurs. Required in critical control applications (e.g., flight control during aircraft takeoff and landing, fly-by-wire systems, etc.)
Fault secure or data integrity	Output correct or error indication if output incorrect. Recovery from failure required. Useful for critical situations in which recovery and retry is adequate (e.g., banking, telephony, networking, transaction processing, etc.)
Fail safe	Output correct or at “safe value.” Useful for situations in which one class of output error is acceptable (e.g., flashing red for faulty traffic control light)

TABLE 25.2 Masking Techniques

Hardware	Voted logic — Each module is replicated. The outputs of all copies of a module are connected to a voter.
	Error correcting codes — Information has extra bits added. Some errors are corrected. Used in RAM and serial memory devices.
	Quadded (interwoven) logic — Each gate is replaced by four gates. Faults are automatically corrected by the interconnection pattern used.
	Fail safe — Output correct or at “safe value.” Useful for situations in which one class of output error is acceptable (e.g., flashing red for faulty traffic control light).
Software	<i>N</i> -version programs — Execute a number of different programs written independently to implement the same specification. Vote on the final result.
	Recovery block — Execute acceptance test program upon completion of procedure. Execute alternate procedure if acceptance test is failed.

**FIGURE 25.2** Voted logic. (a) Simplex, (b) TMR.

25.4.2 Error Masking

Several systems require that no errors are produced at their outputs. This is referred to as *error masking*. Such systems are usually real-time control systems in which outputs cause direct actions. Examples include air or spacecraft control surfaces, control for automobiles, medical systems, and nuclear and manufacturing controls. For such systems, the appropriate reliability parameter is the *fault tolerance*: the total number of failed elements that can be present without causing output errors. For some designs, it is important to consider both the total number of failed elements and the number of simultaneously failing elements that can be tolerated. Major error masking techniques are listed in Table 25.2.

Triple modular redundancy (TMR) is a widely used error working technique. Figure 25.2 illustrates this scheme, in which each module is replaced by three modules whose outputs are passed through a voting network before being transmitted as outputs. The three modules may be identical or different implementations of the same logic function. The concept of TMR was first developed in Von Neumann [56], in the context of models of neurons in the human brain.

One major advantage of TMR is its flexibility in choosing the module that forms the basic unit of replication. This can be as small as a single gate or as large as an entire computer. Any fault that affects only a single module will be masked. A direct extension of the TMR technique is *N-modular redundancy* (NMR), in which each module is replaced by *N* modules and voting is performed on the outputs of all modules. Several approaches to voting in TMR are discussed in Johnson [96], and Mitra [00a].

Suppose the reliability of each individual module of a TMR system is *R*; this is also referred to as the reliability of a simplex system or *simplex reliability*. The reliability of a TMR system is equal to $R^3 + 3R^2(1 - R) = 3R^2 - 2R^3$. Here, we assume that the voter reliability is 1, which is not generally the case. In that case, the TMR reliability must be multiplied by voter reliability. Figure 25.3 shows plots of simplex reliability and TMR reliability. It is assumed that the failure rate is constant, in which case *R* is equal to $e^{-(t/MTTF)}$, where MTTF is the mean time to failure of a simplex system.

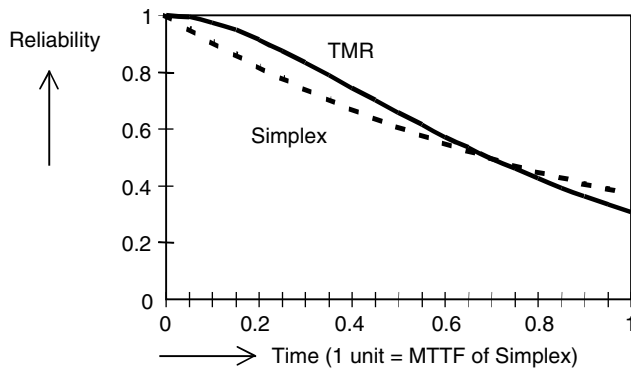

FIGURE 25.3 TMR reliability plot.

The following interesting observations can be made from Figure 25.3. The TMR reliability is greater than simplex reliability until time t equal to roughly seven-tenths (more precisely $\log_e 2$) of the simplex MTTF (by solving for t when $R = 3R^2 - 2R^3$ and $R = e^{-(t/MTTF)}$). In fact, after that point TMR reliability is less than simplex reliability. Thus, TMR systems are effective only for very short mission times, beyond which their reliability is worse than simplex reliability.

As an example, a TMR system may be used during an aircraft landing when the system must produce correct outputs for that short time. This is true for NMR systems in general. For a system with a constant failure rate, the MTTF of a TMR system is roughly eight-tenths the MTTF of a simplex system. Thus, if MTTF is used as the only measure of reliability, then it will seem that the TMR is less reliable than a simplex system. However, this is not true for very short mission times (Figure 25.3). A TMR–simplex system [Siewiorek 98], which switches from a TMR to a simplex system, can be used to overcome the problem related to reliability of TMR for longer mission times. There are several examples of commercial systems using TMR [Riter 95, <http://www.resilience.com>]. Another example of hardware error masking is interwoven redundancy based on the concept of quadded logic [Tryon 62].

Error correcting codes (ECCs) are commonly used for error masking in RAMs and disks. Additional bits are appended to information stored or transmitted. Any faulty bit patterns within the capability of the used code are corrected, so that only correct information is provided at the outputs [Rao 89]. It relies on error correction circuitry to change faulty information bits and is thus effective when this circuitry is fault-free.

Two major software techniques for fault masking are N -version programming [Chen 78] and recovery blocks [Randall 75]. *N-version programming* requires that several versions of a program be written independently. Each program is run on the same data, and the outputs are obtained by voting on the outputs from the individual programs. This technique is claimed to be effective in detecting failures in writing a program.

The other software method, *recovery blocks*, also requires that several programs be written. However, the extra programs are run only when an error has been detected. Upon completion of a procedure, an acceptance test is run to check that no errors are present. If an error is detected, an alternate program for the procedure is run and checked by the acceptance test. One of the difficulties with this technique is the determination of suitable acceptance tests. A classification of acceptance tests into accounting checks, reasonableness tests, and run-time checks is discussed in Hecht [96].

25.4.3 Fault Secure Techniques

Fault secure techniques ensure that the output is correct unless an error indication is present. Errors must be detected but need not be corrected. Thus, the major objective is to preserve system data integrity so that any data corruption due to faults from a given class is detected. Error detection during normal system

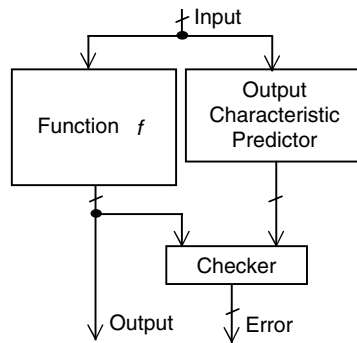

FIGURE 25.4 General architecture of a CED scheme.

operation is also referred to as *concurrent error detection* (CED) or *on-line checking*. CED techniques can be classified mainly into two major groups:

- Hardware redundancy
- Time redundancy

The basic principle behind CED based on hardware redundancy is shown in Figure 25.4 [Mitra 00b]. The system realizes function f and produces output sequence $f(i)$ for any input sequence i . A CED scheme generally contains another unit which independently predicts some special characteristic of the system output $f(i)$ for every input sequence i . Finally, a checker unit checks whether the special characteristic of the actual output produced by the system in response to sequence i matches the predicted characteristic and signals *error* when a mismatch occurs. Some examples of characteristics of $f(i)$ used for error detection purposes are $f(i)$ itself (duplication), its parity (parity prediction), 1s count, 0s count, transition count, etc. Coding schemes using parity and cyclic redundancy check (CRC) [Rao 89] are generally used for error detection in memories and data packets transmitted through computer networks.

A CED scheme is characterized by the class of failures in the presence of which data integrity is guaranteed. For the CED example in Figure 25.4, if the error signal is stuck-at-0, then an error will never be signaled. Thus, the CED system must be able to detect errors in the checking circuitry. An overview of self-checking checker designs can be obtained from Wakerly [78], and McCluskey [90]. Several CED techniques have been developed and used commercially for designing reliable systems [Sellers 68, Hsiao 81, Kraft 81, Chen 92, Webb 97, Spainhower 99]. Some of the important CED techniques are described next.

25.4.3.1 Duplication

Duplication is an example of a classic CED scheme in which there are two implementations, identical or different, of the same logic function. A self-checking comparator based on two-rail checkers is used to check whether the outputs from the two implementations agree. Duplication guarantees data integrity when one of the two implementations produces errors (single-module faults). Duplication has been used in several commercial systems [Kraft 81, Pradhan 96, Siewiorek 98, Webb 97, Spainhower 99].

25.4.3.2 Parity Prediction

The odd parity function indicates whether the number of 1s in a set of binary digits is odd. CED techniques for datapath circuits [Nicolaidis 97] and general combinational and sequential circuits based on parity prediction have been described in De [94], Toubia [97], and Zeng [99]. For a design with parity prediction using a single parity bit, the circuit is designed in such a way that there is no sharing among the logic cones generating the circuit outputs. Thus, if a single fault affects a logic cone, at most one output will be erroneous, so that the error is detected by a parity checker. A self-checking parity checker design is given in McCluskey [90]. The restriction of no logic sharing among different logic cones may result in large

area overhead for circuits with a single parity bit. Synthesis of circuits with multiple parity bits and some sharing among logic cones is described in Touba [97]. It is shown in Mitra [00b] that the area overhead of parity prediction is comparable to duplication, sometimes marginally better, for general combinational circuits. Unlike duplication, which guarantees detection of all failures that cause nonidentical errors at the outputs of the two modules, parity prediction detects failures that cause errors at an odd number of outputs.

For datapath logic circuits, the area overhead of parity prediction becomes very high, because it is difficult to calculate the parity of the result of an addition or multiplication operation from the individual parities of the operands. Residue codes, described next, are used for error detection in these cases [Langdon 70, Avizienis 71].

25.4.3.3 Residue Codes

Given an n -bit binary word, which is the binary representation of the decimal number x , the *residue* modulo b is defined as equal to $y = x \bmod b$. The recommended value of b is of the form $2^m - 1$ for high error detection coverage and low cost of implementation. For example, when $b = 3$, we need two bits to represent y . Suppose we add two numbers x_1 and x_2 and we have the residues of these two numbers for error detection along the datapath: that is, $y_1 = x_1 \bmod b$, and $y_2 = x_2 \bmod b$. The residue of the sum $x_3 = x_1 + x_2$ is given by $y_3 = (y_1 + y_2) \bmod b$; the residue of the product $x_4 = x_1 \times x_2$ is given by $y_4 = (y_1 \times y_2) \bmod b$. Hence, addition and multiplication operations are said to preserve the residues of its operands. The overall structure of error detection using residue codes is shown in Figure 25.5.

25.4.3.4 Application-Specific Techniques

The overhead of error detection can be reduced significantly if the specific characteristics of an application are utilized. For example, for some functions it is very easy to compute the inverse of that function; that is, given the output it is very easy to compute the input. For such functions, a cost-effective error detection scheme is to compute the inverse of a particular output and match the computed inverse with the actual input. The LZ-based compression algorithm is an example of such a function, where computation of the inverse is much easier than computation of the actual function. Compression is a fairly complex process involving string matching; however, decompression is much simpler, involving a memory lookup. Hence, for error detection in compression hardware, the compressed word can be decompressed to check whether it matches the original word. This makes error detection for compression hardware very simple [Huang 00]. Other examples of application-specific techniques for error detection with low hardware overhead are presented in Jou [88] and Austin [99].

Error detection based on time redundancy uses some form of repetition of actual operations on a piece of hardware. For detection of temporary errors, simple repetition may be enough. For detection of permanent faults, it must be ensured that the same faulty hardware is not used in exactly the same way during repetition. Techniques such as alternate data retry [Shedletsky 78b], RESO [Patel 82], and ED⁴I

FIGURE 25.5 Error detection using residue codes.

FIGURE 25.6 A simple fail-safe network.

[Oh 02a] are based on this idea. The performance overhead of error detection based on time redundancy may not be acceptable. Techniques such as multithreading [Saxena 00, Rotenberg 99, Reinhardt 00] or proper scheduling of instructions [Oh 02b] may be used reduce this overhead.

Some error detection techniques rely on a combination of hardware and software resources. Techniques include hardware facilities to check whether a memory access is to an area for which the executing program has authorization and also to verify that the type of access is allowed. Examples of other exception checks are given in Toy [86] and Siewiorek [98]. In a multiprocessor system, it is possible to run the same program on two different processors and compare the results. A more economical technique is to execute a reduced version of the main program on a separate device called a *watchdog processor* [Lu 82, Mahmood 88]. The watchdog processor is used to check the correct control flow of the program executed on the main processor, a technique called *control flow checking*. When the separate device is a simple counter, it is called a *watchdog timer*. Only faults that change the execution time of the main program are detected. Heartbeat signals that indicate the progress of a system are often used to ensure that a system is alive.

For signal processing applications involving matrix operations in a multiprocessor system, the number of processors required to check the errors in results can be significantly fewer than the number of processors required for the application itself, using a technique called *algorithm-based fault tolerance (ABFT)* [Huang 84].

Error detection using only software is very common and effective, but it must be developed for each individual program. Whenever some property of the outputs that ensures correctness can be identified, it is possible to execute a program that checks the property to detect errors. A simple example of checking output properties is the use of daily balance checks in the banking industry. The checked properties are also known as *assertions* [Leveson 83, Mahmood 83, Mahmood 85, Boley 95]. Automated software techniques for error detection without any hardware redundancy are described in Shirvani [00], Lovellette [02], Oh [02a], Oh [02b], and Oh [02c].

25.4.4 Fail-Safe Techniques

Fail-safe mechanisms cause the output state to remain in or revert to a safe state when a fault occurs. They typically involve replicated control signals and cause authorization to be denied when the control signals disagree. A simple example is a check that requires multiple signatures. Any missing or invalid signature causes the check not to be honored.

A simple fail-safe network is shown in Figure 25.6. Signals C1 and C2 have the same value in a fault-free situation. When they are both 0, the output is 0. If a fault causes them to disagree, the output is held at the safe value 0. This type of network is used in the fault-tolerant multiprocessor to control access to buses. No single fault can cause an incorrect bus access [Hopkins 78].

25.5 System Recovery

The rate of temporary failures is generally much higher than the rate of permanent faults [Lin 88]. Hence, when an error is detected, it is usually assumed that the error is due to some temporary failure. This temporary failure is expected to be gone when the operation is retried. If the failure persists even after a predetermined number of retries, it is assumed that the failure is a permanent one and repair routines are invoked.

Before a retry is performed, the system must start from some correct state. One solution is to initialize the entire system by rebooting it. However, a considerable amount of data may be lost as a result. A more systematic method of system recovery to prevent this data loss is checkpointing and rollback. The system state is stored in stable storage protected by ECC and battery backup at regular, predetermined intervals of time. This is referred to as *checkpointing*. Upon error detection, the system state is restored to the last checkpoint and the operation is retried; this is referred to as *rollback*. A particular application determines what system data must be checkpointed. For example, in a microprocessor checkpointing may be performed by copying all register and cache contents modified since the last checkpoint.

Techniques for roll-forward recovery in distributed systems that reduce the performance overhead of rollback recovery are described in Pradhan [94]. In a real-time system, rollback recovery may not be feasible because of the strict timing constraints. In that scenario, roll-forward recovery using TMR-based systems is applicable [Yu 01]. This technique also enables the use of TMR systems for temporary failures in long mission times.

Another useful recovery technique is called *scrubbing*. If the system memory is not used very frequently, then an error affecting a memory bit may not be corrected, because that memory word was not read out. As a result, errors may start accumulating, and used ECC codes may not be able to detect or correct the errors when the memory word is actually read out. Scrubbing techniques can be used to read the memory contents, check errors, and write back correct contents, even when the memory is not used. Scrubbing may be implemented in hardware or as a software process scheduled during idle cycles [Shirvani 00].

25.6 Repair Techniques

Unless a system is to be discarded when failures cause improper operation, failed components must be removed, replaced, or repaired. System repair may be manual or automatic. In the case of component removal, the system is generally reconfigured to run with fewer components, called *failed soft* or *graceful degradation*. If the faulty function can be automatically replaced or repaired, the system is called *self-repairing*. Self-repair techniques are useful for unmanned environments where manual repair is impossible or extremely costly. Examples include satellites, space missions, and remote or dangerous locations.

25.6.1 Built-in Self-Test and Diagnosis

The first error due to a fault typically occurs after a delay. This time is called the *error latency* [Shedletsky 76]. It is present because the output depends on the fault site logic value only for a subset of the possible input values. The error latency can be very long — so long that another fault (e.g., a temporary fault) occurs before the first fault is detected. Because of the limitations of the error-detection circuitry, the double error may be undetectable. In order to avoid this situation, provision is often made to test explicitly for faults that have not caused an output error. This technique is called *built-in self-test*. Built-in self-test is also useful in identifying the faulty unit after error detection.

Built-in self-test is generally executed periodically by interrupting the normal operation or when the system is idle. It is usually implemented by using test routines or diagnostic programs for programmed systems or by using built-in test hardware to apply a sequence of test vectors to the functional circuitry and checking its response [Bardell 87, Mitra 00c].

25.6.2 Fail-Soft Techniques

The most common form of automatic failure management involves disconnecting a failed component from the rest of the system and reconfiguring to continue operation until the bad device can be replaced. This can happen for as small a component as a portion of memory or for an entire processor, in the case of a multiprocessor system. The failed component is generally identified by means of built-in testing. Because no attempt is made to replace the disconnected component automatically, system operation may be degraded. This technique is sometimes called *graceful degradation*.

25.6.3 Self-Repair Techniques

Systems that must operate unattended for long periods require that the faulty components be replaced after being configured out of the system.

25.6.3.1 Standby Spares

One of the earliest self-repair techniques included a number of unused modules, *standby spares*, which could be used to replace failed components. The possibility of not applying power to a spare module until it is connected to the system is attractive for situations in which power is a critical resource or when the failure rate is much higher for powered than for unpowered circuits. Extensive hardware facilities are required to implement this technique, which is sometimes called *dynamic redundancy*. There are several major issues related to switching in a spare module without interrupting system operation.

25.6.3.2 Hybrid Redundancy

Fault masking and self-repair are obtained by combining TMR with standby spares, as shown in Figure 25.7 [Siewiorek 98]. Initially, the three top modules are connected through the switch to the voter inputs. The disagreement detector compares the voter output with each of the module outputs. If a module output disagrees with the voter output, the switch is reconfigured to disconnect the failed module from the voter and to connect a standby module to the voter instead. As long as at least two modules have correct outputs, the voter output will be correct. A failed module will automatically be replaced by a good module, as long as there are good modules available and the reconfiguration circuitry is fault-free. Thus, this system will continue to operate correctly until all spares are exhausted, the reconfiguration circuitry fails, or more than one of the on-line modules fail.

An advantage of this technique is the possibility of not applying power to a spare until it is connected to the voter. A disadvantage is the complexity of the reconfiguration circuitry. The complexity increases the cost of the system and limits its reliability [Ogus 75].

FIGURE 25.7 Hybrid redundancy with a TMR core and standby spares.

25.6.3.3 Self-Purging Redundancy

A self-purging system provides fault masking and self-repair with less complexity than hybrid redundancy [Losq 76]. It requires that all modules are powered until disconnected from the output due to a failure. Initially, all modules have their outputs connected to the voter inputs. The voter is a threshold network whose output agrees with the majority of voter inputs. Whenever one of the module outputs disagrees with the voter output, the module output is disconnected from the voter.

25.6.3.4 Reconfigurable Systems Self-Repair

In a reconfigurable system, such as a system with field programmable gate arrays (FPGAs), no spare modules are required for system self-repair. These systems can be configured multiple times by loading an appropriate configuration which implements logic functions in programmable logic blocks and interconnections among the logic blocks, controlled by switches implanted using pass transistors. After error detection, the failing portion (which can be a programmable logic block or a failing switch) is identified, and a configuration that does not use the failed resource is loaded. For practical purposes, such an approach does not cause any significant reliability or performance degradation of the repaired system. Self-repair and fault isolation techniques for reconfigurable systems are described in Lach [98], Abramovici [99], Huang [01a], Huang [01b], and Mitra [04a, 04b].

25.7 Common-Mode Failures and Design Diversity

Most fault-tolerance techniques are based on a single fault assumption. For example, for a TMR system or for error detection based on duplication, it is assumed that one of the modules will be faulty. However, in an actual scenario, several failure sources may affect more than one module of a redundant system at the same time, generally due to a common cause. These failures are referred to as *common-mode failures* (CMFs) [Lala 94]. Some examples of CMFs include design faults, power-supply disturbances, a single source of radiation creating multiple upsets, etc. For a redundant system with identical modules, it is likely that a CMF will have identical error effects in the individual modules [Tamir 84]. For example, if a CMF affects both modules of a system using duplicated modules for error detection, then data integrity is not guaranteed — both modules can produce identical errors. CMFs are surveyed in Lala [94] and Mitra [00d].

Design diversity is useful in protecting redundant systems against CMFs. Design diversity is an approach in which hardware and software elements of a redundant system are not just replicated; they are independently generated to meet a system's requirements [Avizienis 84]. The basic idea is that, with different implementations generated independently, the effects of a CMF will be different, so error detection is possible. *N*-version programming [Chen 78] is a diversity technique for software systems. Examples of hardware design diversity include flight control systems from Boeing [Riter 95], the space shuttle, Airbus 320 [Briere 93], and many other commercial systems. The conventional notion of diversity is qualitative. A quantitative metric for design diversity is presented in Mitra [02], and techniques for synthesizing diverse implementations of the same logic function are described in Mitra [00e] and Mitra [01]. Use of diversity during high-level synthesis of digital systems is described in Wu [01].

25.8 Fault Injection

Fault injection is generally used to evaluate and validate fault tolerance techniques by injecting faults into a prototype or through simulation of a software model of a system. For example, fault injection may be used to estimate the capability of a concurrent error detection technique to detect errors; on the other hand, fault injection may also be used to validate whether the control state machines designed to perform recovery are correctly designed. Fault injection is useful because of the flexibility in injecting faults at the areas of interest in a controlled fashion, unlike in an actual environment. Also, faults can be injected at a much higher frequency than in an actual scenario, where the failure rate may be very low. Thus, statistical

information about the capabilities of fault-tolerance techniques can be obtained in a much shorter time than in a real environment, where it may take several years to collect the same information.

However, it is questionable whether the injected faults represent actual failures. For example, results from test chip experiments demonstrate that very few manufacturing defects actually behave as single stuck-at faults [McCluskey 00]. Hence, experiments must be performed to validate the effectiveness of fault models used during fault injection. We briefly describe some of the commonly used fault injection techniques [Iyer 96, Shirvani 98].

Disturb signals on the pins of an IC — The signal values at the pins of an IC can be changed at random, or there may be some sequence and timing dependence between error events on the pins [Scheutte 87]. The problem with this approach is that there is no control over errors at the internal nodes of a chip not directly accessible through the pins.

Radiation experiments — Soft errors due to cosmic rays in the internal nodes of a chip can be created by putting the chip under heavy-ion radiation or a high-energy proton beam in radiation facilities. The angle of incidence and the amount of radiation can be controlled very precisely. This technique is used widely in industry.

Power-supply disturbance — Errors can be caused in the system by disturbing the power supply [Cortes 86, Miremadi 95]. This technique models errors due to disturbances in the power supply and in industrial environments.

Simulation techniques — Errors can be introduced at selected nodes of a design, and then the system can be simulated to understand its behavior in the presence of these errors. This technique is applicable at all levels of abstraction: transistor level, gate-level, or even a high-level description language level of the system. The choice of appropriate fault models is very important in this context. One of the drawbacks of simulation-based fault injection is the slow speed of simulation compared to the actual operation speed of a circuit. Several fault injection tools based on simulation have been developed, such as Kanawati [95] and Goswami [97].

25.9 Conclusion

Computing and communication systems constitute an inseparable part of our everyday lives — home appliances, communication, transportation, banking and finance management, embedded computing in space applications, and biomedical applications, including automated remote surgery, ICs implanted in human bodies (the pacemaker being a very simple example), and health monitoring systems. Malfunctions of computing and communication systems have also become an inseparable part of our daily lives. Such malfunctions can cause massive financial losses or loss of human lives for critical applications, such as servers, automobiles, avionics, space vehicles, and biomedical equipment. Security violations due to lapses in security protocol designs or unprecedented attacks by external agents are already a major cause of concern that will significantly grow with our increased reliance on computers and networks.

There is general consensus in the industry that these failure sources will become more pronounced. We need robust system designs ensuring high system availability, maintainability, quality of service, security, and efficient recovery from failures. These systems must be available even during bursts of heaviest demands, must detect errors in processed transactions, and must be able to repair themselves from failures very quickly. They also must be transparent to the user, through retry, reconfiguration, or reorganization through graceful degradation, for example. Hence, design techniques for self-organizing, self-repairing, and self-maintaining adaptive systems are required.

This chapter has surveyed techniques for evaluating and designing such robust systems. We have demonstrated that the issues of error control and repair are distinct and appropriate specifications for each must be matched to the intended applications. We also have presented techniques for satisfying these aspects of the system specifications and discussed fault injection techniques to evaluate the effectiveness of these techniques and validate their design. Some of these techniques are applicable in the context of designing robust, adaptive, self-repairing architectures for molecular and quantum computing systems.

Computational Science

Computational Science unites computational simulation, scientific experimentation, geometry, mathematical models, visualization, and high performance computing to address some of the “grand challenges” of computing in the sciences and engineering. Advanced graphics and parallel architectures enable scientists to analyze physical phenomena and processes, providing a virtual microscope for inquiry at an unprecedented level of detail. These chapters provide detailed illustrations of the computational paradigm as it is used in specific scientific and engineering fields, such as ocean modeling, chemistry, astrophysics, structural mechanics, and biology.

26.1 Introduction

With the advent and rapid development of supercomputers and high-performance workstations, computational field simulation (CFS) is rapidly emerging as an essential analysis tool for science and engineering problems. In particular, CFS has been extensively utilized in analyzing fluid mechanics, heat and mass transfer, biomedics, geophysics, electromagnetics, semiconductor devices, atmospheric and ocean science, hydrodynamics, solid mechanics, civil engineering related transport phenomena, and other physical field problems in many science and engineering firms and laboratories.

The basic equations governing the general physical field can be represented as a set of nonlinear partial differential equations pursuant to a particular set of boundary conditions. For computational simulation, the field is decomposed into a collection of elemental areas (2-D)/volumes (3-D). The governing equations associated with the field under consideration are then approximated by a set of algebraic equations on these elemental volumes and are numerically solved to get discrete values which approximate the solution of the pertinent governing equations over the field. This discretization of the field (domain, region) into finite-elemental areas/volumes is referred to as grid generation, and the collection of discretized elemental areas/volumes is called the grid.

The numerical solution process associated with general CFS applications first involves discretization of the integral or differential form of the governing set of partial differential equations (PDEs) formulated in continuum. The discretization of these equations is usually influenced by the grid strategy under consideration and the solution strategy to be employed. In general, the solution strategies are classified as: finite difference, finite volume, and finite element. In the case of finite differences, the derivatives in the PDEs are represented by algebraic difference expressions obtained by performing Taylor series expansions of the associated solution variables at several neighbors of the point of evaluation [Thompson and Mastin

1983]. The differential forms of the governing equations are utilized in this case. However, the integral forms of the governing equations are used in the cases of finite-element and finite-volume strategies. Here the solution process involves representation of the solution variables over the cell in terms of selected functions, and then these functions are integrated over the volume (in case of finite-element) or the associated fluxes through cell sides (edges) are balanced (in case of finite volume).

The finite-element approach itself comes in two basic forms — the *variational*, where the PDEs are replaced by a more fundamental integral variational principle (from which they arise through the calculus of variations), or the *weighted residual* (Galerkin) approach in which the PDEs are multiplied by certain functions and then integrated over the cell.

In the finite-volume approach the fluxes through the cell sides (which separate discontinuous solution values) are best calculated with a procedure which represents the dissolution of such a discontinuity during the time step (Riemann solver).

The finite-difference approach, using the discrete points, is associated by many with rectangular Cartesian grids since such a regular lattice structure provides easy identification of neighboring points to be used in the representation of derivatives, whereas the finite-element approach has always been, by the nature of its construction on discrete cells, considered well-suited for irregular regions since a network of cells can be made to fill any arbitrarily shaped region and each cell is an entity unto itself, the representation being on a cell, not across cells. In view of the discretization strategy employed, the grids can be classified as structured, unstructured, or hybrid.

26.1.1 Structured Grids

Let $\mathbf{r} = (x, y, z)$ and $\Omega = (\xi, \eta, \zeta)$ denote the coordinates in the physical and computational space. The structured grid is presented by a network of lines of constant ξ , η , and ζ such that a one-to-one mapping can be established between physical and computational space. The computational space is made up of uniformly distributed points within a square in two dimensions or a cube in three dimensions as demonstrated in Figure 26.1. The structured grid involving identity transformation between physical and computational space (that is, $x = \xi, y = \eta, z = \zeta$) is called a Cartesian grid. However, the body-fitted grid generated by utilizing discrete/analytic arbitrary transformations between physical and computational space is classified as a curvilinear grid. A grid around a cylinder demonstrating the Cartesian grid and curvilinear two-dimensional grid demonstrating O, C, and H type strategies and their respective correspondence with the computational domain are displayed in Figure 26.2a through Figure 26.2d.

The curvilinear grid points conform to the solid surfaces/boundaries and hence provide the most economical and accurate way for specifying boundary conditions. For example, in the O-type grid the boundary of the cylinder is specified at $\eta = 1$ boundary, and $\xi = 1$ and $\xi = \xi_{\max}$ boundaries represent the same physical boundary (commonly referred to as a cut line). In the C-type grid the cylinder boundary is mapped into only a part of the ξ boundary, as shown in the Figure 26.2c. Here, the boundary segment in the front of the airfoil in the computational domain and at the tail of the airfoil represent the cut line

FIGURE 26.1 Physical to computational space mapping.

FIGURE 26.2 (a) Cartesian grid, (b) O-type grid, (c) C-type grid, and (d) H-type grid.

FIGURE 26.3 (a) Multiblock grid showing matching, nonmatching, and overlapping strategies and (b) overlaid chimera grid.

boundary. However, in the H-type grid an airfoil is mapped into the middle of the computational domain as shown in Figure 26.2d.

For complicated geometrical configurations, the physical region is divided into subregions, within each of which a structured grid is generated. These subgrids are commonly referred to as composite grids, and the generation process is referred to as domain decomposition [Thompson 1987b]. The resulting subgrids may be patched together at common interfaces, may be overlapped, or may be overlaid. Self-explanatory pictorial views of domain decomposition strategies allowing patched blocks, overlapping blocks, and overlaid blocks are presented in Figure 26.3a and Figure 26.3b. Overlaid grids are also called chimera grids after the composite monster of Greek mythology.

The use of composite grids allowing patched and overlapped blocks is very common in computational fluid dynamics where geometrical configurations representative of the physical space are extremely complex and/or distinct sets of underlying partial differential equations are to be simulated in different regions. An application of a chimera (overlaid) grid simplifies an overall grid generation and solution process when temporally deforming/moving geometrical components are involved in the simulation. The transfer of solution information at the block interface is very critical for successful simulation. In case of chimera and nonmatching blocks, the interface treatment involves interpolation, and these interpolated physical

FIGURE 26.4 Unstructured grid.

variables may not satisfy the conservation requirement associated with the overall simulation process, resulting in spurious oscillations in the vicinity of the interface.

In general, the composite grids are presented as

$$\mathbf{r}_{ijkl}(i = 1, \dots, I\text{MAX}(l), \quad j = 1, \dots, J\text{MAX}(l), \quad k = 1, \dots, K\text{MAX}(l), \quad l = 1, \dots, \text{NBLKS})$$

where i , j , and k identify three curvilinear coordinates, $I\text{MAX}(l)$, $J\text{MAX}(l)$, $K\text{MAX}(l)$ denote the grid dimensions in each direction of block l . NBLKS represents the total number of blocks and vector \mathbf{r} contains the physical variables in x , y , and z direction. In structured grid generation the connections between points are automatically defined from the given (i, j, k) ordering. Such ordering (structure) does not exist in unstructured grids. Unstructured grids are composed of triangles in two dimensions and tetrahedrons in three dimensions. Each elemental volume is called a cell. The grid information is presented by a set of coordinates (nodes) and the connectivity between the nodes. The connectivity table specifies connections between nodes and cells. A pictorial view of a simple unstructured grid is presented in Figure 26.4.

26.1.2 Unstructured Grids

26.1.2.1 Hybrid Grid

A grid formed by a combination of structured–unstructured grids and/or allowing polygonal cells with different numbers of sides is called a hybrid or generalized grid. An usual practice is to generate structured grids near solid components up to desired distance and fill in remaining regions with unstructured (triangular/tetrahedron) grids. A typical hybrid grid is displayed in Figure 26.5.

26.1.3 Generation Process

Regardless of which grid strategy is being considered, creation of a computational grid requires the following:

1. *Computational mapping*: Establishing an appropriate mapping from physical to computational space allowing proper multiblock strategies in case of structured and hybrid grids or establishing an ordering of nodes in case of unstructured grids and hybrid grids.
2. *Geometry generation*: Defining an accurate numerical description of all solid components (surfaces) in conjunction with associated computational mapping criteria and a desired distribution of points.
3. *Computational modeling*: Generating an *appropriate* grid around these surfaces according to some criteria, usually with a specified multiblock strategy, point distribution, smoothness, and orthogonality in case of structured grids and desired background mesh representative of point distribution in case of unstructured grids.

The relationship of geometry to the grid generation process is analogous to the relationship between boundary conditions and the solution of the governing fluid flow equations. An accurate construction of

FIGURE 26.5 Hybrid grid.

the geometry with the proper distribution of points usually consumes 85 to 90 percent of the total time spent on the grid generation process. The geometry specification associated with grid generation involves the following:

1. Determine the desired distribution of grid points. This depends upon the expected flow characteristics.
2. Evaluate boundary segments and surface patches to be defined in order to resolve an accurate mathematical description of the geometry in question.
3. Select the geometry tools to be utilized to define these boundary segments/surface patches.
4. Follow an appropriate logical path to blend the aforementioned tasks obtaining the desired discretized mathematical description of the geometry with properly distributed points.

The accuracy of the numerical algorithm depends not only on the formal order of approximations but also on the distribution of grid points in the computational domain. The grid employed can have a profound influence on the quality and convergence rate of the solution. Grid adaption offers the use of excessively fine, computationally expensive, grids by directing the grid points to congregate so that a functional relationship on these points can represent the physical solution with sufficient accuracy.

Underlying principles and methodologies for grid generation and adaption follow.

26.2 Underlying Principles

26.2.1 Terminology and Grid Characteristics

The differencing and solution techniques involving Cartesian (regular) grids are well developed and well understood. The use of structured curvilinear grids (nonorthogonal in most cases) in the numerical solution of PDEs is not, in principle, any more difficult than using Cartesian grids. This is accomplished by transforming the pertinent PDEs from the physical space to computational space. The following notations will be utilized in the development of structured grids and these transformations; detailed mathematical analysis can be found in Thompson et al. [1985]:

$$\begin{aligned}
 \mathbf{r} &= (x, y, z) \equiv (x_1, x_2, x_3) && = \text{physical space} \\
 \Omega &= (\xi, \eta, \zeta) \equiv (\xi^1, \xi^2, \xi^3) && = \text{computational space} \\
 \mathbf{a}_i &= \mathbf{r}_{\xi^i}, \quad i = 1, 2, 3 && = \text{covariant base vectors} \\
 \mathbf{a}^i &= \nabla^{\xi^i}, \quad i = 1, 2, 3 && = \text{contravariant base vectors} \\
 g_{ij} &= \mathbf{a}_i \cdot \mathbf{a}_j \quad (i = 1, 2, 3), \quad (j = 1, 2, 3) && = \text{covariant metric tensor components} \\
 g^{ij} &= \mathbf{a}^i \cdot \mathbf{a}^j \quad (i = 1, 2, 3), \quad (j = 1, 2, 3) && = \text{contravariant metric tensor components} \\
 \sqrt{g} &= a_1 \cdot (a_2 \times a_3) && = \text{Jacobian of transformation}
 \end{aligned}$$

Also it can be shown that for any tensor \mathbf{u}

$$\nabla \cdot \mathbf{u} = \frac{1}{\sqrt{g}} \sum_{i=1}^3 [(\mathbf{a}_j \cdot \mathbf{a}_k) \cdot \mathbf{u}]_{\xi^i}, \quad (i, j, k) \text{ cyclic} \quad (26.1)$$

and

$$\nabla \cdot \mathbf{u} = \frac{1}{\sqrt{g}} \sum_{i=1}^3 (\mathbf{a}_j \cdot \mathbf{a}_k) \cdot \mathbf{u}_{\xi^i}, \quad (i, j, k) \text{ cyclic} \quad (26.2)$$

Although Equation 26.1 and Equation 26.2 are equivalent expressions, the numerical representations of these two forms may not be equivalent. The form given by Equation 26.1 is called conservative form and that of Equation 26.2 is called the nonconservative form. Equation 26.1 or Equation 26.2 is utilized for transforming derivatives from physical to computational space. With moving grids the time derivatives also must be transformed using the following equation:

$$\left(\frac{\partial \mathbf{u}}{\partial t} \right)_{\mathbf{r}} = \left(\frac{\partial \mathbf{u}}{\partial t} \right)_{\Omega} - \dot{\mathbf{r}} \cdot \nabla \mathbf{u} \quad (26.3)$$

where $\dot{\mathbf{r}}$ indicates the associated grid speed.

The discretization process associated with the finite-volume scheme employed in unstructured or hybrid grids is also very straightforward. Here, the integral equations are utilized. The edge-based data structure is used for connectivity information and can be easily utilized to compute areas of cells and associated fluxes. The area, for example, of a region bounded by a two-dimensional boundary $\partial\Omega$ is

$$A = \int_{\partial\Omega} x \, dy \quad (26.4)$$

which can be approximated to

$$A = \sum_{\text{edges}} x \Delta y \quad (26.5)$$

where x and Δy are interpreted as edge quantities. Also, the governing equations are discretized in similar fashion. For example, consider an integral form of the Navier-Stokes equation without body force as follows:

$$\frac{\partial}{\partial t} \int_V \mathbf{Q} \, dv + \oint_{\partial\Omega} \mathbf{F}(\mathbf{Q}) \cdot \mathbf{n} \, ds = \oint_{\partial\Omega} \mathbf{F}^v(\mathbf{Q}) \cdot \mathbf{n} \, ds \quad (26.6)$$

where \mathbf{n} is the outward normal to the control volume with components n_x and n_y in the x and y directions. The domain of interest is discretized into a set of nonoverlapping polygons (unstructured or hybrid grid), and the cell-averaged variables are stored at the cell center. For each cell the semidiscretized form of the governing Equation 26.6 can be written as

$$V_i \frac{\partial Q}{\partial t} = - \sum_{j=1}^k F_{ij} \cdot n_j \, ds + \sum_{j=1}^k F_{ij}^v \cdot n_j \, ds \quad (26.7)$$

where j varies over the cell faces, and F_{ij} and F_{ij}^v are the convective and viscous part of the numerical flux at j th edge of cell i . Detailed analysis and description of this discretization process can be found in Weatherill [1990] and Koomullil et al. [1996b].

On structured grids the definition of an order of a difference representation is integrally tied to point distribution functions, commonly referred to as stretching functions. The order is determined by the error behavior as the spacing varies with the points fixed in a certain distribution, either by increasing the number of points or by changing a parameter in the distribution. Actually, a global order is not meaningful in case of nonuniform structured grids. The order is relevant only locally in regions where the spacing does in fact

decrease as the point distribution changes. Looking at the truncation error analysis involving nonuniform structured curvilinear grids, the following grid requirements can be outlined: (1) The structured grid system must be either a right-handed system [$\sqrt{g} > 0$ for all (i, j, k)] or a left-handed system [$\sqrt{g} < 0$ for all (i, j, k)]. (2) Application of the distribution function with bounds on higher order derivatives does not change the formal order of approximation. The following functions involving exponential and hyperbolic tangent or hyperbolic sine stretching functions are widely utilized as distribution functions for distributing N points:

$$x(\xi) = \frac{e^{\alpha(s-1)} - 1}{e^\alpha - 1} \quad \text{or} \quad x(\xi) = 1 - \frac{\tanh(\alpha(1-s))}{\tanh(\alpha)} \quad (26.8)$$

where

$$s = (\xi - 1)/(N - 1) \quad 1 \leq \xi \leq N.$$

(3) Numerical derivative evaluation of the distribution function is preferred, i.e., instead of analytical definition of x_ξ , where $x_\xi = [(x_{i+1} - x_{i-1})/2]$. (4) The truncation error is inversely proportional to the sine of the angle between grid lines. This in turn indicates that the mildly skewed grid does not increase truncation error significantly. In fact, as a rule of thumb, nonorthogonality resulting in an angle between grid lines not less than 45° does not increase truncation errors significantly.

26.2.2 Geometry Preparation

The geometry preparation is the most critical and labor intensive part of the overall grid generation process. Most of the geometrical configurations of interest to practical engineering problems are designed in the computer-aided design/computer-aided manufacturing (CAD/CAM) system. There are numerous geometry output formats which require the designer to spend a great deal of time manipulating geometrical entities in order to achieve a useful sculptured geometrical description with appropriate distribution for grid points. Also, there is a danger of loosing fidelity of the underlying geometry in this process. The desired point distribution on the boundary segment/surface patch is achieved by computing a concentration array of unit length. The concentration array is computed using specified spacing and by selecting an exponential or hyperbolic tangent stretching function. The geometry preparation involves the discrete-sculptured definitions of all outer boundaries/surfaces associated with the domain of interest. In case of unstructured or hybrid grids, the geometry preparation involves the definition of discrete points on the boundaries associated with the domain. The following definitions will be utilized in this development.

Definition 26.1 Given a set of points on a curve with physical Cartesian coordinates (x_i, y_i, z_i) , $i = 1, i_1 + 1, \dots, i_2$. A number sequence $r = (r_1, r_2, \dots, r_n)$, with $0 \leq r_j \leq 1$, $r_1 = 0$, $r_n = 1$, $r_i \leq r_j$ for all $i < j$ represents the distribution of points, such that there exists a one-to-one correspondence between the element r_j of r and the triplet (x_j, y_j, z_j) . This number sequence r is called a curve distribution. For example, the normalized chord length with $r_{i_1} = 0$ and

$$r_i = \frac{\sum_{u=i_1+1}^i \sqrt{(x_u - x_{u-1})^2 + (y_u - y_{u-1})^2 + (z_u - z_{u-1})^2}}{\sum_{u=i_1+1}^{i_2} \sqrt{(x_u - x_{u-1})^2 + (y_u - y_{u-1})^2 + (z_u - z_{u-1})^2}} \quad (26.9)$$

where $i = i_1 + 1, \dots, i_2$ satisfies the definition of a curve distribution.

Definition 26.2 Given a set of points on a surface with physical Cartesian coordinates (x_{ij}, y_{ij}, z_{ij}) , $i = 1, i_1 + 1, \dots, i_2$; $j = j_1, j_1 + 1, \dots, j_2$. A mesh (s_{ij}, t_{ij}) , $i = 1, i_1 + 1, \dots, i_2$; $j = j_1, j_1 + 1, \dots, j_2$, is called a surface distribution mesh if $(s_{i_1j}, \dots, s_{i_2j})$ for $j = j_1, \dots, j_2$ represents the curve distribution for the curve $((x_{ij}, y_{ij}, z_{ij}), i = i_1, i_1 + 1, \dots, i_2)$ for $j = j_1, j_1 + 1, \dots, j_2$ and $(t_{j_1i}, \dots, t_{j_2i})$ for $i = i_1, \dots, i_2$ represents the curve distribution for the curve $((x_{ij}, y_{ij}, z_{ij}), j = j_1, j_1 + 1, \dots, j_2)$, for $i = i_1, i_1 + 1, \dots, i_2$.

FIGURE 26.6 Relationship between physical space, distribution mesh, and computational space.

Also, there exists a one-to-one correspondence between the physical domain and the surface distribution mesh and between the surface distribution mesh and the computational domain. These relations are demonstrated in Figure 26.6.

Definition 26.3 Let $(X_{ijk}, Y_{ijk}, Z_{ijk})$, $i = 1, 2, \dots, N$; $j = 1, 2, \dots, M$; $k = 1, 2, \dots, L$ be a single block three-dimensional structured grid. A mesh $(s_{ijk}, t_{ijk}, q_{ijk})$, $i = 1, 2, \dots, N$; $j = 1, 2, \dots, M$; $k = 1, 2, \dots, L$ is called a volume distribution mesh if $(\bar{s}_{ij\bar{k}}, \bar{t}_{ij\bar{k}})$, $i = 1, 2, \dots, N$; $j = 1, 2, \dots, M$ represents the surface distribution mesh for the surface $(\bar{X}_{ij\bar{k}}, \bar{Y}_{ij\bar{k}}, \bar{Z}_{ij\bar{k}})$, $\bar{k} = 1, 2, \dots, L$, $(t_{i\bar{j}k}, q_{i\bar{j}k})$ represents the surface distribution mesh for the surface $(X_{i\bar{j}k}, Y_{i\bar{j}k}, Z_{i\bar{j}k})$, for all \bar{i} and $(s_{i\bar{j}k}, q_{i\bar{j}k})$ represents the surface distribution mesh for the surface $(\bar{X}_{i\bar{j}k}, \bar{Y}_{i\bar{j}k}, \bar{Z}_{i\bar{j}k})$, for all \bar{j} .

26.2.3 Structured Grid Generation

26.2.3.1 Algebraic Generation Methods

An algebraic 3-D generation system based on transfinite interpolation (using either Lagrange or Hermite interpolation) is widely utilized for grid generation [Gordon and Thiel 1982, Soni 1992b]. The interpolation, in general complete transfinite interpolation from all boundaries, can be restricted to any combination of directions or lesser degrees of interpolation, and the form (Lagrange, Hermite, or incomplete Hermite) can be different in different directions or in different blocks. The blending functions can be linear or, more appropriately, based on the distribution surface/volume mesh. Hermite interpolation, based on cubic blending functions, allows orthogonality at the boundary. Incomplete Hermite uses quadratic functions and, hence, can give orthogonality at any one of two opposing boundaries, whereas Lagrange, with its linear functions, does not give orthogonality.

The transfinite interpolation is accomplished by the appropriate combination of 1-D projectors F for the type of interpolation specified. (Each projector is simply the 1-D interpolation in the direction indicated.) For interpolation from all sides of the section, if all three directions are indicated and the section is a volume, this interpolation is from all six sides, and the combination of projectors is the Boolean sum of the three projectors,

$$F_1 \oplus F_2 \oplus F_3 \equiv F_1 + F_2 + F_3 - F_1 F_2 - F_2 F_3 - F_3 F_1 + F_1 F_2 F_3 \quad (26.10)$$

With interpolation in only the two directions j and k , or if the section is a surface on which ξ^i is constant, the combination is the Boolean sum of F_j and F_k

$$F_j \oplus F_k \equiv F_j + F_k - F_j F_k, \quad (i, j, k) \text{ cyclic} \quad (26.11)$$

With interpolation in only a single direction i , or if the section is a line on which ξ^i varies, the interpolation is between the two sides on which ξ^i is constant using only the single projector F_i .

Blocks can be divided into subblocks for the purpose of generation of the algebraic grid. Point distributions on the sides of the subblocks can either be specified or automatically generated by transfinite interpolation from the edge of the side. This allows additional control over the grid in general configurations and is particularly useful in cases where point distributions need to be specified in the interior of a block or to prevent grid overlap in highly curved regions. This also allows points in the interior of the field to be excluded if desired, e.g., to represent holes in the field.

26.2.3.2 Elliptic Generation Method

An elliptic grid generation system [Thompson 1987b] commonly used is

$$\sum_{i=1}^3 \sum_{l=1}^3 g^{il} r_{\xi^i \xi^l} + \sum_{l=1}^3 g^{ll} P_l r_{\xi^l} = 0 \quad (26.12)$$

where the g^{il} , the elements of the contravariant metric tensor, can be evaluated as

$$g^{il} = \frac{1}{g} (g_{jm} g_{kn} - g_{jn} g_{km}), \quad (i = 1, 2, 3), \quad (l = 1, 2, 3) \quad (26.13)$$

(i, j, k) cyclic, (l, m, n) cyclic

where g is the square of the Jacobian.

The P_n are the *control functions*, which serve to control the spacing and orientation of the grid lines in the field. The first and second coordinate derivatives are normally calculated using second-order central differences. One-sided differences dependent on the sign of the control function P_n (backward for $P_n < 0$ and forward for $P_n > 0$) are useful to enhance convergence with very strong control functions. The control functions are evaluated either directly from the initial algebraic grid and then smoothed or by interpolation from the boundary point distributions.

The three components of the elliptic grid generation system provide a set of three equations that can be solved simultaneously at each point for the three control functions P_n ($n = 1, 2, 3$), with the derivatives here represented by central differences.

The elliptic generation system is solved by point successive over relaxation (SOR) iteration using a field of locally optimum acceleration parameters. These optimum parameters make the solution robust and capable of convergence with strong control functions.

Control functions can also be evaluated on the boundaries using the specified boundary point distribution in the generation system, with certain necessary assumptions (orthogonality at the boundary) to eliminate some terms, then they can be interpolated from the boundaries into the field. More general regions can, however, be treated by interpolating elements of the control functions separately. Thus, control functions on a line on which ξ^n varies can be expressed as

$$P_n = A_n + \frac{S_n}{\varrho_n} \quad (26.14)$$

where A_n is the logarithmic derivative of the arc length, S_n is the arc length spacing, and ϱ_n is the radius of curvature of the surface on which ξ^n is constant.

A second-order elliptic generation system allows either the point locations on the boundary or the coordinate line slope at the boundary to be specified, but not both. It is possible, however, to iteratively adjust the control functions in the generation system until not only a specified line slope, but also the spacing of the first coordinate surface off the boundary is achieved, with the point locations on the boundary specified. The extent of the orthogonality into the field can also be controlled. This orthogonality feature is also applicable on specified grid surfaces within the field, allowing grid surfaces in the field to be kept fixed while retaining continuity of slope of the grid line crossing the surface. This is quite useful in controlling the skewness of grid lines in some troublesome areas. Alternatively, boundary orthogonality can be achieved through Neumann boundary conditions, which allow the boundary points to move over a surface spline.

The boundary locations are located by Newton iteration on the spline to be at the foot of normals to the adjacent field points.

26.2.3.3 Hyperbolic Generation Method

It is also possible to base a grid generation system on hyperbolic PDEs rather than elliptic equations. In this case, the grid is generated by numerically solving a hyperbolic system [Steger and Chaussee 1980], marching in the direction of one curvilinear coordinate between two boundary curves in two dimensions or between two boundary surfaces in three dimensions. The hyperbolic system, however, allows only one boundary to be specified and is therefore of interest only for use in calculation on physically unbounded regions where the precise location of a computational outer boundary is not important. The hyperbolic grid generation system has the advantage of being generally faster than elliptic generation systems, but, as just noted, is applicable only to certain configurations. Hyperbolic generation systems can be used to generate orthogonal grids. In two dimensions, the condition of orthogonality is simply $g_{12} = 0$.

If either the cell area \sqrt{g} or the cell diagonal length (squared) $g_{11} + g_{22}$ is a specified function of the curvilinear coordinates, i.e.,

$$\sqrt{g} = F(\xi, \eta) \quad \text{or} \quad g_{11} + g_{22} = F(\xi, \eta) \quad (26.15)$$

then the system consisting of $g_{12} = 0$ and either of the preceding two equations is hyperbolic. Since the system is hyperbolic, a noniterative marching solution can be constructed proceeding in one coordinate direction away from a specified boundary.

26.2.3.4 Multiblock Systems

Although in principle it is possible to establish a correspondence between any physical region and a single empty logically rectangular block for general 3-D configurations, the resulting grid is likely to be much too skewed and irregular to be usable when the boundary geometry is complicated. A better approach with complicated physical boundaries is to segment the physical region into contiguous subregions, each bounded by six curved sides (four in 2-D) and each of which transforms to a logically rectangular block in the computational region. Each subregion has its own curvilinear coordinate system, irrespective of that in the adjacent subregions (see Figure 26.7). This then allows both the grid generation and numerical solutions on the grid to be constructed to operate in a logically rectangular computational region, regardless of the shape or complexity of the full physical region. The full region is treated by performing the solution

FIGURE 26.7 Multiblock grid.

operations in all of the logically rectangular computational blocks. With the composite framework, PDE solution procedures written to operate on logically rectangular regions can be incorporated into a code for general configurations in a straightforward manner, since the code only needs to treat a rectangular block. The entire physical field then can be treated in a loop over all the blocks. Transformation relations for PDEs are covered in detail in Thompson et al. [1985]. Discretization error related to the grid is covered in Thompson and Mastin [1983]. The evaluation and control of grid quality is an ongoing area of active research [Gatlin et al. 1991].

Grid lines at the interfaces may meet with complete continuity, with or without slope continuity, or may not meet at all. Complete continuity of grid lines across the interface requires that the interface [Thompson 1987a] be treated as a branch cut on which the generation system is solved just as it is in the interior of blocks. The interface locations are then not fixed, but are determined by the grid generation system. This is most easily handled in coding by providing an extra layer of points surrounding each block. Here, the grid points on an interface of one block are coincident in physical space with those of another interface of the same or another block, and also the grid points on the surrounding layer outside the first interface are coincident with those just inside the other interface, and vice versa. This coincidence can be maintained during the course of an iterative solution of an elliptic generation system by setting the values on the surrounding layers equal to those at the corresponding interior points after each iteration. All of the blocks are thus iterated to convergence, so that the entire composite grid is generated at once. The same procedure is followed by PDE solution codes on the block-structured grid.

26.2.3.5 Chimera Grids

The *chimera* (overlaid) grids [Belk 1995, Meakin 1991, Benek et al. 1985] are composed of completely independent component grids which may even overlap other component boundary elements, creating holes in the component grids. This requires flagging procedures to locate grid points that lie out of the field of computation, but such holes can be handled even in tridiagonal solvers by placing 1s at the corresponding positions on the matrix diagonal and all 0s off the diagonal. These overlaid grids also require interpolation to transfer data between grids, and that subject is the principal focus of effort with regard to the use of this type of composite grid.

26.2.3.6 Adaptive Grid Generation

With structured grids, the adaptive strategy based on redistribution is by far the most simple to implement, requiring only the regeneration of the grid and interpolation of flow properties at the new grid points at each adaptive stage without modification of the flow solver unless time accuracy is desired. Time accuracy can be achieved, as far as the grid is concerned, by simply transforming the time derivatives, thus adding convectivelike terms that do not alter the basic conservation form of the PDEs.

Adaptive redistribution of points traces its roots to the principle of equidistribution of error [Brackbill 1993, Soni et al. 1993] by which a point distribution is set so as to make the product of the spacing and a weight function constant over the points

$$w \Delta x = \text{const}$$

With the point distribution defined by a function ξ_i , where ξ varies by a unit increment between points, the equidistribution principle can be expressed as

$$w x_\xi = \text{const} \tag{26.16}$$

This one-dimensional equation can be applied in each direction in an alternating fashion. A direct extension to multiple dimensions using algebraic, variational, and elliptic systems has been developed.

The weight function is usually formulated by utilizing scaled gradients and curvatures of the solution variables considered for adaptation.

The control of the characteristics and distribution of a grid system can be achieved by varying the values of the control functions P_i in Equation 26.12. The application of the one-dimensional form of

Equation 26.12 with Equation 26.16 results in the definition of control functions in three dimensions,

$$P_i = \frac{W_{\xi^i}}{W} \quad (i = 1, 2, 3) \quad (26.17)$$

These control functions were generalized by Eiseman [1985] as

$$P_i = \sum_{j=1}^3 \frac{g^{ij} (W_j)_{\xi^i}}{g^{ii} W_i} \quad (i = 1, 2, 3) \quad (26.18)$$

In order to conserve the geometrical characteristics of the existing grid the definition of control functions is extended as

$$P_i = (P_{\text{initial geometry}})_i + c_i(P_{wt}) \quad (i = 1, 2, 3) \quad (26.19)$$

where $(P_{\text{initial geometry}})_i$ is the control function based on initial grid geometry, P_{wt} is the control function based on gradient of flow parameter, and c_i is the constant weight factors.

These control functions are evaluated based on the current grid at the adaptation step. This can be formulated as

$$P_i^{(n)} = P_i^{(n-1)} + c_i(P_{wt})^{(n-1)} \quad (i = 1, 2, 3) \quad (26.20)$$

where

$$P_i^{(1)} = (P_{\text{initial geometry}})_i^{(0)} + c_i(P_{wt})^{(0)} \quad (i = 1, 2, 3) \quad (26.21)$$

26.2.4 Unstructured Grid Generation

26.2.4.1 The Delaunay Triangulation

Dirichlet, in 1850, first proposed a method whereby a domain could be systematically decomposed into a set of packed convex polyhedra. For a given set of points in space, $\{P_k\}, k = 1, \dots, K$, the regions $\{V_k\}, k = 1, \dots, K$, are the territories which can be assigned to each point P_k , such that V_k represents the space closer to P_k than to any other point in the set. Clearly, these regions satisfy

$$V_k = \{P_i : |p - P_i| < |p - P_j| \forall j \neq i\} \quad (26.22)$$

This geometrical construction of tiles is known as the Dirichlet tessellation or Voronoi [1908] diagram. This tessellation of a closed domain results in a set of nonoverlapping convex polyhedra, called Voronoi regions, covering the entire domain. If all point pairs which have some segment of a Voronoi boundary in common are joined, the result is a triangulation of the convex hull of the set of points $\{P_k\}$. This triangulation is known as the *Delaunay triangulation* [Baker 1990, George and Hermeline 1992]. The definition is valid for n -dimensional space.

From the preceding discussion, it is apparent that in two dimensions a line segment of the Voronoi diagram is equidistant from the two points it separates. Hence, the vertices of the Voronoi diagram must be equidistant from each of the three nodes which form the Delaunay triangles. Clearly, it is possible to construct a circle, centered at a Voronoi vertex, which passes through the three points, which form a triangle. Furthermore, it is evident that, given the definition of Voronoi line segments and regions, no circle can contain any point. This latter condition is referred to as the in-circle criterion.

26.2.4.2 Advancing Front Procedure

The advancing front procedure is based on the method originally proposed in Peraire et al. [1987] for two dimensions and then extended to three dimensions in [Peraire et al. 1988, 1990]. The advocated approach is regarded as a generalization of the advancing front technique [George 1971, Lo 1985] with the distinctive feature that elements, i.e., triangles or tetrahedra, and points are generated simultaneously. This enables the

generation of elements of variable size and stretching and differs from the approach followed in tetrahedral generators which are based on Delaunay concepts [Baker 1990, Cavendish et al. 1985], which generally connect grid points which have already been distributed in space.

The generation problem consists of subdividing an arbitrarily complex domain into a consistent assembly of elements. The consistency of the generated mesh is guaranteed if the generated elements cover the entire domain and the intersection between elements occurs only on common points, sides, or triangular faces in the three-dimensional case. The final mesh is constructed in a bottom-up manner. The process starts by discretising each boundary curve. Nodes are placed on the boundary curve components and then contiguous nodes are joined with straight line segments. In later stages of the generation process, these segments will become sides of some triangles. The length of these segments must therefore, be consistent with the desired local distribution of mesh size. This operation is repeated for each boundary curve in turn.

The next stage consists of generating triangular planar faces. For each two-dimensional region or surface to be discretized, all of the edges produced when discretizing its boundary curves are assembled into the so-called initial front. The relative orientation of the curve components with respect to the surface must be taken into account in order to give the correct orientation to the sides in the initial front. The front is a dynamic data structure which changes continuously during the generation process. At any given time, the front contains the set of all of the sides which are currently available to form a triangular face. A side is selected from the front and a triangular element is generated. This may involve creating a new node or simply connecting to an existing one. After the triangle has been generated, the front is updated and the generation proceeds until the front is empty. The size and shape of the generated triangles must be consistent with the local desired size and shape of the final mesh. In the three-dimensional case, these triangles will become faces of the tetrahedra to be generated later.

The geometrical characteristics of a general mesh are locally defined in terms of certain mesh parameters. If $N = (2 \text{ or } 3)$ is the number of dimensions, then the parameters used are a set of N mutually orthogonal directions $\alpha_i, i = 1, \dots, N$, and N associated element sizes $\delta_i, i = 1, \dots, N$. Thus, at a certain point, if all N element sizes are equal, the mesh in the vicinity of that point will consist of approximately equilateral elements. To aid the mesh generation procedure, a transformation T which is a function of α_i and δ_i is defined. This transformation is represented by a symmetric $N \times N$ matrix and maps the physical space onto a space in which elements, in the neighborhood of the point being considered, will be approximately equilateral with unit average size. This new space will be referred to as the normalized space. For a general mesh this transformation will be a function of position. The transformation T is the result of superimposing N scaling operations with factors $1/\delta_i$ in each α_i direction. Thus,

$$T(\alpha_i, \delta_i) = \sum_{i=1}^N \frac{1}{\delta_i} \alpha_i \otimes \alpha_i \quad (26.23)$$

where \otimes denotes the tensor product of two vectors.

26.2.4.3 Grid Adaption Methods

For the solution adaptive grid generation procedure, an error indicator is required that detects and locates appropriate features in the flowfield. In order to provide flexibility in isolating varying features, multiple error indicators are used. Each can isolate a particular type of feature. The error indicators are usually set to the negative and positive components of the gradient in the direction of the velocity vector as given by

$$\begin{aligned} e_1 &= \min[\mathbf{V} \cdot \nabla(\mathbf{u}), 0] \\ e_2 &= \max[\mathbf{V} \cdot \nabla(\mathbf{u}), 0] \end{aligned} \quad (26.24)$$

and the magnitude of the gradient in all directions normal to the velocity vector as given by

$$e_3 = |\nabla \mathbf{u} - \mathbf{V}(\mathbf{V} \cdot \nabla \mathbf{u})/\mathbf{V} \cdot \mathbf{V}| \quad (26.25)$$

Where \mathbf{V} is the velocity vector and \mathbf{u} is any suitable flow property. Typically, density is used as the basis for the error indicator. The first two error indicators represent expansions and compressions in the flow

FIGURE 26.8 Types of h-refinement in two dimensions.

direction and the third represents gradients normal to the flow direction. The indicators can be scaled by the relative element size. Length scaling can improve detection of weak features on a coarse grid with the present procedure. Each error indicator is treated independently, allowing particular features in the flowfield to be isolated. For each error indicator, an error is determined from

$$e_{\text{lim}} = e_m + c_{\text{lim}} \cdot e_s \quad (26.26)$$

where e_{lim} is the error limit, e_m is the mean of the error indicator, e_s is the standard deviation of the error indicator, and c_{lim} is a constant. Typically a value near 1 is used for the constant. The error indicators are used to control the local reduction in relative element size during grid generation.

One of the advantages of an unstructured grid is that it provides a natural environment for grid adaptation using h-refinement or mesh enrichment. Points can be added to the mesh with the consequence that new elements are formed and only local modifications to the connectivity matrix need to be made. In addition, no modification or special treatments are required within the solution algorithm provided that on enriching the mesh the distribution of elements and points remains smooth. Once the regions for enrichment are determined and individual elements are identified there are a number of strategies for adding points. The most suitable methods attempt to ensure smoothness of the enriched mesh, and in this respect local refinement strategies can prove to be useful. Some examples of point enrichment are given in Figure 26.8.

In addition to h-refinement, node movement has been found to be necessary for an efficient implementation of grid adaptation. Node movement can be applied in the form

$$\mathbf{r}_0^{n+1} = \mathbf{r}_0^n + \omega_i \frac{\sum_{i=1}^M C_{i0} (\mathbf{r}_i^n - \mathbf{r}_0^{ni})}{\sum_{i=1}^M C_{i0}} \quad (26.27)$$

where $\mathbf{r} = (x, y)$, \mathbf{r}_0^{n+1} is the position of node 0 at relaxation level $n + 1$, C_{i0} is the adaptive weight function between nodes i and 0, and ω is the relaxation parameter. An adaptive weight function C_{i0} is used which takes the form

$$C_{i0} = k_1 + k_2 \left| \frac{\phi_i - \phi_0}{\phi_i + \phi_0} \right| \quad (26.28)$$

where ϕ is the driving variable e.g., pressure, density, Mach number, etc.; k_1 and k_2 are constants, k_1 acts to damp out noise; and k_2 amplifies the gradients along edges. In practice, this is implemented in a form which guarantees positive area cells after movement, even in regions close to a wall, which for viscous grids can have very small volumes.

26.3 Best Practices

In the last few years, numerical grid generation has evolved as an essential tool in obtaining the numerical solution of the partial differential equations of fluid mechanics. A multitude of techniques and computer codes have been developed to support multiblock structured and unstructured grid generation associated with complex configurations. Structured grid generation methodologies can be grouped in two main categories: direct methods, where algebraic interpolation techniques are utilized, and indirect methods, where a set of partial differential equations is solved. Both of these techniques are utilized either separately or in combination, to efficiently generate grids in the aforementioned codes.

In algebraic methods the most widely used technique is transfinite interpolation. Historically, application of algebraic methods in grid generation has progressed as follows. In the 1970s (and early 1980s) the algebraic methods based on Lagrange and Hermite (mostly cubic) interpolation methods in tensor product form or Coon's patching, commonly referred to as transfinite interpolation technique form, and parametric spline (mostly cubic natural splines) were utilized to construct an initial grid for the iterative grid evaluation associated with a set of partial differential equations (mostly elliptic equations). In the 1980s (and 1990–1991), the development of high-powered graphics workstations along with the application of Bezier B-spline curve/surface definition in a control point form revolutionized the grid generation process with graphically interactive generation strategies and grid quality (smoothness-orthogonality with precise distribution improvements) with fast and efficient parametric curve/surface description based on basis splines. The parametric based nonuniform rational B-spline (NURBS) is a widely utilized representation for geometrical entities in computer-aided geometric design (CAGD) and CAD/CAM systems [Yu 1995]. The convex hull, local support, shape preserving forms, and variation diminishing properties of NURBS are extremely attractive in engineering design applications and in geometry-grid generation. In fact, the NURBS representation is becoming the de facto standard for the geometry description in most of the modern grid generation systems. Recently, the research concentration in algebraic grid generation is placed on utilizing CAGD techniques for efficient and accurate geometric modeling (boundary/surface grid generation). The development of NASA initial graphics exchange specification (IGES) standard [Blake and Chou 1992]; NURBS data structure in the National Grid Project [Thompson 1993]; DTNURBS library and its implementation in various grid systems; the grid systems NGP, ICEM, GRIDGEN, IGG, GENIE++; and computer aided grid interface (CAGI) system is just a partial list of the outcome of this research concentration.

The best practice in grid generation is to transform all geometrical entities associated with the complex configuration under consideration into parametric control points based on NURBS representation allowing standard data structure. The grid generation algorithms are then tailored to exhibit NURBS representation in the generation process. An overall generation process is usually based on utilizing the best features of direct and indirect methods in case of structured grids and Delaunay triangulation and advancing front methods in case of unstructured grids.

26.3.1 Structured Grid Generation

The following observations and evaluations on the structured grid generation methodologies are important to consider before the development of overall grid generation process: algebraic systems are fast and economical; precise spacing control (a well-distributed grid) is always achieved with algebraic systems; grid generation by elliptic systems is always smooth; algebraic systems may cause grids to overlap; however, elliptic systems resist grid line overlapping; the control functions can be formulated to achieve boundary orthogonality and spacing control (near solid boundary surfaces) by elliptic generation systems; the control functions can be formulated to accomplish field orthogonality in a given computational direction (ξ , ζ , or η) and spacing control by elliptic generation systems by iteratively updating various terms in the generation system. This is very time consuming especially in three-dimensional problems. Algebraic systems require a high degree of understanding and visual user interaction. However, elliptic systems can be readily adaptable for generalization. This is extremely useful in grid adaptations. The hyperbolic systems preserve

the orthogonality at the solid boundary and the point distribution in the field. However, their applicability is restricted to external flows where the accurate geometrical shape of the outer boundaries/surfaces is not important as long as their location is a certain distance away from the body. Also in three-dimensional applications of hyperbolic systems the grid quality is directly influenced by the characteristics of the surfaces associated with the computational domain.

26.3.1.1 Transfinite Interpolation Method

In general, the algebraic methods are based on utilizing tensor product form of interpolation (in case of surface generation) and transfinite interpolation (in case of 2-D or full 3-D volume grid generation). Define a one-dimensional interpolation projector as follows:

$$T[r(s)] = \sum_{k=0}^q \sum_{j=0}^p \phi_{j,k}(s) r_j^{(k)} \quad (26.29)$$

where the parameter s is such that $0 \leq s \leq 1$, $\phi_{j,k}$ are the blending functions, and $r_j^{(k)}$ is the k th derivative of the variable r at parametric location s_j ($0 = s_0 \leq s_1 \leq s_2 \cdots \leq s_p = 1$). The following example clarifies Equation 26.29.

Example 26.1

Let

$$\begin{aligned} q &= 0, & p &= 1 \\ \phi_{0,0}(s) &= (1-s), & \phi_{1,0}(s) &= s \end{aligned}$$

then

$$T[r(s)] = \phi_{0,0}(s)r_0^0 + \phi_{1,0}(s)r_1^0 = (1-s)r_0^0 + sr_1^0$$

defines a straight line between two points r_0^0 and r_1^0 .

Example 26.2

Let

$$\begin{aligned} q &= 1, & p &= 1 \\ \phi_{0,0}(s) &= 2s^3 - 3s^2 + 1 \\ \phi_{1,0}(s) &= -2s^3 + 3s^2 \\ \phi_{0,1}(s) &= s^3 - 2s^2 + 1 \\ \phi_{1,1}(s) &= s^3 - s^2 \\ T[r(s)] &= \phi_{0,0}(s)r_0^0 + \phi_{1,0}(s)r_1^0 + \phi_{0,1}(s)r_0^1 + \phi_{1,1}(s)r_1^1 \end{aligned} \quad (26.30)$$

defines a Hermite cubic polynomial between two points r_0^0 and r_1^0 with specified slopes r_0^1 and r_1^1 at the respective end points. The linear interpolation and Hermite cubic interpolation are widely applied in grid generation.

For 2-D grid generation the transfinite interpolation (TFI) method is defined as follows:

$$T[r(s_{ij}, t_{ij})] = T_I[r(s_{ij}, t_{ij})] \oplus T_J[r(s_{ij}, t_{ij})]$$

where T_I is a one-dimensional interpolation projector applied in the $i(\xi)$ direction keeping t_{ij} fixed and T_J is the one-dimensional interpolation projector applied in the $j(\eta)$ direction keeping s_{ij} fixed. $T[r] = (T_I + T_J - T_I T_J)[r]$, and (s_{ij}, t_{ij}) is the distribution mesh for the 2-D grid configuration under consideration. The $T_I T_J$ represents the tensor product of interpolation in both the I and J directions.

The transfinite interpolation method for 3-D grid generation can be defined as

$$T[r(s_{ijk}, t_{ijk}, q_{ijk})] = T_I[r(s_{ijk}, t_{ijk}, q_{ijk})] \oplus T_J[r(s_{ijk}, t_{ijk}, q_{ijk})] \oplus T_K[r(s_{ijk}, t_{ijk}, q_{ijk})] \quad (26.31)$$

where T_I is a one-dimensional interpolation projector applied in the $t(\xi)$ direction keeping t_{ijk} and q_{ijk} fixed, T_J and T_K are similarly defined. Here $(s_{ijk}, t_{ijk}, q_{ijk})$ represents volume distribution mesh associated with 3-D grid generation.

For example, if (s_{ij}, t_{ij}) represents an $N \times M$ size distribution mesh, $((X_{i1}, Y_{i1}), (X_{iM}, Y_{iM}))$, $i = 1, 2, \dots, N$; and $((X_{1j}, Y_{1j}), (X_{Nj}, Y_{Nj}))$, $j = 1, 2, \dots, M$ boundaries are known, T_I is selected as a linear interpolation projector and T_J is selected as a Hermite interpolation projector and then

$$T_I[r(s_{ij}, t_{ij})] = (1 - s_{ij})r_{1j} + s_{ij}r_{Nj} \quad (26.32)$$

and

$$T_J[r(s_{ij}, t_{ij})] = \Phi_{00}(t_{ij})r_{i1} + \Phi_{1,0}(t_{ij})r_{iM} + \Phi_{0,1}(t_{ij})\left.\frac{\partial r}{\partial \eta}\right|_{r_{i1}} + \Phi_{1,1}(t_{ij})\left.\frac{\partial r}{\partial \eta}\right|_{r_{iM}} \quad (26.33)$$

and the respective 2-D grid can be evaluated as

$$r_{ij} = T_I + T_J - T_I T_J$$

where

$$T_I T_J[r(s_{ij}, t_{ij})] = (1 - s_{ij}) \left[\Phi_{0,0}(t_{ij})\gamma_{11} + \Phi_{1,0}(t_{ij})\gamma_{1M} + \Phi_{0,1}(t_{ij})\left.\frac{\partial r}{\partial \eta}\right|_{r_{11}} + \Phi_{1,1}(t_{ij})\left.\frac{\partial r}{\partial \eta}\right|_{1M} \right] + \left[s_{ij} \Phi_{0,0}(t_{ij})r_{N1} + \Phi_{1,0}(t_{ij})r_{NM} + \Phi_{0,0}(t_{ij})\left.\frac{\partial r}{\partial \eta}\right|_{r_{NM}} + \Phi_{1,1}(t_{ij})\left.\frac{\partial r}{\partial \eta}\right|_{NM} \right] \quad (26.34)$$

An important factor in applying the Hermite interpolation projectors in TFI formulation is the evaluation of slopes and twist vectors (cross derivatives). The slope vector $\bar{\mathbf{r}}_\xi$ can be evaluated by solving

$$\begin{aligned} \mathbf{r}_\xi \cdot \mathbf{r}_\eta &= (\sqrt{g_{11}g_{22}}) \cos(\theta_1) \\ \|\mathbf{r}_\xi \times \mathbf{r}_\eta\| &= A \end{aligned} \quad (26.35)$$

where θ_1 is the desired angle between grid lines ξ and η , and A is the desired area of the cell. The metric terms g_{11} and g_{22} can be evaluated using the desired change in arc length or from the appropriate algebraic grid (precise spacing control property of the algebraic grid can be exploited here). The system (26.35) can be uniquely solved to evaluate \mathbf{r}_ξ and \mathbf{r}_η , and \mathbf{r}_ζ can be evaluated similarly. The twist vectors $\mathbf{r}_{\xi\eta}$ and $\mathbf{r}_{\xi\xi}$ can be evaluated by solving

$$\begin{aligned} (\mathbf{r}_\xi \cdot \mathbf{r}_\eta)_\eta &= [(\sqrt{g_{11}g_{22}}) \cos(\theta_1)]_\eta \\ \|\mathbf{r}_\xi \times \mathbf{r}_\eta\|_\eta &= (A)_\eta \end{aligned} \quad (26.36)$$

and

$$\begin{aligned} (\mathbf{r}_\xi \cdot \mathbf{r}_\eta)_\xi &= [(\sqrt{g_{11}g_{22}}) \cos(\theta_1)]_\xi \\ \|\mathbf{r}_\xi \times \mathbf{r}_\eta\|_\xi &= (A)_\xi \end{aligned} \quad (26.37)$$

respectively. The other cross derivatives can be evaluated similarly. Observe that if orthogonality is desired, that is, $\theta_1 = 90^\circ$, then the right-hand side will have zeros except for A , A_ξ , and A_η where A_ξ and A_η represent the change in desired volumes in all areas in the ξ and η directions. This concept can be easily extended to three-dimensional configurations.

26.3.1.2 Elliptic Grid Generation

A multitude of general purpose elliptic generation systems here appeared [Thompson 1987b]. Most of these algorithms are based on an iterative adjustment of control functions to achieve boundary orthogonality. The following analysis is provided to illustrate this development.

Consider

$$\begin{aligned} (g_{ij})_{\xi^k} &\equiv (\text{derivative of } g_{ij} \text{ with respect } \xi^k) \\ &\equiv \mathbf{r}_{\xi^i \xi^k} \cdot \mathbf{r}_{\xi^j} + \mathbf{r}_{\xi^i} \cdot \mathbf{r}_{\xi^j \xi^k} \\ i = 1, 2, 3; \quad j = 1, 2, 3; \quad \text{and} \quad k = 1, 2, 3 \end{aligned} \quad (26.38)$$

Using Equation 26.12, the following statement can be obtained:

$$\mathbf{r}_{\xi^i \xi^j} \cdot \mathbf{r}_{\xi^k} = \frac{(g_{ik})_{\xi^j} - (g_{ij})_{\xi^k} + (g_{jk})_{\xi^i}}{2} \quad i = 1, 2, 3; \quad j = 1, 2, 3; \quad k = 1, 2, 3$$

The three-dimensional elliptic grid generation system presented in Eq. (26.12) can be rewritten by taking the dot product with \mathbf{r}_{ξ^q} , $q = 1, 2, 3$ as

$$\sum_{i=1}^3 \sum_{j=1}^3 g^{ij} \mathbf{r}_{\xi^i \xi^j} \cdot \mathbf{r}_{\xi^q} + \sum_{k=1}^3 \Phi_k g^{kk} \mathbf{r}_{\xi^k} \cdot \mathbf{r}_{\xi^q} = 0 \quad (26.39)$$

This can be written in terms of metric terms and their derivatives as

$$\sum_{i=1}^3 \sum_{j=1}^3 g^{ij} \frac{((g_{iq})_{\xi^j} - (g_{ij})_{\xi^q} + (g_{jq})_{\xi^i})}{2} + \sum_{k=1}^3 \Phi_k g^{kk} g_{kq} = 0 \quad q = 1, 2, 3 \quad (26.40)$$

Now

$$g_{ii} = \bar{\mathbf{r}}_{\xi^i} \cdot \bar{\mathbf{r}}_{\xi^i} = \|\bar{\mathbf{r}}_{\xi^i}\|^2$$

represents an increment of arc length on a coordinate line along which ξ^i varies and

$$g_{ij} = \bar{\mathbf{r}}_{\xi^i} \cdot \bar{\mathbf{r}}_{\xi^j} = |\bar{\mathbf{r}}_{\xi^i}| \cdot |\bar{\mathbf{r}}_{\xi^j}| \cdot \cos \theta \quad i \neq j$$

represents a measure of orthogonality between grid lines along which ξ^i and ξ^j varies. These quantities can be evaluated if the desired increment in the arc length and desired angles between grid lines are known. Looking at the precise control of spacing property of the algebraic grid [Soni 1992a, b], the quantities g_{ij} can be evaluated from the well-defined algebraic grid, and using

$$g_{ij} = (\sqrt{g_{ii}})(\sqrt{g_{jj}}) \cos \theta \quad (26.41)$$

where θ is the desired angle between ξ^i , ξ^j grid lines, the quantities g_{ij} , $i \neq j$, can be evaluated. Once all g_{ij} are known, then Eq. (26.40) can be solved for the forcing functions Φ_k , $k = 1, 2, 3$.

If orthogonality is enforced, i.e., $\theta = 90^\circ$ or $g_{ij} = 0$ for $i \neq j$, then Φ_k , $k = 1, 2, 3$, can be formulated as

$$\hat{\Phi}_k = \frac{1}{2} \frac{d}{d\xi^k} \left(\ln \frac{g_{kk}}{g_{ii} g_{jj}} \right), \quad (i, j, k) \text{ cyclic} \quad k = 1, 2, 3 \quad (26.42)$$

and

$$\Phi_k = -\frac{(g_{ii})(g_{jj})\hat{\Phi}_k}{g}, \quad (i, j, k) \text{ cyclic} \quad k = 1, 2, 3 \quad (26.43)$$

A usual practice is to utilize Equation 26.43 in the following form:

$$\Phi_k = -\frac{\mathbf{r}_{\xi^k} \cdot \mathbf{r}_{\xi^k \xi^k} \mathbf{r}_{\xi^k} \cdot \mathbf{r}_{\xi^i \xi^i} \mathbf{r}_{\xi^k} \cdot \mathbf{r}_{\xi^j \xi^j}}{|\mathbf{r}_{\xi^k}|^2 |\mathbf{r}_{\xi^i}|^2 |\mathbf{r}_{\xi^j}|^2} \quad (26.44)$$

In fact, the firm term of the definition of Φ_k provides the distribution control and the remaining two terms contribute toward the curvature control.

To understand the iterative evaluation of the control function, consider a two-dimensional elliptic system:

$$g_{22}(\mathbf{r}_{\xi\xi} - \phi\mathbf{r}_{\xi}) - 2g_{12}\mathbf{r}_{\xi\eta} + g_{11}(\mathbf{r}_{\eta\eta} - \psi\mathbf{r}_{\eta}) = 0 \quad (26.45)$$

The control functions ϕ and ψ can be formulated as

$$\Phi = -\frac{\mathbf{r}_{\xi} \cdot \mathbf{r}_{\xi\xi}}{|\mathbf{r}_{\xi}|^2} - \frac{\mathbf{r}_{\xi} \cdot \mathbf{r}_{\eta\eta}}{|\mathbf{r}_{\eta}|^2} \quad (26.46)$$

and

$$\Psi = -\frac{\mathbf{r}_{\eta} \cdot \mathbf{r}_{\eta\eta}}{|\mathbf{r}_{\eta}|^2} - \frac{\mathbf{r}_{\eta} \cdot \mathbf{r}_{\xi\xi}}{|\mathbf{r}_{\xi}|^2} \quad (26.47)$$

During the evaluation of ϕ : (1) the quantities \mathbf{r}_{ξ} and $\mathbf{r}_{\xi\xi}$ can be evaluated by utilizing appropriate finite-difference approximations, (2) the \mathbf{r}_{η} are evaluated by solving

$$\mathbf{r}_{\xi} \cdot \mathbf{r}_{\eta} = 0 \quad \text{and} \quad \|\mathbf{r}_{\xi} \times \mathbf{r}_{\eta}\| = (\Delta A) \quad (26.48)$$

where (ΔA) is the desired cell area, and (3) the $\mathbf{r}_{\eta\eta}$ quantities are calculated using the finite-difference approximation on the current grid. These quantities are updated at every iteration. Another approach is to utilize well-distributed algebraic grid characteristics to solve the following equations in order to evaluate $\mathbf{r}_{\eta\eta}$:

$$(\mathbf{r}_{\xi} \cdot \mathbf{r}_{\eta})_{\xi} = 0 \quad \text{and} \quad \|\mathbf{r}_{\xi} \times \mathbf{r}_{\eta}\|_{\xi} = (\Delta A)_{\xi} \quad (26.49)$$

and

$$(\mathbf{r}_{\xi} \cdot \mathbf{r}_{\eta})_{\eta} = 0 \quad \text{and} \quad \|\mathbf{r}_{\xi} \times \mathbf{r}_{\eta}\|_{\eta} = (\Delta A)_{\eta} \quad (26.50)$$

where $(\Delta A)_{\xi}$ and $(\Delta A)_{\eta}$ represent the change of cell area in the ξ and η directions, respectively (they can be computed using finite-difference approximation from a well-distributed algebraic grid or by utilizing desired cell areas on the boundaries). The control functions are usually evaluated on the boundaries and then interpolated in the interior. The distribution mesh can be utilized as a parametric space for doing this interpolation.

26.3.2 The Delaunay Algorithm

The algorithm widely utilized to generate the Delaunay triangulation is based upon the work of Bowyer. The algorithm is based on the in-circle criterion, and is a sequential process with each point introduced into an existing Delaunay satisfying structure, which is broken and then reconnected to form a new Delaunay triangulation [Baker 1990, George and Hermeline 1992]. The algorithm is applicable in two- and three-dimensions and in step-by-step format as follows:

Algorithm I.

1. Define a set of points which forms a convex hull within which all points will lie.
2. Introduce a new point anywhere within the convex hull.
3. Determine all vertices of the Voronoi diagram to be deleted. A point which lies within a circle (sphere), centered at a vertex of the Voronoi diagram and which passes through its three (four) forming points, results in the deletion of that vertex. This follows from the in-circle criterion of the Voronoi construction.

4. Find the forming points of all the deleted Voronoi vertices. These are the contiguous points to the new point.
5. Determine the neighboring Voronoi vertices to the deleted vertices which have not themselves been deleted.
6. Determine the forming points of the new Voronoi vertices. The forming points of new vertices must include the new point together with two (three) points which are contiguous to the new point and form an edge (face) of a neighboring Voronoi diagram data structure, overwriting the entries of the deleted vertices.
7. Repeat steps (2–6) for the next point.

In the preceding algorithm, the interpretation for three dimensions is included in parentheses. This algorithm has been used for the construction of the triangulation in two and three dimensions. It does not differ in content from that used in earlier work, but its implementation has made use of highly efficient search procedures and, hence, the computational time is considerably less than that used in earlier work.

For grid generation purposes the boundary of the domain is defined by points and associated connectivities. It will be assumed that the grid points on the boundary reflect appropriate variations in geometrical slope and curvature. Ideally any method which automatically creates points should ensure that the boundary point distribution is extended into the domain in a spatially smooth manner. An algorithm which achieves this in both two and three dimensions is the following:

Algorithm II.

1. Compute the point distribution function for each boundary point $r_0 = (x, y, z)$ (i.e., for point 0)

$$dp_0 = \frac{1}{M} \sum_{i=1}^M |r_1 - r_0|$$

where $\|$ is the Euclidean distance and it is assumed that point 0 is surrounded by M points, $i = 1, M$.

2. Generate the Delaunay triangulation of the boundary points.
3. Initialize the number of interior field points created, $N = 0$.
4. For all tetrahedra within the domain:
 - a. Define a prospective point Q to be at the centroid of the tetrahedron.
 - b. Derive the point distribution dp for the point Q , by interpolating the point distribution function from the nodes of the tetrahedron, dp_m , $m = 1, \dots, 4$.
 - c. Compute the distances d_m , $m = 1, \dots, 4$, from the prospective point, Q , to each of the four points of the tetrahedron.

If $\{d_m < \alpha dp_m\}$ for any $m = 1, \dots, 4$ then
reject the point :- Return to the beginning of step 4.

If $\{d_m > \alpha dp_m\}$ for any $m = 1, \dots, 4$ then
compute the distance s_j , ($j = 1, \dots, N$), from the prospective point Q , to other points to be inserted, P_j , $j = 1, N$.

If $\{s_j < \beta dp_m\}$ then
reject the point :- Return to the beginning of step 4.

If $\{s_j > \beta dp_m\}$ then
accept the point Q for insertion by the Delaunay triangulation algorithm and include Q in the list P_j , $j = 1, N$.
 - d. Assign the interpolated value of the point distribution function dp to the new node P_N .
 - e. Next tetrahedra.
5. If $N = 0$ go to step 7.
6. Perform the Delaunay triangulation of the derived points, P_j , $j = 1, N$. Go to step 3.
7. Smooth the mesh.

In the preceding algorithm, the term tetrahedron and triangle are interchangeable. The coefficient α controls the grid point density by changing the allowable shape of formed tetrahedra, whereas β has an influence on the regularity of the triangulation by not allowing points within a specified distance of each other to be inserted in the same sweep of the tetrahedra within the field. The effects of the parameters α and β are demonstrated in the following examples, which for convenience are presented for domains in two dimensions.

The interpolation of the boundary point distribution function is linear throughout the field. This can be modified to provide a weighting toward the boundaries so as to ensure greater point density in such regions. The implementation of such a procedure involves a scaling of the point distribution of the nodes, which form an element on the boundary. It should be noted that this point creation algorithm can be implemented very efficiently within the Delaunay triangulation procedure. In particular, if a point is accepted for insertion, then in the Delaunay algorithm a tetrahedron is known which contains this point, since by the very nature of the procedure the tetrahedron from which the point was created is known. However, after the insertion of one point the tetrahedron numbering can be changed, and if the tetrahedra formed from the inserted points overlap, then the tetrahedron numbers which have been flagged for each new point can be then incorrect. However, the exclusion zone, controlled by the parameter β , ensures that the points created from one sweep through the tetrahedra are sufficiently spatially separated that on the insertion of each point the resulting tetrahedra do not overlap and, hence, the original tetrahedron numbers associated with each new point are valid. Hence, in this way β improves the regularity of the tetrahedra and also ensures that no search is required to find a circle which includes the point.

The procedure outlined creates points consistent with the point distribution on the boundaries. Simple modifications provide greater flexibility.

26.3.2.1 Point Creation by the Use of Sources

In somewhat of an analogous way to point sources used as control functions with elliptic partial differential equations, it is possible to define line and point sources to provide grid control for unstructured meshes. Local point spacing, at position r , can be defined as

$$dp(r) = A_j e^{B_j |R_j - r|}$$

where A_j and B_j are the user specified amplification and decay parameters of the sources j , $j = 1, M$, and R_j is the position of each point source. Grid point creation is then performed as outlined in Algorithm II but in step 4b the appropriate point distribution function at the centroid is determined by Equation 26.2. Various forms of implementation of this can be devised. One simple modification is to define the point spacing as

$$dp(r) = \min \left(dp_{\text{boundary}}, A_j e^{B_j |R_j - r|} \right)$$

In this case dp_{boundary} is the point distribution from the boundary spacing. This then provides the desired point clustering in regions influenced by the sources but farther away the boundary point distribution has a dominant effect.

26.3.2.2 Point Creation Controlled by a Background Mesh

Another way to control the point spacing in the domain is to use a background mesh. A mesh is overlaid over the domain and at each node a point spacing is specified. To encompass this approach within the framework of Algorithm II, the point distribution function dp for a prospective point is obtained from the interpolated spacing from the background mesh. Within Algorithm II step 4b is replaced by the interpolation of dp from the background mesh. The effect is similar to that achieved by sources.

26.3.2.3 Boundary Integrity

This problem is widely recognized as a problem inherent to the generation of boundary conforming grids using the Delaunay triangulation. Several approaches to its solution have been proposed. The procedure

followed here is an extension of earlier work and is closely related to the work of George. Both these approaches involve the addition of points to *block* the penetration of tetrahedra through the boundary surface. In the former approach, points were added on the boundary, which were then connected to the surrounding points using the Delaunay triangulation procedure. In two dimensions and in some cases in three dimensions, this approach proves to be adequate. Hence, the approach used in two dimensions uses this technique. However, in three dimensions, for some severe cases, it proves to be difficult to completely ensure the reconstruction of surface triangles. Hence, a different approach has been devised for three dimensions, which also involves the addition of points, but these are connected directly to the tetrahedral construction rather than using the Delaunay triangulation. A finite number of direct connections can be formulated for all types of tetrahedral penetration and hence in the proposed procedure the recovery of the surface can be guaranteed.

The necessary and sufficient conditions for a face with nodes (P, Q, R) to be present in the triangulation $\{\tau_l\}, l = 1, T$ are as follows:

1. The nodes $P, Q,$ and R exist in the tetrahedral construction $\{\tau_l\}, l = 1, T$.
2. The cyclic combinations of $P, Q,$ and R that is, PQ, QR, RP occur in one of the tetrahedra in the construction $\{\tau_l\}, l = 1, T$.
3. The combination (P, Q, R) exists in one of the tetrahedra in $\{\tau_l\}, l = 1, T$.

Hence, to recover an arbitrary set of triangular faces, these three conditions must be met for each face. The first condition appears to be self-evident.

If a boundary face is not in τ , this is because edges and faces of the tetrahedra $\{\tau\}$ intersect the required face. Since a face is formed from edges, and it is assumed that the points P, Q and R are present, it is necessary to firstly recover edges PQ, QR, RP and then the face (P, Q, R) . This is achieved, for a given face PQR , by firstly finding the tetrahedra which are intersected by the edges $PQ, QR,$ and RP . These tetrahedra are then modified and new tetrahedra created so that the required edges are present. Once edges are present, a similar procedure follows to recover the face. If the edges $PQ, QR,$ and RP exist but the face (P, Q, R) does not exist, then all tetrahedra which possess at least one edge which intersects the face (P, Q, R) are determined. These tetrahedra are then modified accordingly to recover the missing faces.

26.3.2.4 Edge Swapping

In circumstances where it is required to have a complete surface, although there is not a fixed constraint that a given set of faces is recovered, it is possible to ensure boundary faces are coincident with faces within the tetrahedral construction by swapping edges within the boundary surface triangulation. If in the tetrahedral construction faces ABC and BCD exist, but in the surface triangulation faces ACD and ABD exist, then the two can be made to agree if in the surface triangulation edge AD is replaced by BC . There are conditions under which such a transformation is not allowed and these must be checked.

Edge swapping can be incorporated as an option. However, if it can be used, it can greatly reduce the amount of work to be carried out in the edge and face recovery routines.

26.3.2.5 Boundary Edge Recovery

The procedure to recover a missing edge of a boundary face involves two steps. First, it is necessary to identify the faces, edges, and points of tetrahedra which the edge intersects. Second, local transformations involving tetrahedra are performed to recover the edge. The intersections of edges with tetrahedra can be readily computed. Once this has been performed, a set of transformations are used to recover edges.

26.3.2.6 Boundary Face Recovery

After the recovery of all boundary face edges, the boundary faces can then be recovered. Clearly, although the edges of all boundary faces are present, this does not imply that boundary faces are present, since other

FIGURE 26.9 Volume grid of Ford Explorer.

FIGURE 26.10 Surface grid of Ford Explorer interior.

tetrahedra can penetrate the interior of a face but not the boundary face edges. If a boundary face is not present, it is necessary to determine all tetrahedra which intersect the face. One, two, three, or four edges and associated segments of a tetrahedra can intersect a face. Hence, for each missing face, all tetrahedra which have an edge or edges which intersect the face are determined and each of the tetrahedra are then classified accordingly.

26.3.2.7 Removal of Added Points

Most of the transformations used to recover the edges and faces in both 2-D and 3-D grids involve the creation of one or more points. These added surface points are used purely as part of the boundary recovery procedure and are removed after the boundary is complete. The mechanics of node removal involve taking each added point in turn and finding all elements connected to it. These elements are deleted leaving an empty polyhedron, which is then triangulated in a direct manner by finding point connections which lead to the optimum-shaped tetrahedral construction. This is a rapid process since this operation is performed locally for a relatively small number of points. A pictorial view of an unstructured grid for automotive application is presented in Figure 26.9 and Figure 26.10. The grid is generated by advancing front local reconnection algorithm [Marcum 1995].

26.3.3 Hybrid Grid Generation

A hybrid grid consists of structured grid in part of the physical domain and unstructured grid in rest of the field. In general, a hybrid grid can be defined as an agglomeration of cells having polygons with a different number of sides. This necessitates a hybrid grid generation process as a combination of structured and unstructured grid methodologies. The truncation error of a triangular cell is inversely proportional to

FIGURE 26.11 Hybrid grid around a launch vehicle with boosters: (a) grid at an initial state and (b) grid after booster separation.

the sine of the minimum angle of the triangle. Therefore, to reduce the truncation error the number of triangles in the boundary layer has to increase and, consequently, it will increase the total number of cells in the field. This will lead to more memory and central processing unit (CPU) time for the flow solver. The structured grid in the boundary layer will help to overcome these difficulties.

The basic steps involved in hybrid grid generation are the following. The first step is to decompose the complex geometries into simple geometric entities. A structured grid is generated around these geometric entities using an advancing layer-type method based on the surface normals together with the application of a local elliptic solver [Koomullil et al. 1996a]. The second step involves the trimming of the overlapping structured grid from different solid bodies in the domain, by comparing the aspect ratio. Cells having aspect ratio less than unity are removed. In the third step the void in the physical domain after the trimming of the structured grid is filled with unstructured grid.

The hybrid grid for dynamic motion-type geometries can be generated quickly and efficiently using the approach present in Koomullil et al. [1996a]. An example of a hybrid grid for the moving geometry problem is illustrated in Figure 26.11. The strap-on separation from the main launch vehicle booster is shown in this figure. The relative position of the strap-ons and booster rockets at different times and the hybrid grid around this configuration is shown in Figures 26.11a and b.

26.3.3.1 Grid Adaption: Construction of Weight Functions

Application of the equidistribution law results in grid spacing inversely proportional to the weight function, and hence, the weight function determines the grid point distribution. Ideally, the weight would be the local truncation error ensuring a uniform distribution of error. Determination of this function is one of the most challenging areas of adaptive grid generation. The overall solution is only as accurate as the least accurate region. Thus, excessive resolution in certain regions does not increase the accuracy of the overall solution.

Evaluation of higher order derivatives from discrete data is progressively less accurate and subject to noise. However, lower order derivatives must be nonzero in regions of wide variations of higher order derivatives, and are proportional to the rate of variation. Therefore, it is possible to employ lower order derivatives as a proxy for the truncation error.

Analysis of the weight functions explored to date indicates that density or velocity derivatives are not independently sufficient to represent the different types and strengths of flow features. Density, or pressure for that manner, varies insufficiently in the boundary layer to be used to construct weight functions for representation of these features. Whereas velocity derivatives for viscous flows by themselves are dominated by the boundary layer, additional variables must be included to represent other flow features. The weight

function [Thornburg et al. 1996] consists of relative derivatives of density and the three conservative velocities,

$$W_{ijk}^k = 1.0 + \frac{|\hat{q}_{ijk}|}{|\hat{q}_{ijk} + e|_{\max}} + \frac{|(\hat{q}_{\xi^k})_{ijk}/\hat{q}_{ijk}|}{|(\hat{q}_{\xi^k})_{ijk}/\hat{q}_{ijk} + e|_{\max}} + \frac{|(\hat{q}_{\xi^k \xi^k})_{ijk}/\hat{q}_{ijk}|}{|(\hat{q}_{\xi^k \xi^k})_{ijk}/\hat{q}_{ijk} + e|_{\max}}$$

where $\hat{q} = (\rho, \rho u, \rho v, \rho w)$. The relative derivatives are necessary to detect features of varying intensity, so that weaker, but important structures such as vortices are accurately reflected in the weight function. One-sided differences are used at boundaries, and no-slip boundaries require special treatment since the velocity is zero. This case is handled in the same manner as zero velocity regions in the field. A small value, epsilon in the preceding equation, is added to all normalizing quantities. Also it appears that the Boolean sum construction method of Thornburg et al. [1998] would balance the weight functions more evenly, as several features are reflected in multiple variables, whereas some are reflected in only one.

26.4 Grid Systems

A multitude of general purpose grid generation codes to address complex three-dimensional structured–unstructured grid generation needs are newly available in the public domain or as proprietary commercial code. A brief description of the widely utilized candidate general-purpose codes follows.

The National Grid Project (NGP) system of Mississippi State University is an interactive geometry and grid generation system for block-structured and tetrahedral grids. The system reads CAD data via IGES and converts all surface patches to NURBS. A carpet, composed of interfacing NURBS patches, is then laid over the CAD patches to correct for gaps and overlaps. The system also has internal CAD capability for the construction or repair of surfaces. Surface grids are generated on the NURBS carpet, and can be projected onto the original CAD patches. Both the surface grids and the subsequent volume grid can be generated as block structured via elliptic, hyperbolic, or TFI methods, or as unstructured via Delaunay or advancing front procedure. A pictorial view demonstrating the graphical interface is displayed in Figure 26.12.

The ICEM–CFD [Akdag and Wulf 1992] system is a commercial code which offers block-structured grids, tetrahedral grids, and unstructured hexahedral grids. The system interfaces with numerous CAD systems and has been connected to a number of flow solvers.

The GRIDGEN [Steinbrenner and Chawner 1993] system is a graphically interactive block-structured commercial code. The user constructs curves, which are in turn used to build the topological surface and

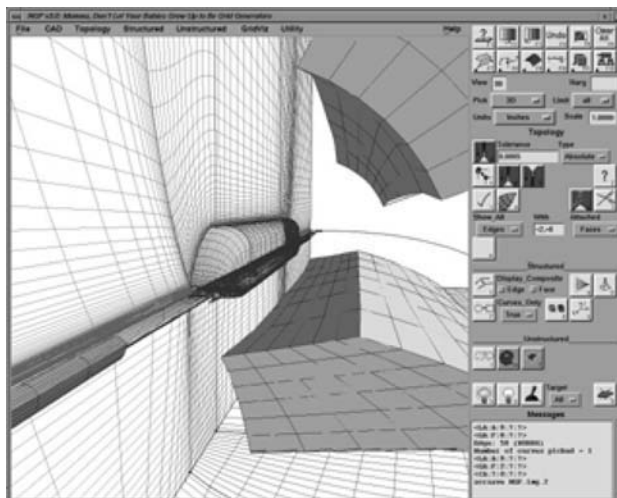

FIGURE 26.12 NGP code interface demonstrating multiblock grid.

volume components. The user then selects curves as the boundaries of surface grids, and finally surfaces as the boundaries of volume grids (blocks). With this system, grid generation is a user-in-the-loop task.

EAGLEView [Soni et al. 1992] is a graphical system that allows interactive construction of geometry and block-structured grids with journaling capability.

GridPro/az3000 [Eiseman 1995] is a commercial block-structured code topology input language (TIL) to define both the surface and the block-structured grid. The language includes components (objects) that can be invoked, and therefore admits the formation of element libraries.

CFD-GEOM [Hufford et al. 1995] is an interactive geometric modeling and grid generation system for block structured grids, tetrahedral (advancing front) grids, and hybrid grids. All elements are linked so that updates are propagated throughout the database. The geometry is NURBS based, reads IGES files, and has some internal CAD capabilities. The system also has macrolibrary capability.

The GEMS [Dener et al. 1994] block-structured grid generation system of SAMTEK-ITC in Turkey is based on object-oriented programming and C++ that uses case-based reasoning and reinforcement learning to capture CFD expertise. The system selects the case that is best suited for a particular geometry from among known ones.

The 3-DGRAPE/AL [Sorenson and Alta 1995] system of NASA Ames is a block-structured grid generator that now includes the specification of arbitrary intersection angles at boundary surfaces, as well as the orthogonality pioneered by Steger–Sorenson.

The GENIE++ [Soni et al. 1992] block-structured grid generation system of Mississippi State was also introduced in the late 1980s and has been continually enhanced over the years. This system uses TFI with elliptic smoothing and includes various splining methods.

VGRID [Parikh and Pirzadeh 1992] of NASA Langley is a tetrahedral grid generator which uses advancing front with a Cartesian background grid to control resolution.

TGrid of Fluent is a tetrahedral grid generator based on the Delaunay approach.

The first general-purpose-domain connectivity codes for chimera grids were the PEGSUS (from the Air Force Arnold Engineering Development Center) and CMPGRD (from IBM) codes in the late 1980s [Meakin 1995], which continue to be enhanced. Advances in CMPGRD are detailed in Henshaw et al. [1992]. Later codes are DCF3D of NASA Ames and Overset Methods (MEAKIN 1991) and BEGGAR of the Air Force Wright Laboratory at Eglin [Belk 1995, Maple and Belk 1994]. A detailed description of these codes and a comprehensive review of existing codes and technology can be found in Thompson [1996].

26.5 Research Issues and Summary

The first step of the CFS process is the construction of a discrete approximation of the general region of interest. This representation could be multiblock structured, unstructured, or hybrid. Only for the simplest of applications can a grid be generated quickly or easily. In fact, geometry-grid generation is by far the most time consuming aspect of the entire CFS process. Rapid turnaround, reliable accuracy, and affordability are the three key requirements to be addressed for CFS to play its rightful role in supporting multidisciplinary design environment. To this end, industry is targeting grid generation in 1 h for complex configuration, i.e., reliable 1-h grid generation turnaround for one-time geometries when run by designers. The system must include CAD-to-grid links, which resolve tolerance issues and produce grids with a quality good enough for the CFS solver. The designer has to feel that the grid generation process is under control and is predictable. The following critical barriers must be overcome to fulfill the aforesaid industrial requirements.

The time-consuming aspects of grid generation are usually related to the geometry definition, i.e., the input of the geometry information into the grid system. Today, trimming the surfaces associated with their intersection is a significant barrier. The trimmed surfaces are a widely utilized entity in the construction of complex geometrical configurations in CAD/CAM systems. Algorithms which utilize surface triangulation techniques and solid modeling schemes need to be developed. Reliable methodologies for representing triangulated surfaces into a single surface represented by the NURBS are needed. The

CAD/CAM technology and methodology evolution based on solid modeling will also reduce this present barrier of addressing geometries undergoing design perturbations.

Automatic (noninteractive) algorithms for domain decomposition for the development of multiblock structured grids pose a barrier for addressing multidisciplinary design applications involving geometry optimization. The solution grid adaptive algorithms, at present, are limited to simple three-dimensional configurations. Techniques are needed to enhance the applicability of adaptive schemes pertaining to complex configurations. Parallel and distributed processing of grid generation algorithms is also essential for these multidisciplinary applications. Algorithms need to be developed to improve the quality of unstructured surface grids since they highly influence the quality of unstructured volume grids. Hybrid-generalized grid techniques are promising, especially for multidisciplinary CFS applications that include dynamic motion. This technology does not exist for full three-dimensional configurations.

Further Information

For complete in-depth literature on grid generation, the reader is referred to Thompson et al. [1985] and five proceedings associated with the 1985, 1988, 1992, 1994, and 1996 International Conferences on Numerical Grid Generation in Computational Fluid Dynamics and Related Areas. (The first four proceedings were published by Pineridge Press and the fifth conference proceedings was published by the Engineering Research Center at Mississippi State University.) The literature on surface grid generation and practical applications can also be found in the NASA conference *Proceedings on Surface Modeling, Grid Generation, and Related Issues in Computational Fluid Dynamics Solutions* of 1992 and 1995.

In view of the importance of and worldwide interest in grid generation, the organizing committee of the 5th International Conference has proposed an establishment of the International Society of Grid Generation (ISGG). The ISGG will be a focal point for assimilating the progress and advances realized in grid generation by publishing a quarterly electronic journal of grid generation and a newsletter and by maintaining a grid generation Internet index to the grid generation literature, researchers, test cases, and information on public domain and commercial geometry-grid systems. The ISGG can also be the focal point for organizing future grid generation related workshops and conferences. The organization committee feels that the time is right for the emergence of a formal society and journal for grid generation. Additional information on the ISGG can be obtained from Bharat Soni, NSF Engineering Research Center, Mississippi State University, by e-mailing: bsoni@erc.msstate.edu.

27.5 Research Issues and Summary

27.1 Introduction

The field of scientific visualization is broad and requires technical knowledge and an understanding of many communication issues. This chapter provides information about its evolution, its uses in computational science, and the creative process involved. Also included are descriptions of various software tools currently available and examples of work which illustrate various visualization techniques. Relevant concerns, such as visual perception, representation, audience communication, and information design, are discussed throughout the chapter and are referenced for further investigation. An overview of current research efforts provides insight into the future directions of this field.

27.2 Historic Overview

Visualization did not begin after the advent of computers. There has always been a need for people to visualize information. At the dawn of human history, humans began spreading pigment on surfaces to convey events that took place and later to indicate quantities of goods. From that time on, the medium of choice for representing such information has continued to evolve ([Figure 27.1](#)).

In general, visualization efforts required that the creators of the image represent their data by hand. Often this was a painstaking process that involved an artistic ability to mentally envision a pictorial representation of a phenomenon and the manual skills required to transpose the mental image into a suitable medium.

FIGURE 27.1 A combination of scientific representations from the fifteenth century and today demonstrates that the craft of visualization has been practiced for many years. (Courtesy of U. Tiede, T. Schiemann, and K. H. Hohné, IMDM, University of Hamburg, Germany, 1996.)

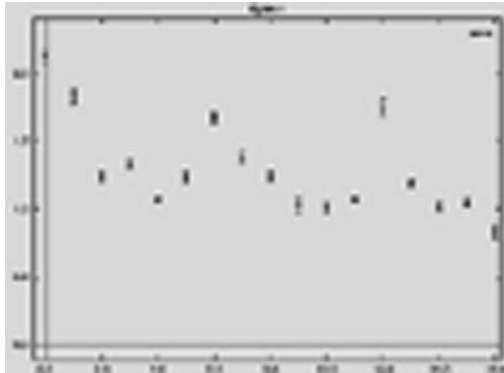

FIGURE 27.2 An XY plot with error bars.

The researcher had to be a capable artist and craftsman as well as a scientist. Usually, the visualizer would render the representation onto paper. However, other media for visualization were used as well.

As the scientific method developed, certain forms of visualization became accepted practices. As a scientist observed a phenomenon, it could be recorded onto an XY plot, representing the relationship between two quantities. A line was often drawn through the data to show the probable continuous pattern. Error bars were added to represent uncertainty in the data (Figure 27.2). We can now render detailed, data-based visual images by machine to show both quantitative relationships and qualitative overviews. How this process is accomplished, and its value to the scientific method, demand investigation.

27.2.1 The Motivation for Computer-Generated Visualization

The advent of the digital computer brought about the ability to collect, create, and store more information than previously. It also brought about a new method of science: *computational* [Kaufmann and Smarr 1993].

Computational science is the process of simulating a relevant subset of the laws of nature using a supercomputer. The laws of nature are described by a set of equations, which yield numeric solutions regarding the science being studied. Because these computational simulations of nature produce vast

amounts of numeric information, a scientist may not be able to see, much less interpret, all the results. Fortunately, as the computational power of computers has increased, allowing these complex simulations to be calculated, so has the graphical power of computers increased. Thus, we also have access to a medium capable of creating and presenting all this information in a way useful to the researcher.

There are tradeoffs in how numeric information can be visualized. Interactive visualization gives the researcher the ability to control specific portions of the dataset to examine and to control the type and parameters of the visual output. Interactivity, though, may limit the percentage of the data that can be examined at a given moment and limit the types of representation available. Alternatively, the data display may be created as a batch process, allowing complex representations which are not possible in real time. The researcher may take advantage of both methods by beginning with interactive exploration and, when an interesting region of the data is located, producing a detailed animation.

Another consideration when creating visualization is whether to render a view of the entire dataset (a qualitative overview) or to precisely represent a subset of the data that the scientist can analyze (a quantitative study). Both are important in computational science. The qualitative overview can give the scientist a sense of the entire simulation, which can help in comparisons with observed nature. Because it gives an overall understanding of the dataset, it provides a sense of context when looking at the details.

The details are in the quantitative representation provided by a precise mathematical description. Qualitative information is helpful to this process, but high-resolution quantitative displays are essential. Representations such as contour plots and two-dimensional (2-D) vector diagrams are precise and aid in data analysis. Quantitative representations, such as these, provide the ability to pore over a particular subset of the data, even to the point of measuring phenomenon from the display. Because there is a limit to the amount of useful information that can be rendered on a screen, focusing on a subset allows the data to be more completely displayed.

27.2.2 The Process of Computational Science in Relation to Visualization

To understand the role of scientific visualization in the computational science process, we must first review the scientific process itself. Figure 27.3 depicts the steps involved in the computational science process [Arrott and Latta 1992]. Computational science begins with observations of some natural phenomenon,

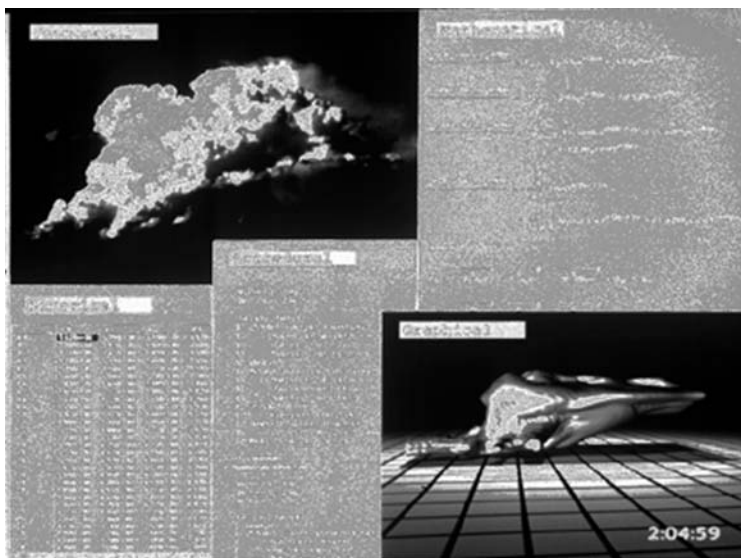

FIGURE 27.3 Computational science consists of observations, equations, algorithms, numerical solutions, and graphical representations. (Courtesy of Matthew Arrott; NCSA.)

in this particular case the formation of a severe thunderstorm. The scientist then expresses the observations in mathematics — the language of science. These equations can be manipulated by the researcher, though the problems are generally of a complexity sufficient to require solution on a supercomputer. In today's computing environment, the mathematical representation of the phenomenon is not a suitable means of input to typical computing systems. The computer requires the phenomenon be simulated in discrete steps of space and time, whereas mathematics allows a continuous representation. The mathematical representation is therefore translated into a programming language, implementing appropriate algorithms for a discrete numerical solution.

The resultant solution is typically a numeric value or set of values — a **dataset**. While the scientist may be able to gain insight from these numeric representations, a more intuitive visual form often aids in understanding. Also, others are often much more likely to understand the scientist's work when it is presented visually than as numbers only.

27.2.3 What Exactly Is Scientific Visualization?

Although we have previously discussed methods by which scientific data were represented before the advent of computers, for our purposes, **scientific visualization** is the use of data-driven computer graphics to aid in the understanding of scientific information. We will refer to an artist's rendering of a concept as illustration, or more specifically **scientific illustration**.

Is scientific visualization just computer graphics, then? Computer graphics is the medium in which modern visualization is practiced; however, visualization is more than simply computer graphics. Visualization uses graphics as the tool to represent data and concepts from computer simulations and collected data. Visualization is actually the process of selecting and combining representations and packaging this information in understandable presentations.

27.2.4 Other Modes of Presenting Information

There are ways to present information other than visually, of course. The primary of these is aurally, but one also might imagine the use of haptic (force, texture, temperature, etc.) display [Brooks et al. 1990], or even display to our other senses. Currently, sound (sonification) is increasingly recognized as an important method of information display for special types of data [Scaletti and Craig 1991].

Perhaps the field of representing information would be more appropriately termed **perceptualization**. The goal is, after all, to increase the information observer's perception of what is taking place in the data.

27.2.5 Application Areas

The use of scientific visualization to represent data is as broad as science itself. It spans the range of scales from the atomic and subatomic worlds to the vastness of the universe. It encompasses the study of complicated molecules and the building of complicated machinery. It looks at dynamic systems of living creatures and at the dynamics of whole ecosystems. Each of the areas touched by scientific visualization has representations that are particular to itself. Yet, there is much overlap in the techniques used by visualization developers due to commonality in the underlying mathematical expressions of natural systems.

Often a variety of what would seem unrelated sciences share similar or identical computational techniques. For example, computational fluid dynamics is used to study atmospheric effects, ocean currents, cosmology, mixing, injection molding, blood flow, and aeronautics. Finite-element analysis is used for solid and structural mechanics, fracture mechanics, crash-worthiness, heat transfer, electromagnetic fields, soil mechanics, metal forming, etc. Beyond these, there are many other fields that benefit from similar computational algorithms, including molecular modeling, population dynamics, diffusion, wave theory, and n -body problems.

27.2.6 Evolution of Scientific Visualization

The representation of the numeric output of simulations has developed from the simple printing of characters on paper, to vector display and plotter graphics, to three-dimensional (3-D) static images, to animated 2-D and then 3-D renderings of a simulation over time. The level of interaction has increased from the creation of visualization animations in batch mode, to real-time viewpoint control of fixed geometries, to interactive rendering allowing modification of the simulation in real time, and now to interacting with the simulation and representations in an immersive virtual environment.

As the underlying tools have improved, so have the idioms for representing information. New idioms are developed, and old ones are used in new ways. Many advances in representation are able to occur because of the advance of computing power and of computer input and output enhancements. Faster computing means more graphical computations can be done to create images, and higher-resolution displays allow for more detail to be presented.

These advances bring higher expectations. When 3-D pictures, animated 2-D pictures, and then finely rendered 3-D animations were first used by researchers to present their work, the visualization might have been considered the highlight of the presentation rather than the underlying science. The broader the audience, the more likely for this to be the case, giving rise to a situation where the scientists' credibility to the audience may be more correlated with the beauty of their images than with the underlying scientific theory. If scientists do not use the latest methods of computer graphics and animation to present their work, then it may not receive the attention it deserves. We are not arguing that this is how it *should* work, but it is important for scientists to be aware of the impact that visualization has on the communication of their research.

27.3 Underlying Principles

In this section, we will look at the various reasons for using scientific visualization and the effect they have on how a visualization is produced. We will also examine the basic concepts of visualization production and some of the considerations a producer should think about. Why are these important? Because scientific visualization is a means of communication. Sometimes the communication is between the raw numeric data and the researcher, and sometimes it is between the researcher and a group of people. Either way, for effective communication, it is important that both the producer of the visuals (or the tools used to create the visuals) and the audience have a grasp on what happens to the information as it passes from numbers to pictures.

27.3.1 The Goal of Scientific Visualization

Recall that the reason scientific visualization is employed as a tool is to more readily gain insight into a natural process. There are other similar goals that may be accomplished with scientific visualization. For instance, the goal might be to demonstrate a scientific concept to others, in which case the medium, representation, and the degree of detail chosen vary with the audience. A presentation shown to other scientists in the field will differ widely from one shown to the public or to government bodies.

The amount and the level of explanation required in a visualization is based on the experience of the intended audience. Also, design choices should be made which determine the amount of interactivity possible for wider audiences. For example, presentations designed for a mass audience are typically designed as noninteractive video animations. Alternatively, by utilizing computer delivered media, such as CD-ROMs, or multimedia presentations over the Internet, a limited dataset can be presented with a limited selection of visualization options, allowing for some experimentation by the audience.

When the audience is only the individual scientist, the primary goal is to uncover patterns in the data. Still, the goals of the study can vary. The goal might be to compare the patterns in the simulated data with patterns observed in nature. The closer these patterns match, the more confidence the scientist has in the theory expressed in the computational algorithm. Or the goal might be to discover new patterns that

give clues to a better mathematical expression of the process. This is more frequently the case when the process is less well understood and the data are collected rather than simulated. For example, in analysis of the stock market, researchers might look for patterns that give rise to the ability to determine profitable opportunities.

27.3.2 The Basic Steps of the Scientific Visualization Process

Though it is possible to jump right into using visualization as a tool, there are several important steps that occur in the process of creating an effective visualization. At one level, scientific visualization can be thought of analytically as simply a transfer function between numbers and images, bearing in mind that this transfer may be irreversible and cause distortion of meaning.

At another level, visualization involves a barrage of procedures, each of which influences the final outcome and its ability to convey meaningful information. That is, the process of visualization includes consideration for data filtering, representation, potential inaccuracy, and human perception.

27.3.2.1 Data Filtering

Seldom is it possible to make pictures straight from the data source (a computational simulation or data acquisition system). Typically, work needs to be done on the data before they can be appropriately visualized. This can include cleaning up the data and performing operations on them that yield more useful data. Examples of cleaning up data are removing noise, replacing missing values, clamping values to be within the range of interest, etc. New numeric forms of the data often are derived in order to produce a dataset which will lead to greater insight. For example, the vertical vorticity of a fluid flow can be calculated from the horizontal wind velocity.

The medium of presentation may also be the cause of data filtering. From a practical point of view, it is often necessary to adjust the data so that they can be conveniently produced within the constraints of a particular medium. For example, a standard NTSC video device displays at a rate of 30 frames per second. Thus, the dataset must be adjusted to produce 30 images for each second of the animation. This is done by interpolating the data over time. To fill spatial gaps in the visual imagery, interpolation is also frequently done over space.

No matter what the medium, whenever any form of interpolation or other data-filtering operation is used, there are problems that can arise which may cause the imagery to be misleading to viewers who don't know or understand what has happened to the data.

27.3.2.2 Representation Issues

As noted at the beginning of this chapter, computational science involves choosing appropriate representations of the phenomenon being studied (e.g., numeric, mathematical, etc.). The representations of the data appropriate for computer manipulation are not necessarily the most conducive to human understanding. Representing numeric data so that they can be more readily perceived by the audience involves mapping those numbers to a geometric form, sonic waves, etc.

Visual representation of information requires a certain literacy on the part of the developer and the viewer [Keates 1996]. Minimal information will be communicated if the viewer is not able to understand the visual language the developer has chosen. The language elements (symbols) of visualization come primarily from the adoption and evolution of symbols used in other visual domains, particularly scientific illustration. When new symbols are created, care must be taken to ensure that adequate explanation is given.

Beyond representing the numerical output of the simulation, it is desirable to indicate information about the simulation itself. This includes items such as a representation of the grid of the computational domain, the coordinate system, scale information, and the resolution of the computation.

When choosing which representational idiom to use, it is important to consider several issues before coming to a decision. What type of information is being investigated? Is the primary goal to convey quantitative or qualitative information? How detailed should the representations be? Making these determinations

depends to a great extent on the characteristics of the audience for which the visualization is intended. The resolution of the display affects the ability to present quantitative information and thus is a factor in which idioms can be chosen.

The goal of the visualization limits the medium of delivery. The medium, in turn, puts constraints on the possible choice of representation and interaction. So, for example, if motion is important to show some aspect of the data, then a medium that can support time-varying imagery needs to be used (e.g., film, videotape, interactive computer graphics). If the delivery medium is constrained to be a single image, then one must find a means to represent motion statically.

The ability to communicate with the audience relies on a well-designed presentation of information. A common problem is to give equal visual importance to all the elements in a scene, making it difficult to comprehend. We can learn techniques for making effective imagery from experts in information presentation such as graphic designers and instructional designers.

27.3.2.3 Accuracy

It is good practice for scientists to question the accuracy and validity of any information they are presented. All too often, compelling visualizations are used without the audience really questioning what they are seeing. Today, visualizations sometimes accompany peer-reviewed publications without being subjected to the same critical examination as the paper.

Where does inaccuracy come from, and what forms does it take? Whenever data change representation, the possibility for the introduction of error exists. Illusions are a danger in any medium. This is especially true when representing three-dimensional imagery on a two-dimensional display. For example, parallax can lead to misreading sizes of objects. The bias of the visualization producer often can affect the accuracy of the presentation. This does not necessarily imply that they might deliberately misrepresent the information, but many of the choices made during the production can add up to a presentation that gives an inaccurate view of the results. Some of these might include the choice of which representation to focus on, and which to leave in the background, or the selection of viewpoint or color and lighting that can make objects look ominous or insignificant.

High production values often lead to a sense of quality. The quality of the imagery does not necessarily reflect the quality of the underlying science or representations. The computer graphics techniques used should not get more emphasis than the science (i.e., should not have “glitz” merely for its own sake). Adding glitz can make a visualization appealing but can also occlude the important elements of the presentation. High production values and accuracy are two separate factors and should not be confused. The overuse of glitz in visualization is satirically treated in the animation *The Dangers of Glitziness and Other Visualization Faux Pas* (Figure 27.4) [Lytle 1993].

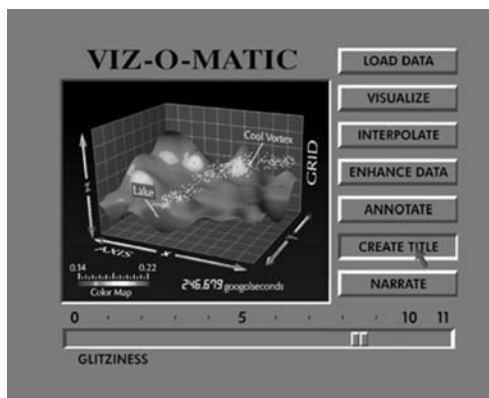

FIGURE 27.4 The Viz-o-matic animation pokes fun at the tendency to overuse graphic elements at the expense of accurate portrayal of the data. (Courtesy of Wayne Lytle; CTC.)

Labels can be used in any visualization, both as a tool for showing features of the visual representations and as a means to help clarify potentially confusing or unclear items. By adding labels, the viewer can be shown the size of the domain, the range of the values, the coarseness of the simulation, etc. Labels make the visualization more clear, understandable, and, therefore, a more useful means of communication.

27.3.2.4 Human Perception

One filter that will always have an effect on how data are viewed is the human perceptual system [Weintraub and Walker 1969]. Our perception of the world does not exactly match with physical reality. In fact, there are many elements of the real world that we cannot directly perceive at all. For example, human vision covers only a small range of the electromagnetic spectrum; human hearing perceives only air pressure changes within a specific range of frequencies; human olfactory nerves have limited precision and no real ability to determine directionality of smells. Each sense has its own perceptual anomalies.

It is likely that some animals are able to perceive phenomena that humans cannot consciously perceive. For example, many species of birds can sense the earth's magnetic field and use it as a navigational aid (magnetoperception). Fortunately, we are able to use instruments that can sense elements of the physical world that we are unable to sense. These instruments then translate the sensory input into a display that humans are able to interpret. Visualization often involves the mapping of information from imperceptible forms to something we can interpret and analyze.

The field of *human factors* studied the relationship between people and machines and has a deep body of research to draw upon. It will be beneficial for anyone creating visualizations to familiarize themselves with the work of this field [Wickens et al. 1994].

All human perception, however, suffers from the additional problem that each of our brains interprets the incoming signals differently. Our experiences through life have trained our perceptual systems uniquely. Many biases are fairly consistent throughout a culture because the individuals within that culture will have had many similar experiences. Symbols in a culture lead to an understanding of what lies ahead or within; a skull and crossbones has a specific meaning in western culture, as does a railroad crossing sign. Colors are also culturally biased. Red can mean danger or stop; yellow, caution; and green, go. But for some, green also implies money or envy. In science, colors often are used to represent a scale of information, but this might not be understood by the rest of the culture. Which colors should represent high and low values, and which should signify the interesting data?

It is important to take human perceptual biases into account when designing an information display, but one also must recognize that these biases are not necessarily universal. Thus, a scale or legend should always be used to illustrate how information is being mapped.

27.4 The Practice of Scientific Visualization

In this section, we examine the process and visual components of visualization, we discuss several types of tools available for producing visualization, and we look at examples of how visualization has been applied to particular sciences and evolved over the course of several years.

27.4.1 Representation Techniques

One of the most important elements in creating scientific visualizations is the choice of visual representation, or **visual idioms**. This section surveys a variety of commonly used visual idioms, each of which is appropriate in different situations. The visual representation is created by combining the elements of form, color, and motion that together show features of the data. This representation can range from very realistic renderings of real physical objects to abstract glyphs used to combine many pieces of information in a single idiom.

The traditional forms of data display should not be dismissed. Quantitative data can readily be retrieved from such representations as the *XY* plot, the contour map, and the bar chart (Figure 27.5).

FIGURE 27.5 Simple 2-D graph representations convey both quantitative and qualitative information.

FIGURE 27.6 A realistic graphic representation of a front-end loader rendered from CAD data. (Courtesy of Caterpillar; Mark Bajuk; NCSA.)

27.4.1.1 Realism Continuum

Accurate representation of information does not necessitate that the display be realistic. Information can be represented in a very abstract form, and its contents can be read accurately by someone that knows what the form symbolizes. Sometimes it is useful, though not always possible, to show a realistic representation of what the data symbolize, as in many architectural visualizations and prototype designs (Figure 27.6).

In contrast, it is often more useful to create an abstract representation. This is especially true when there is not a direct physical counterpart to the concept being displayed. This is a convenient way of representing many variables simultaneously. The drawback with using very abstract representational schemes is that it takes time for the viewer to learn and become fluent with the symbols. In Figure 27.7, symbols (or glyphs) represent different aspects of current weather conditions.

27.4.1.2 Color

Color adds to the appeal of a visualization. More importantly, color is used to convey information about data. Some fields, including atmospheric sciences, chemistry, and seismic analysis, have developed common conventions about color use within their application areas. Colors must be chosen carefully, with a view to the goal of the visual analysis. For example, visual displays often are used to identify the quantitative value at a point. Color can be used for this task by assigning colors to specific data values. The number of colors should be limited to about seven, and the colors should be easily distinguished from each other. Alternatively, the visualization task might be to determine the overall structure of the data slice, so that a color map that is continuously varying can be more effective.

Figure 27.8 shows the use of a variety of color palettes to color the same 2-D slice of data. The top two color maps use a wide range of hues — these are variations of a “rainbow” palette. These color maps

FIGURE 27.7 Weather maps often include an abstract symbol which depicts wind speed and direction, cloud coverage, etc.

FIGURE 27.8 (See Plate 27.8 in the color insert following page 29-22.) A variety of color palettes used to color the the same two-dimensional slice of data. The top two color maps use a wide range of hues and introduce discontinuities into the image that may not be present in the data. If we are looking for overall structure, a smoothly changing palette with a restricted hue - such as the “fire” palette shown in the lower right - is more appropriate. (Courtesy of NCSA, Yale University.)

introduce discontinuities into the image that may not be present in the data. For example, the edge from yellow to green or yellow to red suggests a distinct change in the data, which may or may not be there. The distinct bands may be useful if we’re trying to isolate all the data values within a particular range. However, if we’re looking for overall structure, a smoothly changing palette with a restricted hue, such as the “fire” palette shown in the lower right, is more appropriate.

27.4.1.3 Form

27.4.1.3.1 Two-Dimensional Plane

The simplest form to present on a sheet of paper or a computer screen is a 2-D plane. Depending on the dimensionality of the data, there can be tradeoffs between representing data purely in two dimensions and giving a 3-D view of the data. In a 2-D representation, we do not have to deal with perspective projection or other potentially confusing 3-D cues, thus making it much easier to make quantitative determinations from the rendering. Of course, this works best for data which inherently lie on a 2-D grid. Higher-dimensional datasets can be examined a slice at a time by cutting 2-D planes through it.

FIGURE 27.9 (See Plate 27.9 in the color insert following page 29-22.) Discrete color mapping is used to depict the age of the forest in Yellowstone National Park [Kovacic et al. 1990]. (Courtesy of D. Kovacic, A. Craig, and R. Patterson; UIUC, NCSA.)

One can represent data on a 2-D raster image (also known as a false-color map). An example of this is the visualization of a 2-D fluid flow problem involving a jet of high-density material into a lower-density material.

The range of values is mapped to a range of colors. The choice of colors requires considerable thought in order to produce a meaningful image. Choosing colors arbitrarily may lead to false impressions of what the data indicate. It is not always necessary to employ a continuous range of color values. Sometimes a few colors chosen to indicate discrete states can convey information more effectively. In Figure 27.9, discrete shades of yellow and green represent the age of the forest since the last fire in the region, red indicates a current fire, and black represents areas of nonvegetation.

There are several other idioms for representing information on a 2-D plane, many of which extend into 3-D forms. Contour lines and vector plots are two examples. Contour lines can be drawn on a 2-D plane of data indicating where specific values of the data are located. Typically, multiple contours are drawn in a single visualization to show the range of values. Vector values on a 2-D plane of data often are represented as arrows that point in the direction of the vector, with a length proportional to the magnitude. To view the entire domain, arrows are placed at the location of each data element.

27.4.1.3.2 Height

If a goal is to see correlations between two variables in the dataset, one can add the element of height to the aforementioned color mapping idiom. One variable is mapped to the color, and the other is used to determine the height of the surface (e.g., Figure 27.10). One must be careful in viewing such representations so as to avoid inaccuracies due to poor viewpoint selection. For example, in the extreme case, viewing a height-color rendering from directly above causes the height information to be lost.

27.4.1.3.3 Volume Rendering

The technique of color-mapping a single variable of a 2-D dataset can be extended to a 3-D dataset using a computer graphics technique called volume rendering [Drebin et al. 1988]. In looking at 3-D data, a viewpoint must be selected, and then an image is rendered by traversing through the elements of the dataset and assigning color and transparency values. A common usage is to volume-render medical data, such as the dog heart in Figure 27.11. In this example, the less dense material is assigned a high transparency value, so we can see through to the higher density material of the muscle and bone [Moran and Potter 1992].

27.4.1.3.4 Vectors: Arrows, Tracers, Streamlines, etc.

There are several common idioms used for displaying vector data. A standard representation of a 2-D vector field is to simply draw an arrow from each cell in the data in the direction of the vector, with the length proportional to the magnitude (Figure 27.12).

FIGURE 27.10 Visualization of gravitational effects of colliding black holes. (Courtesy of Mark Bajuk, Edward Seidel; NCSA [Anninos et al. 1993].)

FIGURE 27.11 (See Plate 27.11 in the color insert following page 29-22.) Volume rendering of a dog's heart. (Courtesy of E. Hoffman, P. Moran, C. Potter; NCSA.)

FIGURE 27.12 Wind vector field and pressure contours.

FIGURE 27.13 (See Plate 27.13 in the color insert following page 29-22.) Tracers clarify the wind flow within a simulation of a severe thunderstorm. (Courtesy of Robert Wilhelmson et al. NCSA.)

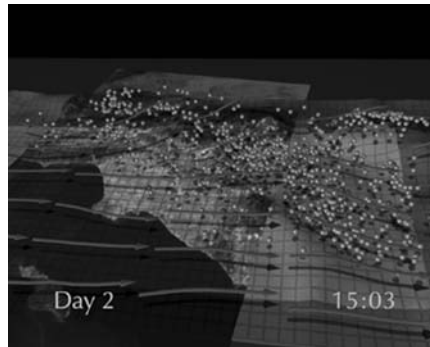

FIGURE 27.14 (See Plate 27.14 in the color insert following page 29-22.) Streaklines and particles depict smog in Los Angeles. Each green particle represents 10 tons of reactive organic gases; each yellow particle, carbon monoxide; and each red particle, nitrogen oxide. (Courtesy of W. Sherman, M. McNeill et al. NCSA.)

Just as techniques such as colored smoke are used to visualize fluid flows in the laboratory, computer graphics equivalents of smoke may be used to display flowfields in computational simulations [Merzkirch 1987]. There are several idioms that give an effective qualitative view of the data. The simplest utilizes particles to indicate the flow. By adding lines showing the history of the paths taken by the particles, we derive a different technique often called **tracers** (Figure 27.13). These are also referred to as **streamlines**, especially when the particle itself is not represented. A similar idiom, the **streakline**, shows a path through the vector field for a static moment of time (Figure 27.14). In other words, it shows a portion of the path a particle would take if it were traveling infinitely fast.

As with many geometric representations, additional information (age, velocity, temperature, etc.) can be mapped onto a tracer, streamline, or streakline. This information can be represented with color, transparency, texture, or twist. Figure 27.15 shows a good example of representing the streamwise vorticity of a fluid flow simulation. In this representation, the twist along a streamline is proportional to the amount of vorticity at the particular location of the domain.

27.4.1.3.5 Isosurfaces

Extending the isoline (or contour line) to three dimensions gives us the isosurface [Lorenson and Cline 1987]. An **isosurface** is a surface of constant value in three dimensions. All points inside the surface have values below the threshold level, and all outside have values above the threshold level, or vice versa. For

FIGURE 27.15 (See Plate 27.15 in the color insert following page 29-22.) A ribbon's rate of twist indicates the streamwise vorticity. (Courtesy of Robert Wilhelmson et al. NCSA.)

FIGURE 27.16 Isosurfaces depict regions of electron-density change. (Courtesy of Jeffrey Thingvold; NCSA.)

example, the isosurfaces shown in the cloud surface shown in Figure 27.16 represent changes in electron density.

27.4.1.3.6 Forms from Traditional Science

It often is desirable to choose representational idioms with which the audience is already familiar. For example, chemists are familiar with representing molecular structure with ball-and-stick models. These can be replicated in computer graphics. Using computer-generated imagery, however, removes certain physical constraints, and additional information may be given. For example, Figure 27.17 shows a picture of a leukotriene molecule in which colored, orthographic shadow views are projected onto a three-walled stage to give the viewer a better clue to the 3-D shape.

27.4.1.3.7 Cutting Plane

Sometimes it is useful when looking at a 3-D dataset to cut the 3-D cube with what is called a cutting plane, revealing data along a single 2-D slice of that cube. Figure 27.18 shows a cutting plane, together with the 3-D isosurface. The black line in the isosurface indicates where the plane intersects it. The scale alongside the cutting place shows the mapping between the level of water content and the colors.

27.4.1.3.8 Alpha Shapes

A technique called **alpha shapes** allows one to represent the concept of shape applied to a collection of points in space [Edelsbrunner and Mucke 1994]. Alpha is the name of the parameter that, when varied,

FIGURE 27.17 (See Plate 27.17 in the color insert following page 29-22.) A computer-generated ball-and-stick model of a leukotriene molecule. Colored shadows aid in perceiving the 3-D shape. (Courtesy of D. Herron, Eli Lilly & Co.; J. Thingvold, W. Sherman, NCSA.)

FIGURE 27.18 (See Plate 27.18 in the color insert following page 29-22.) A cutting plane displays additional detail of a particular slice of a 3-D dataset. (Courtesy of Robert Wilhelmson et al. NCSA.)

affects the complexity of the resultant shape. Large values of alpha produce a simple representation of the shape — a convex hull. As the value of alpha is continuously decreased, more complex shapes are created, revealing cavities, tunnels, and voids inherent in the dataset. For example, [Figure 27.19](#) shows a geometric representation of a molecule of gramicidin A, the first clinically used antibiotic (predating penicillin).

27.4.1.4 Motion

Motion can be a very important cue to the viewer for understanding the data being portrayed. It provides a qualitative overview of dynamic data by showing how the system evolves over time. Of course, the medium in which the imagery is presented affects the ability to indicate motion. In a book, for example, motion must be indicated by techniques such as motion blur, tracers, or series of still images from a time sequence (small multiples) [Tuft 1996a] ([Figure 27.31](#)).

Motion also can be used to aid the viewer in discerning the three-dimensionality of the object. [Figure 27.20](#) shows an example of a 3-D set of molecules. The image in this book looks flat. However, when the molecules are rotating on a screen, a strong sense of the 3-D structure is conveyed. This representation also demonstrates how motion through the simulation can be represented in a single static geometry. In this visualization, the collection of small spheres represents the positions the atoms take over the course of the entire simulation.

FIGURE 27.19 Alpha-shape representation of gramicidin A molecule. (Courtesy of H. Edelsbrunner, P. Fu, UIUC, NCSA.)

FIGURE 27.20 This image shows all of simulation time in a single geometric form and uses motion in the animation to aid the viewer in discerning the 3-D structure. (Courtesy of D. Herron, Eli Lilly & Co.; J. Thingvold, W. Sherman, NCSA.)

27.4.1.5 Transparency

Sometimes it is desirable to show something that's inside or behind something else in the scene. By increasing the transparency of the geometry, the visualizer can allow internal structure or hidden objects to be viewed. When using transparency, often many of the shadings and other cues that indicate shape are less compelling. In Figure 27.15, a transparency technique was used to allow the twisting ribbons inside the cloud structure to be seen. If the cloud had been made uniformly transparent, it would be difficult to see its shape. Here, the transparency is dependent on how nearly perpendicular the surface is to the viewpoint. This makes it easy to see the twisting ribbons in the center, while maintaining a well-defined edge to the surface.

27.4.1.6 Combining Techniques

Any of the above idioms may be combined to illustrate different aspects of the dataset (e.g., see [Figure 27.21](#)). The benefit of this is the ability to show correlations between various parameters. When combining idioms, however, care must be taken not to overload the display or occlude important information.

27.4.2 The Visualization Process

This subsection provides an overview of the process of creating various kinds of visualizations. We begin by looking at basic still images. We then add features such as choreography, real-time interaction, and, finally, simulation control from within the visualization process.

FIGURE 27.21 Multiple techniques combine to show gravity pull on the surface of Mars's moon Phobos. (Courtesy of Wayne Lytle, CTC.)

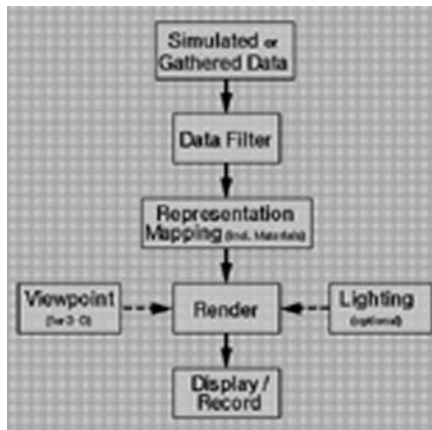

FIGURE 27.22 The basic visualization process. (Courtesy of W. Sherman.)

27.4.2.1 Still Imagery

The basic method for transforming numeric data into visual output is depicted in Figure 27.22. In this diagram, information flow follows the arrows, with dashed lines indicating optional parameters. At the top, data are provided from some numeric source such as a mathematically based computational model, a conceptually based computational model, or a collection of observed values. Data filtering involves a wide range of operations. Data must be translated into a form that is required by the visualization software. Additionally, the filtering process is used to sift out the most relevant aspects and discard unnecessary values.

After the data are filtered, they are mapped to some geometric form. At that point, decisions must be made about the materials and the characteristics of what these objects will look like — are they shiny, are they smooth, are they rough, are they dull, are they red, are they green, are they semitransparent? These parameters can also be driven by the computational model within the constraints imposed by the visualization software. Lighting information — i.e., how many lights, how diffuse they are, their relative location, etc. — is then combined with the viewpoint and information about the geometry by a computer program called the renderer. The renderer takes this information and computes the 2-D image which the eyes see. For a stereoscopic view, two images are rendered, from the point of view of each eye. The resultant images are then either recorded on film or video tape or displayed on a computer screen or other output device.

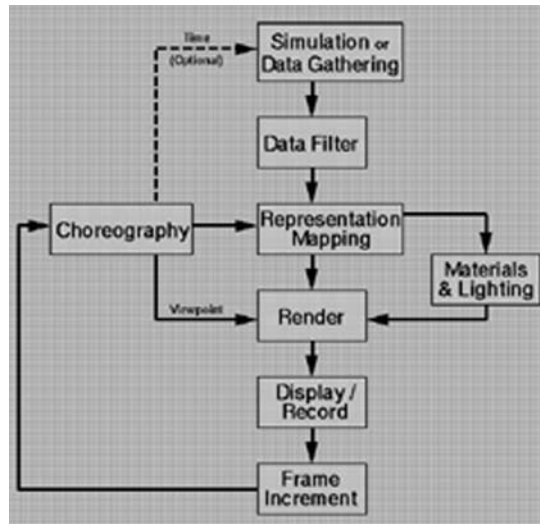

FIGURE 27.23 Process of creating a scientific visualization animation. (Courtesy of W. Sherman.)

27.4.2.2 Animation

The basic methodology for creating a computer animation is an extension of the process used to create the still image. The major extension is the concept of choreography. Now, the same steps are followed as in Figure 27.22, but the viewpoint information can be choreographed, along with the objects, their representations, and the passage of simulation time itself, resulting in the diagram in Figure 27.23. Animation is the result of rendering the scene repeatedly while varying the choreographic information and then displaying the images in rapid succession.

Choreography is that part of the process which controls the viewpoint of the scene and the movement of objects within the scene. Choreography can also be used to control how representations of the data change during an animation, such as the transparency of a material of a particular idiom.

Another important element of the dataset that can be controlled by the choreographer is *time*. Usually, time is considered to be constantly moving, at least as long as the animation is playing. However, there are two notions of time in a visualization animation. One is the passage of time of the viewer while watching the animation. The other, for visualizations of time-varying datasets, is the notion of time within the data. There is no requirement that data time move at a steady pace through the animation. It often can be insightful to hold time constant while other parameters of the representation are choreographed, revealing additional information. Moving time at different rates may reveal features that otherwise would be hidden.

27.4.2.3 Interaction

Animated sequences are made of several still images displayed in rapid succession. Often these images take longer to create than the fraction of a second that they will be displayed. This results in a situation where the choreography for all the action is planned ahead of time and is then unchangeable once the animation is complete. This is not generally the optimal method for a researcher who wants to probe a dataset interactively.

To have a more insightful experience with the data, scientists want to be able to spend more time looking at specific pieces. They want to be able to look at them from different angles, change representation parameters, and watch them at different rates of speed. To allow this kind of interaction, the images that are animated on the screen must be created as fast as they are displayed (i.e., in *real time*). Thus, the rendering stage in our visualization figure becomes a real-time (RT) process, and the display–record stage is now display only, with the option of recording (Figure 27.24).

FIGURE 27.24 Interactive visualization allows the user to control the data filter, the representation, and the viewpoint. (Courtesy of W. Sherman.)

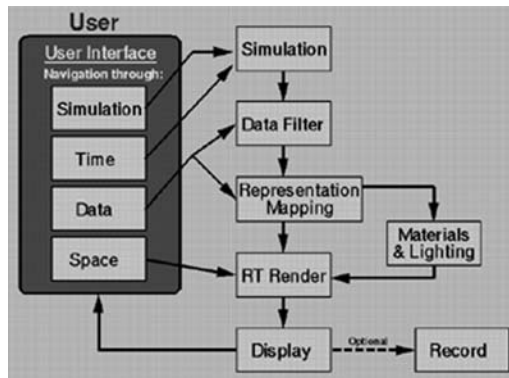

FIGURE 27.25 Interactive steering allows the user to manipulate the simulation in addition to the visualization. (Courtesy of W. Sherman.)

The most significant change in the interactive visualization process is that the choreography now happens in real time too; instead of an animator creating the choreography, the scientists themselves choreograph the scene through the package's user interface (UI). At this level of interaction, users are able to guide themselves through space and time and control the representation of the data (Figure 27.24).

27.4.2.4 Interactive Steering

Interactive steering is the ability for the user to alter the course of the simulation in real time [Haber 1989]. Figure 27.25 further extends the visualization flow chart to include user control of the simulation — including direct control over passage of time. It is vital that both the simulation and graphics system provide real-time performance and allow for user input. The user can then interactively steer the simulation by modifying variables and data in the simulation, as shown in the figure. The user can still steer the processing of the data into graphical representations and steer the viewpoint of the scene.

27.4.3 Visualization Tools

A number of tools are available for creating visualizations of information. The choices have improved with the evolution of computer technology. Visualization tools provide varying elements of the visualization processes shown in the figures. They can be categorized as follows: plotting libraries, turnkey packages,

dataflow packages, and animation packages. There is also the option of creating the visualization by writing the software in-house.

Each package (and type of package) has certain advantages and limitations that may make one more suitable for a particular application or situation. We will examine some examples of each type of visualization tool.

27.4.3.1 Plotting Libraries

Historically, computer-graphics-based visualization originated with the use of alphanumeric printouts to mimic a bar graph, a shaded “color” map, or values from which contours can be hand-plotted. Computer visualization began to take shape with the flexibility brought about by new output devices, such as pen plotters and vector displays. These new devices made the creation of computer-generated contour and vector plots more feasible.

Software libraries were developed that enabled researchers to generate charts, graphs, and plots without the need for reinventing the graphics themselves. These packages have evolved as the computers and computer I/O have improved and are still available today. Since these packages are basically programming interfaces, they do not typically involve any form of interaction other than through programming and (perhaps) a command-line interface.

The limits on the interactivity of these tools suggest that they are of limited functionality. Although this is partially true, there are also some benefits. Because scientists often want to work with quantitative representations of their data, plotting libraries can provide the easiest means for producing the appropriate output. Print output has much higher resolution than screen output, and these libraries can produce high-resolution plots specifically for output to such printers. Screen-based interactive packages often limit their resolution to what is available on the screen, thus limiting their ability to produce quantitative visualization.

27.4.3.2 Turnkey Visualization Packages

A turnkey visualization package is a program designed specifically for doing visualization and contains controls (widgets) for most options a user would want to exercise when visualizing the data. This is accomplished through the use of pulldown menus or popup windows with control panels.

A number of commercial and no-cost visualization software packages are available. Most packages are available for Unix workstations, and many are also available for PC compatibles and Apple Macintoshes. Commercial packages include Fluent’s CFD software package [Fluent], NASA/Sterling Software’s FAST [FAST], and Fortner Research’s visualization suite [Fortner]. Freely available packages include VIS-5D from the University of Wisconsin [Vis5D], Sci-An from Florida State University [Sci-An], and Gnu-Plot from Dartmouth College [Gnuplot].

There are definite advantages to using turnkey visualization software. The primary advantage is that one can often read one’s data directly into the packages and immediately begin manipulating the controls to look at various aspects of them. This assumes that the data are initially in a format readable by the package and that the controls are intuitive enough for someone to experiment with and get good results.

These packages are designed as interactive tools; their ability to manipulate the view and the visualization parameters is key to putting the visualization process into the hands of individual researchers. Also, because the target user is a scientist, the user interface is usually designed for ease of learning and use.

Off-the-shelf packages also have some limitations, however. Foremost is that their flexibility is often limited. For instance, the user won’t be able to add visualization representations that are not provided by the software. Also, if too many representations are included, then the user interface may suffer from an overwhelming number of control selections, making it hard for the user to find the control needed to perform a specific operation.

The desire for interactivity also imposes limits on these packages. To be interactive, data must be easily retrievable, and the representational forms should not be rapidly changing. This means that displaying features of time-dependent data may be too slow to be very interactive or may not be allowed by the package at all. To have interactive real-time rendering, many constraints are put on the amount of complexity the

images can have. Generally, very beautiful imagery requires more complexity than can be achieved in real time. One solution for this is to allow the user to experiment with representations and choreography of the data; when a satisfactory situation is selected, information can be sent to a noninteractive rendering system to produce nicer images.

27.4.3.3 Dataflow Packages

Like the turnkey visualization packages above, dataflow visualization packages are designed as tools to be used directly by the scientist. However, dataflow packages are much more modular, with each stage of the visualization process represented as an independent unit. These units are then connected in the appropriate manner to allow data to be passed (or *flow*) from one unit to the next. This style of interface is inherently more flexible and also provides a map of the visualization process the system is using. These packages also are designed to be more extensible, allowing the user to add features and functionality that are not provided off the shelf.

Dataflow software currently requires the availability of a Unix workstation. Most packages now run across different brands of workstations. Despite the narrowing gap between PC and workstation, not many run on PCs. Three factors that contribute to this situation are the requirement for doing a considerable amount of processing of the data, the use of large amounts of memory, and the need for large-screen displays with reasonable graphics performance.

The dataflow concept consists in breaking down tasks into small programs, each of which does one thing. Each task is represented as a *module* (a software building block, or “black box”) that performs the specified operation. Each module has a defined set of required inputs and outputs for passing information between modules. Figure 27.26 shows a simple connection network of some modules. In this example, data are retrieved with the Read HDF module and flow to the Isosurface module, which creates a geometric representation of the data, passing the new information to the Render module, which renders a pixel map, which in turn is passed to the Display module, which puts the image on the screen.

Though the dataflow concept had been described for doing other tasks (such as image manipulation), AVS (Application Visualization System) was probably the first package to apply the dataflow concept to the task of doing visualization [Upson et al. 1989, AVS]. AVS is available on most Unix workstations. IRIS Explorer [IRIS Explorer], originally developed for Silicon Graphics workstations, is also now available on other workstations. IBM’s Data Explorer [IBM Data Explorer] is another example of commercially available software. Khoros [Khoros] is one freely available package of this nature. SCIRun, a powerful new implementation of the dataflow paradigm, is also freely available to some institutions [Johnson and Parker 1995]. The user interfaces for most of these programs are surprisingly similar, and familiarity with one package makes learning another easier.

FIGURE 27.26 (See Plate 27.26 in the color insert following page 29-22.) Dataflow packages such as AVS connect modules to customize a visualization. (Courtesy of W. Sherman, NCSA.)

FIGURE 27.27 (See Plate 27.27 in the color insert following page 29-22.) Customization capabilities allow the package to be extended to new display paradigms, such as in this stereo image linked to a virtual-reality viewing device. (Courtesy of W. Sherman, NCSA.)

Advantages of systems designed around the dataflow paradigm are numerous. As with turnkey packages, real-time rendering coupled with user control of the viewpoint and visualization parameters allows researchers to experience their data first hand. Flexibility is enhanced by the user's ability to connect modules together, creating a network of modules specific to the task at hand.

Flexibility is raised another degree by having the option to create new modules that perform operations not provided by the base collection of modules provided with the system. New modules may be written in common programming languages, such as C or Fortran. By utilizing routines provided with the system, the new modules will exhibit the same user interface and data handling as the standard modules. Since many people typically share the same desire for specific extensions, sharing of modules is common practice, thus making these packages even more valuable.

There are some disadvantages to this form of visualization package. For many, the primary disadvantage is the fact that most dataflow packages are available only on Unix workstations. Another is the difficulty with which this type of package handles data that change over time as part of a real-time visualization. Typically, data flowing down the network is for a particular time step of the computational simulation, and the modules that provide the representation of particle flow through a vector field will not be able to get the data fast enough to give smooth-flowing animation of those particles in a changing dataset (though they generally can handle particles flowing through a time-static dataset).

And last, the dataflow interface *is* a type of programming; thus, the end user at one level must learn how to program the system. While easier than writing code in C or Fortran, this process is more complicated than in the turnkey approach. The degree of difficulty increases as the networks become complex and the application has greater requirements, such as looping time-varying data that are flowing through the system.

The modularity of the dataflow paradigm also allows for the addition of a new style of interfacing with the user. New input devices such as Spaceballs™ and 3-D trackers can allow the system to control the viewpoint of the environment. New output devices can provide a head-tracked, stereo view, allowing *virtual reality* to become a potential method of interacting with a visualization [Sherman 1990] (Figure 27.27).

27.4.3.4 Animation

Today, presentation-quality visualization animations typically use standard computer animation packages [Fangmeier 1988]. Until recently, computer animation packages were the only off-the-shelf software

available that provided 3-D rendering of any sort. Thus, these were often used to provide the rendering stage of the visualization process.

Computer animation packages are designed for all types of computer animation, not just for use in scientific visualization. However, it can be said that whatever they are used for, they are used to show (or visualize) the world the animator has conceptualized. For scientific visualization, the objects in the scene are typically derived from data. An animation package typically has separate components that allow the modeling of objects; the choreography of the objects, lights, and viewpoint; and the ability to design visual material qualities for each of the objects. These are all tied together into an image or series of images by the rendering component.

The primary advantage of using animation packages is that they are extremely flexible. The user is able to create objects of any type or size to represent the subject of the visualization and any supporting objects that might be required to give context to the representations. In a visualization environment, most of the objects are created by writing specialized programs that convert data from their native format to a format suitable for the animation package. This flexibility does have limits, however, such as when there is a need to represent the data using a method not available in the package. For example, a volume rendering technique may be required, and the renderer for the package may support only polygonal techniques.

Another advantage of animation packages is the ability to create very high-quality imagery. It is important to note, though, that the image quality is also dependent on the work done by the visualization creator.

The flexibility and complexity of animation packages also can be a disadvantage. These tools can be sufficiently complex that to use them as a visualization tool requires an outside expert to bring the visualization to fruition. Such an expert would be able to write the custom programs that convert data from their original state to an appropriate format. The fact that the consultant doing the visualization work is usually not an expert in the field of study being represented also can be a disadvantage.

Because each image in an animation can be very detailed, rendered using computationally expensive techniques that give rise to high-quality scenes, the time required to create the image is unlikely to be short enough to allow for what is referred to as real-time rendering. In fact, it can take several minutes to several hours to produce an image that will be viewed for one-thirtieth of a second (at video rates). The time required is a disadvantage even in situations where months are available to produce the animation, because of the delay between the time a small change is made and the time the scientist can view the resulting work.

Another disadvantage of using an animation package is the increased potential loss of data integrity that can occur in the process of translating the data from their original form to a form suitable for the animation package. The likelihood of data integrity problems is higher in this environment for two reasons: more custom work is done to translate the data, and the animation package may have options to make the output look good at the expense of giving an accurate view of the object being rendered. In an off-the-shelf visualization package, the techniques used to bring data to the screen are often well-known ones that a user can research and learn how they may affect the resulting image. Custom code used with animation packages may not be as heavily scrutinized if it is used only once for a particular application. Also, animation packages have features such as automatic smoothing that take the rough spots out of the data. This changed representation probably will not give an accurate view of the original information.

27.4.3.5 WYOS: Write Your Own Software

Before visualization and animation packages were available, tools to look at data were custom programmed for the task at hand. This is still done for certain visualizations — especially ones that handle large amounts of time-varying data or require new computer graphics techniques that have not been implemented in off-the-shelf software (e.g., certain volume visualization techniques). Now, however, users generally choose to use off-the-shelf software, perhaps with a few modifications.

Some examples of visualizations requiring custom renderers include *L.A. — The Movie* [Hussey et al. 1986], which used special techniques for overlaying satellite imagery onto a topological map of the Los Angeles region, and *The Deluge* [Sims 1989], which brings a still image to life by using a renderer written specifically for that task.

The only advantage to writing your own application software is in situations where that is the only way you can obtain the visualization you need.

27.4.3.6 Tools Summary

In summary, many tools have been developed which aid in visualizing scientific data. These tools are improving, making visualization an easier task to perform. However, even with a very easy user interface, the skill of the visualization developer is the overriding issue. No tool, no matter how easy to use, can replace the skill and insight of a visualization expert.

27.4.4 Examples of Scientific Visualizations

We have explained the components of scientific visualization and examined how these are used to create output that the researcher can use. In order to have a better understanding of how visualization is typically used in practice, and to look at how representational idioms have evolved, we will describe a selection of visualizations used as a means for scientific study.

27.4.4.1 The Study of a Severe Thunderstorm

The primary example of scientific visualization we will examine in this chapter is the computational simulation of severe thunderstorms. The simulation of meteorological processes has a long history in the computational sciences and consequently can be used to demonstrate the evolution of many visualization techniques. In particular, we will look at the research performed by Robert Wilhelmson's research group at NCSA and the Department of Atmospheric Sciences at UIUC and the visualizations done by his group and the NCSA Visualization Group.

27.4.4.1.1 Evolution of Atmospheric Simulations and Visualization

Wilhelmson's group has been studying the process of thunderstorm development computationally for 25 years. Over this period, several developments have been made in scientific visualization, and these are reflected in the many visualizations made of his work.

In the 1950s, the simulations run on digital computers were so simple that the researchers could literally examine every number produced. In the 1960s, digital computers had become fast enough to be used to execute 2-D simulations of atmospheric conditions over time. At first, the data were examined simply by printing the numbers in a 2-D array on paper. The researcher could then actually draw contours through the data by hand based on the printed numbers. An alternative early technique was to print a 2-D array of letters, with each letter representing a range of data values (this was often referred to as "gray-shading," with each character effectively representing a different level of gray) (Figure 27.28). About this time, a package for producing standard visualizations of 2-D data was released by the National Center for Atmospheric Research (NCAR). This package, known as *NCAR-graphics* [NCAR] could produce representations such as the image of contour levels within the developing storm front shown in Figure 27.29. In general, all the visual output of the simulations were of a static slice of time.

The 1970s saw the true advent of 3-D simulation models for all areas of atmospheric science. With the expansion into three dimensions, it became more difficult to interpret and explain the results. By this time, *NCAR-graphics* was the primary visualization package used by atmospheric sciences. With the addition of the ability to produce 3-D isocontours (i.e., isosurfaces) (Figure 27.30), Wilhelmson was able to view storms from a real-world perspective and from a radar perspective, among others.

Other techniques that began to be used in the late 1970s include the use of color to visually separate different representations, giving the ability to view them simultaneously. Color also was used to draw different layers of isosurfaces within a 3-D structure. In addition to color, Wilhelmson began to look at the change of the system over time; initially, this was limited to an alternation between two images on a raster-frame storage device.

In the early 1980s, the use of flow tracers (particles) to visualize flow through a field began in earnest — though some had been done in the late 1970s. Computing particle location was a new way to represent

FIGURE 27.28 Early visualization attempts included hand-drawn contours and shaded images constructed from a judicious choice of ASCII characters.

FIGURE 27.29 Developing storm front.

FIGURE 27.30 An early isosurface representing the late stage of the storm.

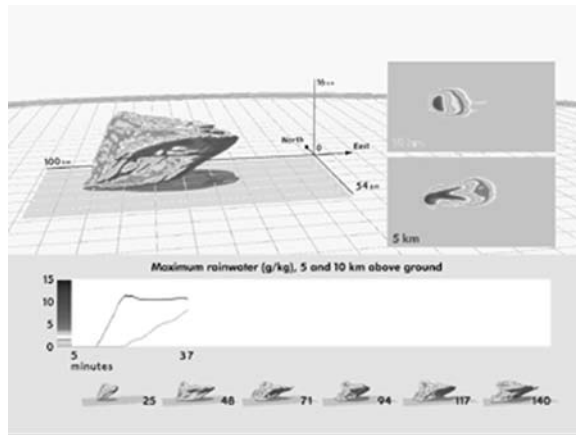

FIGURE 27.31 The thunderstorm visualization was redesigned with less contrast between the grid and the ground and small multiples added to represent changes in time. (Courtesy of Yale University, NCSA.)

flow through a fluid substance, providing the ability to view a large region of the simulation at one time. In practice, the visualization creator experiments with where the particles should be released to show specific aspects of the simulation. Several examples of the storm visualization produced in 1989 can be seen in [Figures 27.13](#), [27.15](#), and [Figure 27.18](#).

In line with the development of visualization technology is the continued exploration of effective information design. The goal of visualization is to communicate aspects of the data clearly. To achieve this clarity, one must be aware of basic design principles and have the ability to effectively critique the design quality of visualization. Issues of visual hierarchy, composition, choreography, color theory, and typography cannot be disregarded. Attempts to demonstrate scale, provide a sense of context, combine qualitative and quantitative information simultaneously, direct the viewer's eye, create multiple representations, and point out intentional manipulations in the data are tasks that the creator must work through in order to produce quality information design [Tuft 1996a].

The storm visualization shown in [Figure 27.18](#) was redesigned to illustrate several issues of information design. In the new design ([Figure 27.31](#)), the contrast between the elements of the scene was adjusted so that visual emphasis is placed on the important details of the visualization. The grid floor in the original animation is a strong visual element and distracts from the dynamics of the cloud development. Reference information was added to the scene, such as the dimensions of the computational domain and the diagrammatic clock at the bottom. This clock includes a stripe of small images that illustrate the entire duration of the visualization. This gives contextual information by indicating which portion of the animation one is viewing and in addition shows the numerical time step for specific reference. The two-dimensional cutting planes in the scene in conjunction with the three-dimensional cloud, and the quantitative scale at the bottom, provide multiple representations of the data for comparison and clarification [Baker and Bushell 1995, Tuft 1996b].

Today, we are reaching the point where the flow of large numbers of particles can be computed and visualized. Too many particles, however, can make it hard to see what is going on, so the technique of selectively choosing to display specific particles is being explored. In the picture in [Figure 27.32](#), particles are used to represent the flow of a tornado. To highlight just the tornado, only particles with high vertical vorticity, within a certain region, are shown. The amount of data and objects required to represent it also brings about a logistical problem of where all this information is stored. Large disk drives are required to create visualizations of massive numbers of particles, and files must be carefully managed to stay within the constraints of the storage.

Virtual reality (VR) also is being experimented with as a means of gaining insights from simulated scientific experiments [Baker and Wickens 1995]. VR experiences have been designed for the VROOM

FIGURE 27.32 Thousands of particles show the shape of a tornado. (Courtesy of Matthew Arrott.)

[Brown 1994] and SuperVROOM [Korab and Brown 1995] venues at SIGGRAPH '94 and SuperComputing '95, respectively. In these experiences, the domain of the data is represented by a bounding box, with various tools available to represent the data, including isosurfaces, and particle flow. In a CAVE™ [Cruz-Neira et al. 1992] VR system, the user can easily navigate the data space and has the ability to control the representations. In the particle flow representation, the user can control the release of particles with a hand-held device. As the user releases the particles, a flow simulation program is begun that updates the particle positions. This program (and any of the representation modules) can execute on a separate larger supercomputer for better interactivity.

It is hard to judge how much additional insight can be gained by immersive interactive visualizations (i.e., virtual reality). This stems from the deep knowledge atmospheric scientists already have of their simulations. Major concerns of the scientist in using virtual reality include: Would I use a device that requires me to be standing or walking for an extended period? Analyzing the data requires knowing where one is with respect to the cloud, which is easier when viewing the cloud from the outside — in which case, what is the advantage over the desktop? To be truly immersed, the user should feel the wind, hear the thunder, see the lightning, none of which is accurately representable with current VR technology.

Scientists have become proficient at deciphering the 3-D content from flat 2-D displays from years of experience. Because of this, they see less need for the improved 3-D cues that VR provides. However, they are continuing to explore the use of virtual reality as a visualization tool. Since it is a new medium, there are many technological and user interface improvements ahead; VR still may prove to provide unique insight not obtainable through other means.

The World Wide Web (Figure 27.33) is viewed as a very useful tool for disseminating research information. It can be used by the public to access weather forecast information or by other atmospheric researchers to directly examine the simulation data themselves. It can be the complete tool for a researcher — the notebook that contains all the diary entries over the course of a study, including explanations, data, images, animations, and interactive visualization tools. It can be made available not only to the researcher but also to colleagues, advisors, and (if desired) the scientific community [Jewett and Wilhelmson 1995].

27.4.4.1.2 What Does the Scientist Use Today?

With all that is available to the scientist today, what tools are actually used? To be specific, everything. Line graphs, 2-D contours, and 2-D vector plots still provide the basis for closely investigating the results of a simulation. Three-dimensional stills and animations are excellent tools for illustrating concepts. Interactive visualization tools help to find out what's in the dataset and to locate interesting regions that demand close inspection.

Animation, while a good tool for presenting the overall contents of a research study, poses problems when it comes to publishing the study. Scientific publishing still exists primarily as a print medium, and

FIGURE 27.33 Portion of a WWW page used to document a research project. (Courtesy of Brian Jewett; NCSA.)

thus it is difficult to include animation. Indeed, even submitting an animation for inclusion in the review process is difficult. The World Wide Web is beginning to provide a solution to these problems. The entire research submission, including animations and interactive tools, can be included as one comprehensive document for the review. Once reviewed, such a submission can be published on CD-ROM, while still remaining available online where it can be periodically updated.

27.4.5 Visualizing Smog

Smog: Visualizing the Components is another animation visualization in the domain of atmospheric science. However, there are some interesting information presentation features that are highlighted in this animation.

One segment of the *Smog* animation has particles that represent different forms of pollutants flowing through the atmosphere, based on air movement data. Unlike most particle flow animations where particles are released from locations within the simulation to highlight specific aspects of flow, the particles in this animation emanate from actual locations of pollution sources, at a rate based on measured releases. This animation also demonstrates a slightly different form of the wind-tracing ribbons known as streaklines (Figure 27.14).

An additional representation of the data in this animation was made through the use of sound. A sirenlike tone reinforces the information displayed in the XY plot (Figure 27.34). It also experimented with mapping the ozone level to the repetition rate of digital recordings of coughs.

FIGURE 27.34 Los Angeles smog visualization. (Courtesy of NCSA.)

27.5 Research Issues and Summary

Though great strides have been taken in developing scientific visualization as a tool in computational science, a multitude of issues remain for further research and development. As computer power increases, the need for effective visualization tools increases due to the larger volume of information being produced. Fortunately, the increase in computer power also allows us to develop more compelling visualization tools with more flexibility, better performance, and higher fidelity.

When studying the field of visualization, it is important to recognize that visualization is being done effectively in a variety of fields outside of the realm of computational science. Medical imaging, factory automation, and financial researchers, to name a few, are taking advantage of the power of visual representation of information.

Additionally, there is a growing wealth of knowledge about the visual representation of information, and how we perceive and interpret visual information, being published by researchers in fields such as cognitive psychology, perceptual psychology, human factors, etc. As visualization researchers and tool developers incorporate new findings, we may take better advantage of visualization as a powerful analysis and communication tool. The art and design community also is demonstrating new ways of presenting and representing information. The use of sound in representing scientific data is becoming more important. Research is being done to find what types of information are best represented in audio.

In order to move beyond the current level of visualization tools, we must continue to develop the basic technologies and algorithms involved in the image-generation aspects of the process — for example, improved rendering algorithms, improved user interface, improved representations, etc.

In the ideal world, the computational scientist would not be required to think about human visual perception, optical illusions, how cultural biases affect the interpretation of imagery, or how color is understood. If research in the appropriate areas can be integrated into the tools which scientists use, we can raise the level of effectiveness of the visual analysis and presentation of science and, indeed, the science itself. Research is currently under way [Baker 1994] to develop tools which do automatic idiom selection. Based on input from the scientists regarding the type of data, the insight they are trying to achieve, etc., the tool will generate representations that have a high likelihood of being useful.

Visualization is rapidly moving beyond the researcher's workstation and videotape presentations. New media and communications systems are allowing the scientist to collaborate remotely over networks and share data, imagery, etc. The Internet and the World Wide Web are allowing the scientist to publish findings, including visual representations, to a worldwide audience. These new media bring a variety of new concerns and research issues. Some examples include the size and resolution of imagery that it is possible to share. Current network speeds render it impractical to share multiple large, high-resolution images. Animations also are just beginning to be practical over the network. As data compression techniques and sharing of executable code over the network improve, the scientist will truly be able to explore this new medium.

Current work in VR techniques is enabling scientists to see and interact with their research in many new ways. Stereoscopic imagery, wide fields of view, and tracking of the viewer's head enable the scientist

to become immersed within the simulation and become a part of the system. Current systems suffer from a lack of resolution, tracker lag, etc. As these improve, virtual reality promises to be a powerful tool for computational scientists. Many scientists who have currently abandoned virtual reality systems with their clumsy, low-resolution head-mounted displays are finding that the less intrusive, higher-resolution projection-based displays such as the CAVE™ are transforming virtual reality from a novelty to a useful tool for analysis and display.

In summary, the field of scientific visualization is sufficiently mature to allow the scientist to harness the power of the eye–brain connection for data analysis and presentation. At the same time, it is breaking new ground with respect to online collaborative computing, worldwide publication, and fully immersive interaction through virtual reality.

Acknowledgments

We would like to thank Robert Wilhelmson for sharing his wealth of experience and historical perspective on visualization in computational science; also, from the Atmospheric Science Group, Crystal Shaw and Brian Jewett for additional support. Thanks also to the reviewers and editors for helpful comments and suggestions to improve this chapter.

Many of the ideas in this chapter were the result of our interactions with a variety of scientists. We have had the opportunity to work on a wide variety of challenging visualization problems with numerous world-class researchers.

We gained a much greater insight into the field of scientific visualization as a direct result of interaction with the participants of the Representation Project, including the guest speakers from a wide variety of disciplines and institutions. In particular, the members of the former Visualization Group at NCSA including Boss Dan Brady, Matthew Arrott, Mark Bajuk, Ingrid Kallick, Mike Krogh, Mike McNeill, Gautam Mehrotra, Jeff Thingvold, and Deanna Spivey. This group was intellectually stimulating, an endless source of talent and ideas, and most of all, our friends. We feel honored to have been part of such a magical team.

Defining Terms

Alpha shapes: A technique that allows one to represent the concept of shape applied to a collection of points in space.

Choreography: In computer animation, the timing and sequencing of activity and representation.

Computer graphics: The medium in which modern visualization is practiced.

Dataset: A value or set of values that is the input or output of a computational simulation.

Glyph: Generally, a symbol used to represent information. For example, in visualizing vector fields, an arrow often is used to show the direction and magnitude of the vector value at each location.

Interactive steering: The practice of dynamically modifying the parameters of a running simulation, guided by a real-time visualization of the simulation's progress.

Isosurface: The shape defined within a volume of scalar values on which all the values are equal to some constant.

Parallax: The difference in the apparent position of an object caused by a change in the point of observation.

Perceptualization: A term perhaps more suitable than “visualization,” in recognition of the efficacy of using auditory and tactile techniques for representing and communicating about scientific data.

Scientific illustration: The traditional use of graphics created by an artist to show scientific concepts.

Scientific visualization: The use of computer-generated graphics, often animated, interactive, and three-dimensional, to represent scientific data and concepts.

Simulation: A computer model of natural phenomena.

Streakline: A line showing the path taken by all particles that pass through a given location in a vector field.

- Streamline:** A line drawn in a vector field such that, at any instant, the tangent to the line at any point on the line is the direction of the flow. Often restricted to fields with steady flow, in which case the streamline shows the path of a tracer particle.
- Tracer:** An animated symbol, usually a sphere, showing the path that would be taken by a particle in a vector field.
- Vector field:** An n -dimensional collection of vector values arranged in space, such as the wind velocity over a two-dimensional surface.
- Virtual reality:** A medium composed of highly interactive computer simulations that utilizes data about the participant's position and replaces or augments one or more of their senses — giving the feeling of being immersed, or being present, in the simulation [Sherman and Craig 1996].
- Visual idiom:** A technique for representing scientific data that has a commonly accepted interpretation.

28.1 Introduction

Structural mechanics deals with (1) the idealization of actual structures and their environments and (2) prediction of response, failure, life, and performance of structures. In the last three decades the discipline of computational structural mechanics (CSM) has emerged as an insightful blend between structural mechanics, on the one hand, and other disciplines such as computer science, numerical analysis, and

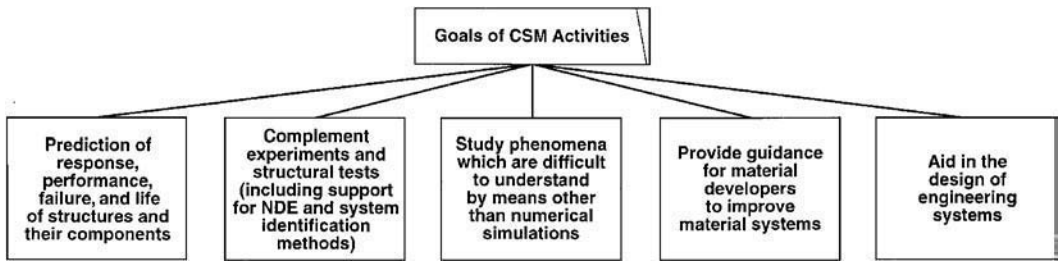

FIGURE 28.1 Five major goals of CSM activities (NDE refers to nondestructive evaluation techniques).

approximation theory, on the other hand. This rapidly evolving discipline is having a major impact on the development of structures technology, as well as on its application to various engineering systems. Development of the modern finite-element method during the 1950s marks the beginning of CSM. Finite-element technology is the backbone of many structural analysis software systems which are widely used by government, academia, and industry to solve complex structures problems.

The five major goals of CSM activities are shown in Figure 28.1. In support of these goals, current activities of CSM cover the study of phenomena, through numerical simulations, at a wide range of length scales ranging from the microscopic level to the structural level. Today, no important design can be completed without CSM, nor can any new theory be validated without it.

A number of survey papers and monographs have been written on various aspects of CSM (see, for example, Noor and Atluri [1987], Noor and Venneri [1990, 1995], and Ju [1995]). Also, a number of workshops and symposia have been devoted to CSM and proceedings have been published (for example, Grandhi et al. [1989], Noor et al. [1992], Onaté et al. [1992], Ladevéze and Zienkiewicz [1992], Stein [1993], and Storaasli and Housner [1994]). The present chapter attempts to present, in a concise manner, the broad spectrum of problems covered by CSM along with the basic principles, formulations, and solution techniques for these problems. A brief history is given of the development of software systems used for the modeling and analysis of structures. The research areas in CSM, which have high potential for meeting future technological needs, are identified.

28.2 Classification of Structural Mechanics Problems

28.2.1 Structural Characteristics and Source Variables

The functions which govern the response, failure, life, and performance of structures can be grouped into four categories, namely:

Kinematic variables: e.g., displacements, velocities, strains, and strain rates

Kinetic variables: e.g., stresses and internal forces (or stress resultants)

Material characteristics: e.g., material stiffness and compliance coefficients

Source variables: which include environmental effects and external forces (e.g., mechanical, aerodynamic, thermal, optical, and electromagnetic forces)

The relations between the external forces and response quantities are shown in [Table 28.1](#).

28.2.2 Different Classes of Structural Mechanics Problems

A number of classifications can be made for structural mechanics problems depending on: (1) presence or absence of uncertainties about the structural characteristics and source variables, (2) nature of the functions which govern the behavior of the structure (e.g., time dependence or independence), (3) the functional

TABLE 28.1 Relations Between External Forces and Response Quantities

Quantities	Relation	Type of Relation
External forces	Balance equations	Physical (conservation) laws
Stresses	Constitutive relations	Semi-empirical based on experiments
Strains Displacements	Strain-displacement relations	Geometric-based on logic

form of the relations between the source variables and response quantities (e.g., linear or nonlinear), and (4) the geometric characteristics of the structure and its components. A general classification, incorporating the aforementioned factors, is shown in Figure 28.2. Additional classifications can be made based on: (1) material response (e.g., homogeneous or nonhomogeneous, isotropic or anisotropic), (2) nature of source variables (e.g., conservative or nonconservative), and (3) coupling or noncoupling between source variables and response quantities (e.g., whether the changes in the source variables with structural deformations are pronounced or not).

28.2.3 Deterministic and Nondeterministic Methods

Deterministic methods of structural mechanics have become quite elaborate and include sophisticated mathematical models, highly refined computational methods, and optimization techniques. However, there is a growing realization among engineers during the past 25 years that unavoidable uncertainties in geometry, material properties, boundary conditions, loading, and operational environment must be taken into account to produce meaningful designs.

Three possible approaches for handling uncertainty can be identified, depending on the type of uncertainty and the amount of information available about the structural characteristics and the operational environment. The three approaches are: *probabilistic analysis*, *fuzzy-logic approach*, and *set theoretical, convex* (or antioptimization) *approach*. A discussion of the three approaches and their combinations is given in Elishakoff [1995]. In the probabilistic analysis, the structural characteristics and/or the source variables are assumed to be random variables (or functions), and the joint probability density functions of these variables are selected. The main objective of the analysis is the determination of the reliability of the system. Reliability is defined as the probability that the structure will adequately perform its intended mission for a specified interval of time, when operating under specified environmental conditions.

If the uncertainty is due to vague definition of structural and/or operational characteristics, imprecision of data and subjectivity of opinion or judgment, then fuzzy logic-based treatment is appropriate. The distinction between randomness and fuzziness is the fact that whereas randomness describes the uncertainty in the occurrence of an event (e.g., damage or failure of the structure), fuzziness describes the ambiguity of the event (e.g., imprecisely defined criteria for failure or damage — see Ross [1995]).

When the information about the structural and/or operational characteristics is fragmentary (e.g., only a bound on a maximum possible response function is known), then convex modeling can be used. Convex modeling produces the maximum or least favorable response, and the minimum or most favorable response, of the structure under the constraints within the set-theoretical description.

28.3 Formulation of Structural Mechanics Problems

28.3.1 Different Formulations of Structural Mechanics Problems

Several classifications can be made of the different formulations used for structural mechanics problems. Two of the major classifications are discussed next.

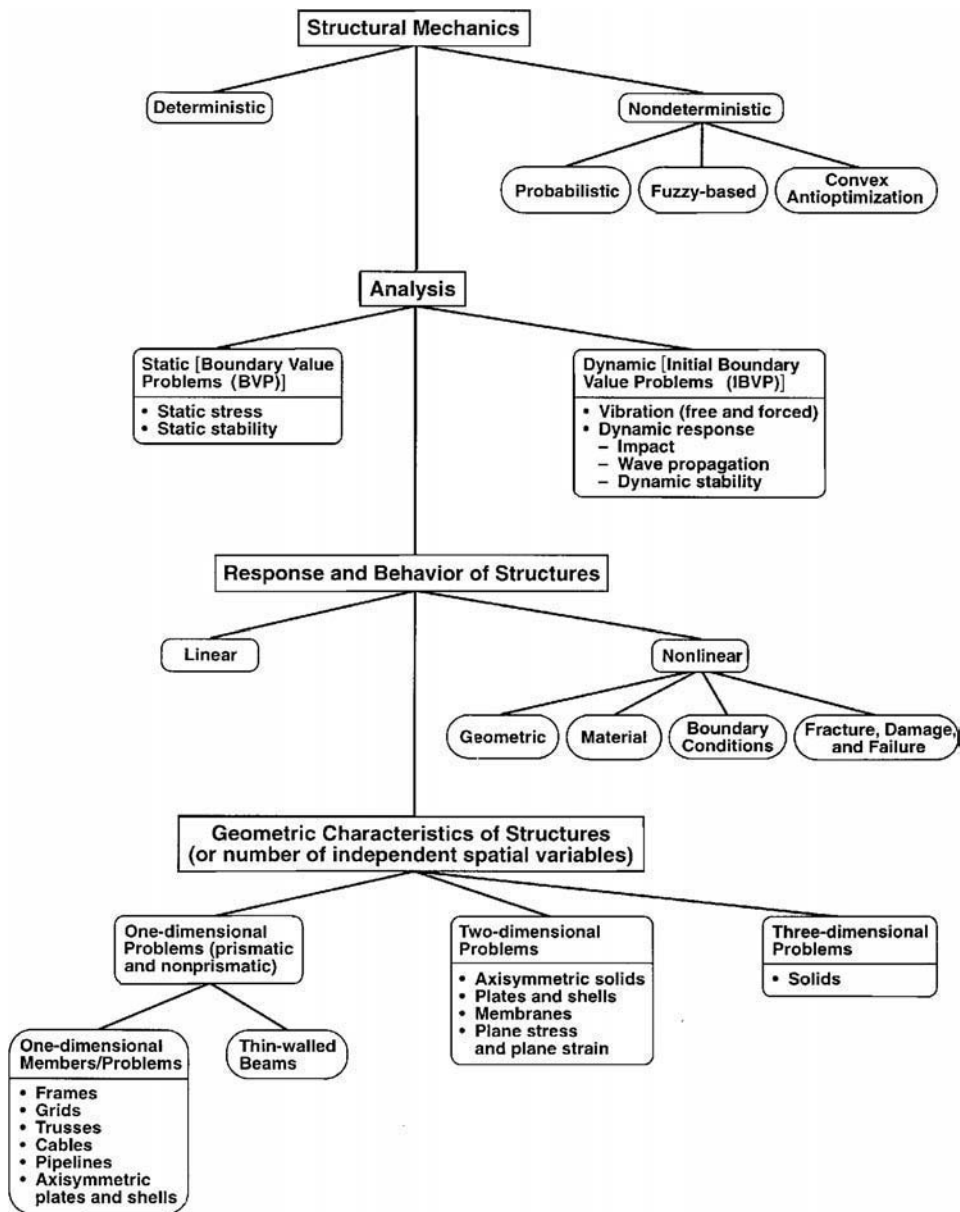

FIGURE 28.2 Classification of structural mechanics problems.

First, with respect to the approach used in deriving governing equations:

1. Differential equation formulation. This is the classical approach which is referred to as the *strong statement* of the problem.
2. Variational formulation. This is based on application of the principle of virtual displacements, and is referred to as the *weak statement* of the problem. A variety of variational principles for static and dynamic problems can be derived from the principle of virtual displacements (see, for example, Washizu [1982] and Geradin [1980]).
3. Integral, integro-differential or boundary integral equation formulation.

Some of the discretization techniques can be applied directly to the strong statement of the problem. The most notable example is the finite-difference method. Other techniques, such as finite elements, are typically used with the weak statement. Boundary element methods are generally used with the third formulation. Second, with respect to fundamental unknowns in the governing equations or the governing functional:

1. Single-field formulation in which the fundamental unknowns belong to one field. The most commonly used formulation is the displacement formulation.
2. Multifield formulation in which the fundamental unknowns belong to more than one field, i.e., stresses and displacements. A detailed discussion of multifield formulations is given in Noor [1980].

28.3.2 Description of the Motion of a Structure

For nonlinear structural problems, three basic choices need to be made, namely, the approach used for describing the motion, the kinematic description (i.e., deformation measure), and the kinetic description (i.e., stress measure). Typically, the choice of the deformation measure determines the stress measure since the two have to be work conjugates. The two most commonly used approaches for describing the motion are as follows.

First is a *total Lagrangian description*, in which all the kinematic and kinetic variables are referred to the initial (undeformed) configuration. The Green–Lagrange strain tensor is used as the measure of deformation, and the associated second Piola–Kirchhoff stress tensor is used as the stress measure. For large-rotation problems, it is useful to separate the rigid-body movement from stretching by using *local corotational frames* and the polar decomposition method. This eliminates the problems associated with approximating finite rotations using trigonometric functions (or series expansions thereof).

Second is an *updated Lagrangian description*, in which the kinematic and kinetic variables are referred to the current configuration. For small-strain problems, the Almansi strain is used as the measure of deformation and the associated Cauchy stress is used as the stress measure. For large-strain problems, it is convenient to use the velocity strain (or rate of deformation) and the Jaumann stress rate as the deformation and stress measures.

A detailed discussion of the aforementioned formulations and their combinations, along with the appropriate deformation and stress measures is given in Bathe [1996] and Cescotto et al. [1979].

28.4 Steps Involved in the Application of Computational Structural Mechanics to Practical Engineering Problems

28.4.1 Major Steps in the Application of Computational Structural Mechanics

The application of CSM to contemporary structural problems involves a sequence of five steps, namely (Figure 28.3):

- Observation of response phenomena of interest.
- Development of computational models for the numerical simulation of these phenomena. This in turn includes: (1) selecting mathematical models which represent the environmental effects and external forces and describe the phenomena, analyzing the models to ensure that the problem is properly formulated, and testing the range of validity of the models; and (2) development of a discrete model, computational strategy, and numerical algorithms to approximate the mathematical model. Successful computational models for structures are based on a thorough familiarity with the response phenomena being simulated and a good understanding of the mathematical models available to describe them.
- Development and assembly of software and/or hardware to implement the computational model.
- Postprocessing and interpretation of the predictions of the computational model.
- Utilization of the computational model in the analysis and design of engineering structures.

FIGURE 28.3 Application of CSM to practical structural problems.

Within this general framework, CSM is being used today in a broad range of practical applications. To date, large structural calculations are performed which account for complicated geometry, complex loading history, and material behavior. The applications span several industries, including aerospace, automotive, naval, nuclear, and microelectronics.

28.4.2 Selection of the Mathematical Models

The mathematical models are idealized representations of the real structure and its environment. Proper selection of the mathematical models is strongly influenced by the goals of the computation. The models will represent reality only if they take into consideration all factors which affect the conclusions drawn from them. The mathematical models are described by their governing equations (in one of the forms described in the previous section).

It is useful to view a particular mathematical model as one in a sequence (or hierarchy) of models of progressively increasing complexity. The effect of the model selection on the accuracy of the response predictions for simple structures, boundary conditions, and joints is discussed in Szabo and Babuska [1991]. A number of comparisons can be made between the predictions of the model being formulated and more elaborate models, i.e., models which account for a greater number of potentially relevant phenomena.

28.4.3 Discretization Techniques

Because of the complexity of the governing equations of the mathematical models used in representing real structures, exact solutions can only be obtained in very few cases, and one has to resort to approximate or numerical discretization techniques. A variety of approximate and numerical discretization techniques have been applied to structural mechanics problems. Two possible classifications of these techniques are shown in Figure 28.4 and are based on: (1) the formulation used, namely, differential equation, variational, or integral-equation formulation; and (2) modifications made in the form of the governing equations (replacement of the governing equations by an equivalent form).

The finite-element method is the most commonly used discretization technique to date. Extensive literature exists on various aspects of the finite-element method. A list of monographs, books, and conference proceedings on the method is given in Noor [1991]. The boundary element method is a computational tool for the boundary integral equation formulation. The method works with values of the dependent

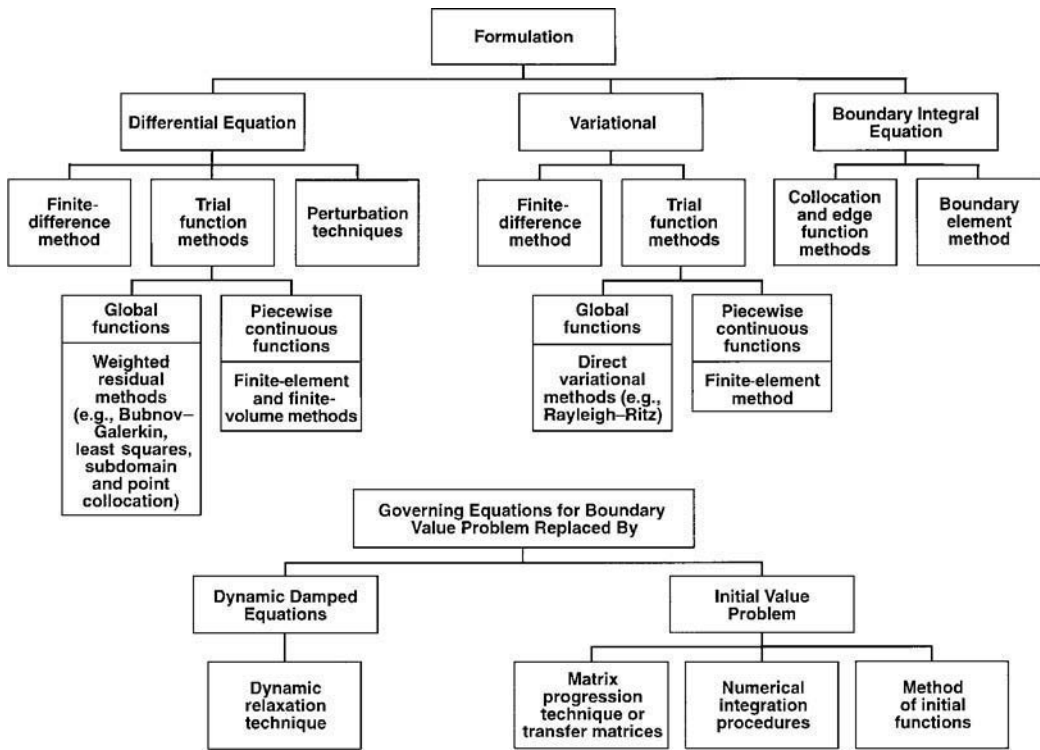

FIGURE 28.4 Approximate and numerical discretization techniques for structural mechanics problem.

variables on the boundary only, and therefore, is well suited to problems involving a large volume to surface ratio (Kane et al. [1993], Banerjee [1994]). In a number of applications, hybrid combinations of analytical and numerical discretization techniques were shown to be more effective than individual techniques, and resulted in dramatic savings in the computational effort (see, for example, Noor and Andersen [1992] and Noor [1994]).

28.4.4 Model and Mesh Generation

The reliability of the predictions of numerical discretization techniques (e.g., finite differences, finite elements, finite volumes, and boundary elements), and the computational effort involved in obtaining them, is very much influenced by the selection of the mesh and the procedure for generating it. Considerable effort has been devoted to the development of robust mesh generation procedures capable of producing controlled meshes over domains of arbitrary complex geometry. Finite-element mesh generation activities have been approached from both geometric modeling and adaptive finite-element viewpoints. Overviews and classifications of finite-element mesh generation methods are given in Shephard and Wentorf [1994], Shephard [1988], Ho-Le [1988], George [1991], Sabin [1991], and Mackerle [1993].

Among the recent activities on model generation are: (1) application of knowledge-based analysis-assistance tools, which allow a simple description of the analysis objectives and generate the corresponding discrete models appropriate for these objectives (Turkiyyah and Fenves [1996]); and (2) the development of paving and plastering techniques for automated generation of quadrilateral and hexahedral finite-element grids. These techniques generate well-formed elements (with reasonably small distortion metric), and are based on iteratively layering or paving rows of elements to the interior of a region's boundary (see Blacker and Stephenson [1991]).

28.4.5 Quality Assessment and Control of Numerical Solutions

Assessment of the reliability of computational models has been the focus of intense efforts in recent years. These efforts can be grouped into three general categories (see, for example, Noor and Babuska [1987], Noor [1992], Demkowicz et al. [1992], Krizek and Neittaanmaki [1987]): a posteriori error estimation, superconvergent recovery techniques, and adaptive improvement strategies. A posteriori error estimates use information generated during the solution process to assess the discretization errors. In superconvergent recovery techniques, more accurate values of certain response quantities (e.g., derivatives of fundamental unknowns) are calculated than those obtained by direct finite-element calculations. Adaptive strategies attempt to improve the reliability of the computational model by controlling the discretization error.

28.4.5.1 Error Estimation

Two broad classes of error estimation schemes are currently used: residual methods and interpolation methods. Residual methods involve the use of local residuals, usually as data in a local auxiliary problem designed to generate the local error to an acceptable accuracy. A significant amount of computation may be required in implementing these methods. In interpolation methods the available approximate solution for a given mesh (or time step) is used to estimate higher derivatives locally (e.g., local gradients or second derivatives). The higher derivatives are used in turn to determine the local error. Although these error estimates can be very crude, they are portable: a subroutine for computing local estimates can be added to virtually any existing code that operates on unstructured meshes with some effort.

Although significant progress has been made in developing a posteriori error estimates for linear elliptic problems, the error estimates for nonlinear and time-dependent problems are considerably less developed. This is particularly true for bifurcation problems, problems with multiple scales, and problems with resonance. Work on error estimation for highly nonlinear problems has mainly been a subject of ad hoc experimentation.

28.4.5.2 Superconvergent Recovery Techniques

Superconvergent recovery techniques refer to simple postprocessing techniques which provide increased accuracy of the sought quantities at some isolated points (e.g., Gauss-Legendre, Jacobi, or Lobatto); in a subdomain; or even in the whole domain (Krizek and Neittaanmaki [1987]). In the latter two cases, the techniques are referred to as local- and global-superconvergent recovery techniques, respectively. Recent work included development of local-superconvergent patch derivative techniques for both interior and boundary (or material interface) points (Babuska and Miller [1984a, 1984b], Zienkiewicz and Zhu [1992], Zienkiewicz et al. [1993], Tabbara et al. [1994]). It was shown in Zienkiewicz and Zhu [1992] and Zienkiewicz et al. [1993] that the superconvergent recovery technique can be used to obtain a posteriori error estimates for the finite-element solution.

28.4.5.3 Adaptive Strategies

Different strategies have been used for adaptive improvement of the numerical solutions, including: (1) mesh refinement (or derefinement) schemes, h methods; (2) moving mesh (node redistribution) schemes, r methods; (3) subspace enrichment schemes (selection of the local order of approximation), p methods; (4) mesh superposition schemes (overlapping local finite-element meshes on the global one), s methods (see, for example, Fish and Markolefas [1993, 1994]); and (5) hybrid (or combined) schemes. Examples of these schemes are: (1) simultaneous selection of the meshes and local order of approximation, h - p methods; recent theoretical results have shown that the fastest possible convergence rates can be attained by optimally decreasing the mesh size h and increasing the degree of the polynomial degree p in a special way; and (2) simultaneous selection of the meshes and node redistribution, h - r method. These methods can be effective in shock problems since an r -method might align the mesh along discontinuities prior to a mesh refinement.

28.5 Overview of Static, Stability, and Dynamic Analysis

Flow charts for the basic components of the solution methods for static stability and dynamic problems are given in Figure 28.5 and Figure 28.6. In this section a brief summary is given of the fundamental equations and solution techniques used in static, stability, and dynamic analysis. A single-field displacement formulation is used, and the spatial discretization of the structure is assumed to have been performed. The external load vector and associated displacement vector will henceforth be denoted by $\{F^{ext}\}$ and $\{X\}$, respectively. For linear problems $\{X\}$ is a linear function of the components of $\{F^{ext}\}$, and for nonlinear problems $\{X\}$ is a nonlinear function of these components.

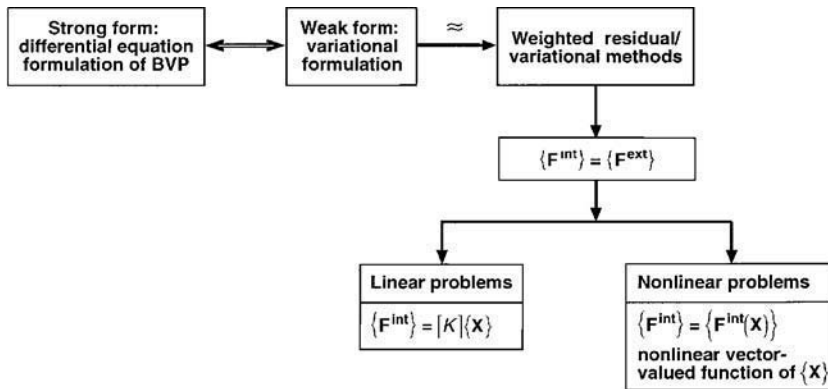

FIGURE 28.5 Basic components of solution methods for static problems.

FIGURE 28.6 Basic components of solution methods for dynamic problems.

28.5.1 Static Analysis

The equilibrium equations for the discretized structure can be written in the following form:

$$\{\mathbf{F}^{\text{int}}(\mathbf{X})\} = \{\mathbf{F}^{\text{ext}}\} \quad (28.1)$$

where $\{\mathbf{F}^{\text{int}}(\mathbf{X})\}$ is the vector of internal forces, which is a vector-valued function of the displacements $\{\mathbf{X}\}$. For conservative loading $\{\mathbf{F}^{\text{ext}}\}$ is independent of $\{\mathbf{X}\}$, and for nonconservative loading it is a function of $\{\mathbf{X}\}$.

The equilibrium path is usually expressed in terms of one or more variable path parameters (typically taken as load, displacement, or arc-length parameters in the solution space). For simplicity, in subsequent discussion the loading is assumed to be conservative and proportional to a single path parameter p . The displacement vector is therefore a function of p , i.e., $\{\mathbf{X}\} = \{\mathbf{X}(p)\}$.

For linear problems

$$\{\mathbf{F}^{\text{int}}(\mathbf{X})\} = [K]\{\mathbf{X}\} \quad (28.2)$$

where $[K]$ is the stiffness matrix of the discretized structure.

For nonlinear problems the solution of Equation 28.1 can be obtained by using an incremental or an incremental/iterative procedure. The two procedures are described next.

28.5.1.1 Incremental Procedure

If a purely incremental procedure (without iteration) is used, the equilibrium equations associated with the n th increment of the path parameter can be written in the following form:

$$\{\mathbf{F}^{\text{int}}\}_{n+1} = \{\mathbf{F}^{\text{int}}\}_n + \{\Delta\mathbf{F}^{\text{int}}\}_n \quad (28.3)$$

$$\{\mathbf{X}\}_{n+1} = \{\mathbf{X}\}_n + \{\Delta\mathbf{X}\}_n \quad (28.4)$$

where

$$\{\Delta\mathbf{F}^{\text{int}}\}_n = \{\mathbf{F}^{\text{ext}}\}_{n+1} - \{\mathbf{F}^{\text{int}}\}_n \quad (28.5)$$

$$\cong [K]_n\{\Delta\mathbf{X}\}_n \quad (28.6)$$

and

$$[K]_n = \left[\frac{\partial\{\mathbf{F}^{\text{int}}\}}{\partial\{\mathbf{X}\}} \right]_n \quad (28.7)$$

In Equation 28.3, Equation 28.4, and Equation 28.6, $\{\mathbf{F}^{\text{int}}\}_n$, $[K]_n$ and $\{\mathbf{X}\}_n$ refer to the vector of internal forces, tangent stiffness matrix, and displacement vector at the beginning of the n th increment.

Note that Equation 28.6 is approximate, and therefore, a purely incremental approach should be used with a sufficiently small step of the path parameter, so that the departure from the equilibrium position is small.

28.5.1.2 Incremental-Iterative Procedures

Incremental-iterative procedures are predictor-corrector continuation methods. For any increment of the path parameter, the displacement vector at the beginning of the increment is used to calculate suitable approximations (predictors) for the displacement vectors and the internal force vectors at the end of that increment. The approximations are then chosen as initial estimates for $\{\mathbf{X}\}$ and $\{\mathbf{F}^{\text{int}}\}$ in a corrective-iterative scheme. The process is described by the following recursive equations for the i th iteration cycle of the n th increment.

$$\{\mathbf{R}\}^{(i)} = \{\mathbf{F}^{\text{ext}}\}_{n+1} - \{\mathbf{F}^{\text{int}}\}_{n+1}^{(i-1)} \quad (28.8)$$

$$= [K]\{\Delta\mathbf{X}\}_n^{(i)} \quad (28.9)$$

and

$$\{\mathbf{X}\}_{n+1}^{(i)} = \{\mathbf{X}\}_{n+1}^{(i-1)} + \{\Delta\mathbf{X}\}_n^{(i)} \quad (28.10)$$

where $\{\mathbf{R}\}$ is the residual force vector.

The iterational process is continued until convergence. As a test for convergence, a number of error norms can be used. Two of the error norms are described next. First is the modified Euclidean (spectral) norm,

$$|e| = \frac{1}{n} |\Delta\mathbf{X}|/|\mathbf{X}| \leq \text{tolerance} \quad (28.11)$$

where n is the total number of displacement parameters in the model. Second is the energy norm,

$$|e| = \frac{[\{\Delta\mathbf{X}\}^{(i)}]^T [\{\mathbf{F}^{\text{ext}}\}_{n+1} - \{\mathbf{F}^{\text{int}}\}_{n+1}^{(i-1)}]}{[\{\Delta\mathbf{X}\}^{(1)}]^T [\{\mathbf{F}^{\text{ext}}\}_{n+1} - \{\mathbf{F}^{\text{int}}\}_n]} \leq \text{tolerance} \quad (28.12)$$

In Equation 28.8 to Equation 28.10 superscripts $(i - 1)$ and (i) refer to the values of the vectors at the beginning and end of the i th iteration cycle and $[K]$ is an approximation to the tangent stiffness matrix. A number of different iterative processes are distinguished by the choice of $[K]$.

28.5.1.3 Newton–Raphson Technique

The matrix $[K]$ is selected to be the tangent stiffness matrix based on the solution at the end of iteration cycle $(i - 1)$, i.e.,

$$[K] = \left[\frac{\partial \{\mathbf{F}^{\text{int}}\}}{\partial \{\mathbf{X}\}} \right]_{n+1}^{(i-1)} = [K]_{n+1}^{(i-1)} \quad (28.13)$$

28.5.1.4 Modified Newton Method

The matrix $[K]$ is selected to be the tangent stiffness matrix associated with increment m of the path parameter, where $m \leq n$, i.e.,

$$[K] = [K]_m \quad (28.14)$$

28.5.1.5 Broyden–Fletcher–Goldfarb–Shanno (BFGS) Method

A secant approximation to the stiffness matrix is used in successive iterations, through updating the inverse of the stiffness matrix using vector products. This is equivalent to updating the stiffness matrix, based on iteration history, as follows:

$$[K] = [K]_{n+1}^{(i-1)} \quad (28.15)$$

28.5.2 Dynamic Analysis

The balance equations of the discretized structure can be written in the form of a system of ordinary differential equations in time as follows:

$$[M]\{\ddot{\mathbf{X}}\} = \{\mathbf{F}^{\text{ext}}\} - \{\mathbf{F}^{\text{int}}\} \quad (28.16)$$

where $[M]$ is the global mass matrix and $\{\ddot{\mathbf{X}}\}$ is the acceleration vector. The explicit characterization of $[M]$, $\{\ddot{\mathbf{X}}\}$, and $\{\mathbf{F}^{\text{int}}\}$ depends on the particular structure under consideration. When damping or viscous effects exist, the vector $\{\mathbf{F}^{\text{int}}\}$ is a function of both the displacement vector and the velocity vector, i.e.,

$$\{\mathbf{F}^{\text{int}}\} = \{\mathbf{F}^{\text{int}}(\mathbf{X}, \dot{\mathbf{X}})\} \quad (28.17)$$

For linear problems, $\{\mathbf{F}^{\text{int}}\}$ is a linear function of both $\{\mathbf{X}\}$ and $\{\dot{\mathbf{X}}\}$, i.e.,

$$\{\mathbf{F}^{\text{int}}\} = [K]\{\mathbf{X}\} + [C]\{\dot{\mathbf{X}}\} \quad (28.18)$$

where $[C]$ is the global damping matrix.

For nonlinear problems $\{\mathbf{F}^{\text{int}}\}$ is a nonlinear function of $\{\mathbf{X}\}$ and $\{\dot{\mathbf{X}}\}$. At any time instant, the tangent stiffness and tangent damping matrices are given by

$$[K] = \left[\frac{\partial \{\mathbf{F}^{\text{int}}\}}{\partial \{\mathbf{X}\}} \right] \quad (28.19)$$

$$[C] = \left[\frac{\partial \{\mathbf{F}^{\text{int}}\}}{\partial \{\dot{\mathbf{X}}\}} \right] \quad (28.20)$$

The approaches used for obtaining the response-time history of the structure [solution of Equation 28.16] can be divided into two general categories, namely, direct integration techniques and modal superposition methods. The application of the two approaches to nonlinear dynamic analysis is described next.

28.5.2.1 Direct Integration Techniques

Direct temporal integration techniques are time-stepping (or step-by-step) strategies in which the response vectors at an initial time are used to generate the corresponding vectors at subsequent times. The techniques are based on: (1) satisfying the balance equations only at discrete time intervals and (2) assuming the functional dependence of the response vectors within each time interval. A variety of approximations for the response vectors within each time interval have been applied to structural dynamics problems. The approximations for the velocity and displacement vectors in the n th time step can be expressed as follows:

$$\{\dot{\mathbf{X}}\}_{n+1} = \frac{\alpha_1}{\Delta t} \{\dot{\mathbf{X}}\}_{n+1} + L(\{\dot{\mathbf{X}}\}_n, \{\dot{\mathbf{X}}\}_n, \dots) \quad (28.21)$$

$$\{\mathbf{X}\}_{n+1} = \frac{\alpha_2}{(\Delta t)^2} \{\mathbf{X}\}_{n+1} + M(\{\mathbf{X}\}_n, \{\dot{\mathbf{X}}\}_n, \{\dot{\mathbf{X}}\}_n, \dots) \quad (28.22)$$

where Δt is the time-step size, α_1 and α_2 are coefficients used in the approximation, L and M are functions of the response vectors, and subscripts n and $n + 1$ refer to the values of the vectors at the beginning and end of the n th time step.

Temporal integration techniques can be classified into two general categories, namely, explicit and implicit techniques. In explicit methods the response at the end of a time step is evaluated using the balance equations at the beginning of the time step [α_1 and α_2 in Equation 28.21 and Equation 28.22 are both zero]. By contrast, implicit methods use the balance equations at the end of the time step, with either α_1 and/or α_2 in Equation 28.21 and Equation 28.22 as nonzero.

Explicit techniques generally require fewer computations per time step than implicit techniques and can easily handle complex nonlinearities. However, the time-step size must often be very small to ensure numerical stability. By contrast, for linear problems, the time-step size in implicit techniques is only restricted by accuracy requirements. However, based on available information, unconditional stability of implicit methods in linear problems does not necessarily extend to nonlinear problems. Explicit and implicit techniques can also be classified into *single-step* and *multistep methods* according to whether the response at any instant is related to the response at one or more previous times. Detailed discussions and assessments of different explicit and implicit techniques are given in Belytschko and Hughes [1983] and Belytschko et al. [1987]. Mixed explicit-implicit techniques are described in Belytschko and Hughes [1983].

Herein, the application of two of the widely used temporal integration techniques, central difference explicit scheme and the Newmark implicit scheme is described. Both are single-step methods.

28.5.2.1.1 Central Difference Explicit Scheme

The central difference scheme is based on the following approximations for the velocity and the acceleration vectors:

$$\{\dot{\mathbf{X}}\}_{n+\frac{1}{2}} = \frac{1}{\Delta t} (\{\mathbf{X}\}_{n+1} - \{\mathbf{X}\}_n) \quad (28.23)$$

$$\{\ddot{\mathbf{X}}\}_n = \frac{1}{(\Delta t)^2} [\{\mathbf{X}\}_{n-1} - 2\{\mathbf{X}\}_n + \{\mathbf{X}\}_{n+1}] \quad (28.24)$$

where Δt is the time-step size, and subscripts n , $n + \frac{1}{2}$, and $n + 1$ refer to the values of the vectors at the beginning, middle, and end of the n th time step.

Based on Equation 28.25 and Equation 28.26, the update formulas for the velocity and displacement vectors are

$$\{\dot{\mathbf{X}}\}_{n+\frac{1}{2}} = \{\dot{\mathbf{X}}\}_{n-\frac{1}{2}} + \Delta t [M]^{-1} (\{\mathbf{F}^{\text{ext}}\}_n - \{\mathbf{F}^{\text{int}}\}_n) \quad (28.25)$$

$$\{\mathbf{X}\}_{n+1} = \{\mathbf{X}\}_n + \Delta t \{\dot{\mathbf{X}}\}_{n+\frac{1}{2}} \quad (28.26)$$

If a lumped (diagonal) mass matrix is used, then Equation 28.25 uncouples.

Initially (at $t = 0$), Equation 28.25 and Equation 28.26 are replaced by

$$\{\dot{\mathbf{X}}\}_{\frac{\Delta t}{2}} = \{\dot{\mathbf{X}}\}_0 + \frac{\Delta t}{2} [M]^{-1} (\{\mathbf{F}^{\text{ext}}\}_0 - \{\mathbf{F}^{\text{int}}\}_0) \quad (28.27)$$

and

$$\{\mathbf{X}\}_{\Delta t} = \{\mathbf{X}\}_0 + \frac{\Delta t}{2} \{\dot{\mathbf{X}}\}_{\frac{\Delta t}{2}} \quad (28.28)$$

where subscript 0 in Equation 28.27 and Equation 28.28 refers to the value of the vector at $t = 0$.

Note that the central difference scheme is only conditionally stable. Therefore, the time step Δt must be smaller than a critical value Δt_{cr} , which for linear problems is calculated from the smallest period of vibration T_{min} . Specifically,

$$\Delta t \leq \Delta t_{\text{cr}} = \frac{T_{\text{min}}}{\pi} = \frac{2}{\omega_{\text{max}}}$$

For nonlinear problems experience has shown that a 10–20% reduction in the time step is usually sufficient to maintain stability.

28.5.2.1.2 Newmark's Method

Newmark's method is based on the following approximations for the displacement and velocity vectors:

$$\{\mathbf{X}\}_{n+1} = \{\mathbf{X}\}_n + \Delta t \{\dot{\mathbf{X}}\}_n + (\Delta t)^2 \left[\left(\frac{1}{2} - \beta \right) \{\ddot{\mathbf{X}}\}_n + \beta \{\ddot{\mathbf{X}}\}_{n+1} \right] \quad (28.29)$$

$$\{\dot{\mathbf{X}}\}_{n+1} = \{\dot{\mathbf{X}}\}_n + \Delta t [(1 - \gamma) \{\ddot{\mathbf{X}}\}_n + \gamma \{\ddot{\mathbf{X}}\}_{n+1}] \quad (28.30)$$

where β and γ are free parameters of Newmark's method. The particular choice $\beta = 1/6$, $\gamma = 1/2$ corresponds to a linear approximation of the acceleration over the n th time step. The choice $\beta = 1/4$, $\gamma = 1/2$ corresponds to a constant average acceleration (trapezoidal rule), which is unconditionally stable for linear systems. The central difference scheme corresponds to $\beta = 0$, $\gamma = 1/2$.

If Equation 28.29 and Equation 28.30 are combined with the balance equations, Equation 28.16, a set of simultaneous algebraic equations result at each time step. For nonlinear problems, the equations are

nonlinear and are expressed by the following process for the n th time step:

1. Predict velocities and displacements using the explicit approximations

$$\{\tilde{\mathbf{X}}\}_{n+1} = \{\dot{\mathbf{X}}\}_n + \Delta t(1 - \gamma)\{\ddot{\mathbf{X}}\}_n \quad (28.31)$$

$$\{\tilde{\mathbf{X}}\}_{n+1} = \{\mathbf{X}\}_n + \Delta t\{\dot{\mathbf{X}}\}_n + (\Delta t)^2 \left(\frac{1}{2} - \beta \right) \{\ddot{\mathbf{X}}\}_n \quad (28.32)$$

where a tilde (\sim) refers to the predicted value of the vector.

2. Obtain corrections to the displacements, velocities, and accelerations by the following iterative process:

$$[K^*]\{\Delta\mathbf{X}\}_{n+1}^{(i)} = \{\mathbf{R}\}_{n+1}^{(i)} \quad (28.33)$$

$$\{\mathbf{X}\}_{n+1}^{(i+1)} = \{\mathbf{X}\}_{n+1}^{(i)} + \{\Delta\mathbf{X}\}_{n+1}^{(i)} \quad (28.34)$$

$$\{\dot{\mathbf{X}}\}_{n+1}^{(i+1)} = \{\dot{\mathbf{X}}\}_{n+1}^{(i)} + \gamma\Delta t\{\ddot{\mathbf{X}}\}_{n+1}^{(i+1)} \quad (28.35)$$

$$\{\ddot{\mathbf{X}}\}_{n+1}^{(i+1)} = \frac{1}{\beta(\Delta t)^2} \left[\{\mathbf{X}\}_{n+1}^{(i+1)} - \{\tilde{\mathbf{X}}\}_{n+1} \right] \quad (28.36)$$

For $i = 0$, the following values are used for the displacement, velocity, and acceleration vectors

$$\{\mathbf{X}\}_{n+1}^{(0)} = \{\tilde{\mathbf{X}}\}_{n+1}$$

$$\{\dot{\mathbf{X}}\}_{n+1}^{(0)} = \{\tilde{\dot{\mathbf{X}}}\}_{n+1}$$

$$\{\ddot{\mathbf{X}}\}_{n+1}^{(0)} = 0$$

where superscript (0) refers to the value of the vector associated with $i = 0$, $[K^*]$ and $\{\mathbf{R}\}$ in Equation 28.33 are the effective stiffness matrix and the residual vector given by

$$[K^*] = [K] + \frac{\gamma}{\beta\Delta t}[C] + \frac{1}{\beta(\Delta t)^2}[M] \quad (28.37)$$

$$\{\mathbf{R}\}_{n+1}^{(i)} = \{\mathbf{F}^{\text{ext}}\}_{n+1} - [M]\{\ddot{\mathbf{X}}\}_{n+1}^{(i)} - \{\mathbf{F}^{\text{int}}\}_{n+1}^{(i)} \quad (28.38)$$

Superscripts i and $i + 1$ refer to the values of the vectors at the beginning and end of the i th iteration cycle. As for nonlinear static problems, the choice of $[K^*]$ depends on the iterative procedure used.

28.5.2.1.3 Modal Superposition Method

In this method the structural response at any time is expressed as a linear combination of a number of preselected modes (or basis vectors). This is expressed by the following transformation:

$$\{\mathbf{X}\} = [\Gamma]\{\boldsymbol{\psi}\} \quad (28.39)$$

where $[\Gamma]$ is the transformation matrix whose columns are the modes (or basis vectors) and $\{\boldsymbol{\psi}\}$ is a vector of unknown coefficients (amplitudes of the preselected modes).

The number of modes (or basis vectors) is usually selected to be much smaller than the number of degrees of freedom of the discretized structure (components of the vector $\{\mathbf{X}\}$). A Bubnov–Galerkin technique is used to approximate the balance equations of the discretized structure, Equation 28.16, by a much smaller system of equations in $\{\boldsymbol{\psi}\}$. The resulting equations have the following form:

$$[\Gamma]^T[M][\Gamma]\{\ddot{\boldsymbol{\psi}}\} = [\Gamma]^T\{\mathbf{F}^{\text{ext}}\} - [\Gamma]^T\{\mathbf{F}^{\text{int}}(\boldsymbol{\psi})\} \quad (28.40)$$

For linear problems, if the basis vectors are selected to be the free vibration modes of the structure, Equation 28.40 uncouples in the components of $\{\Psi\}$. For nonlinear problems the free vibration modes and frequencies of the structure change with time.

The mode superposition technique is effective when the response can be adequately represented by few modes and the time integration has to be carried out over many time steps (e.g., earthquake loading), and the cost of calculating the required modes is reasonable.

28.5.3 Energy Balance in Transient Dynamic Analysis

Energy balance (conservation) in transient analysis is a reflection of the accuracy of the time integrator. Furthermore, conservation properties are intimately related to stability. The construction of stable integrators is often approached by enforcing conservation laws.

In linear problems, instability can be easily detected by the spurious growth in velocities. On the other hand, in large structural problems with material nonlinearities the energy generated by an instability may be rapidly dissipated as the material becomes inelastic and the erroneous results does not become obvious to the user. This kind of instability has been termed *arrested instability* in Belytschko and Hughes [1983] and the energy balance check described subsequently was suggested to detect it.

Let $\{\Delta \mathbf{X}\}_n$ be the increment of the displacement vector from time t_n to time t_{n+1} , and let the internal energy, and the increment of external work be approximated by the trapezoidal rule as follows:

$$U_j = \sum_{l=1}^{j-1} \frac{1}{2} \{\Delta \mathbf{X}\}_l^T \left(\{\mathbf{F}^{\text{int}}\}_l + \{\mathbf{F}^{\text{int}}\}_{l+1} \right) \quad (28.41)$$

$$\Delta W_j = \frac{1}{2} \{\Delta \mathbf{X}\}_j^T \left(\{\mathbf{F}^{\text{ext}}\}_j + \{\mathbf{F}^{\text{ext}}\}_{j+1} \right) \quad (28.42)$$

The kinetic energy T_j at time t_j is given by

$$T_j = \frac{1}{2} \{\dot{\mathbf{X}}\}_j^T [M] \{\dot{\mathbf{X}}\}_j \quad (28.43)$$

If the mass matrix is positive definite, then the energy and the displacements of the structure at time t_{n+1} are bounded if the following inequality is satisfied:

$$T_{n+1} + U_{n+1} \leq (1 + \epsilon)(T_n + U_n) + \Delta W_n \quad (28.44)$$

where ϵ is a small number. Equation 28.44 provides an energy balance check provided $U_n \geq 0$.

Detailed discussion of the stability, convergence, and decay of energy is given in Hughes [1976]. Examples of the construction of integrators through energy conservation are given in Hughes et al. [1978] and Haug et al. [1977].

28.5.4 Stability Analysis

A number of instability phenomena can occur in structures depending on the structural characteristics and operational environment. These instabilities can be either time dependent or time invariant. Time-dependent instability analysis can be performed by using Lyapunov's method (see Kratzig and Eller [1992] and Kounadis and Kratzig [1995]). Time-invariant instabilities can be in the form of bifurcation points (simple or multiple) or limit points in the solution path. The *critical loads* associated with these points are referred to as bifurcation buckling and limit loads, respectively.

The algorithmic tools for *time-invariant instability analysis* encompass three distinct aspects: (1) nonlinear (or linear) analysis of the prebuckling state, using the nonlinear equations — Equation 28.1 [or the linearized version, Equation 28.2]; (2) determination of the critical points (e.g., bifurcation and/or limit points) on the equilibrium path; and (3) tracing the postcritical response. Critical points can be detected by the singularity of the tangent stiffness matrix, Equation 28.19. Bifurcation loads associated with linear

prebuckling state can be determined by solving a linear eigenvalue problem as described in the succeeding subsection. Special numerical algorithms are available for overcoming the difficulties associated with commonly used iterative techniques near critical points (see, for example, Riks [1984] and Crisfield [1983]).

28.5.5 Eigenvalue Problems

Undamped free vibration and linear (bifurcation) buckling problems of structures can be represented by the general linear matrix eigenvalue equation

$$[K]\{\mathbf{X}\} = \lambda[B]\{\mathbf{X}\} \quad (28.45)$$

where $[K]$ is the stiffness matrix of the discretized structure, $\{\mathbf{X}\}$ is the displacement vector, $[B]$ is the mass matrix for free vibration problems or the negative of the geometric stiffness matrix for buckling problems, and λ is the eigenvalue square of vibration frequency or buckling load parameter. Typically, most of the elements of $[K]$ and $[B]$ are zero and only a few pairs $(\lambda, \{\mathbf{X}\})$ are wanted.

Although the governing equations for both the free vibration and linear buckling problems are similar, the properties of the two matrices $[K]$ and $[B]$ are different. For vibration problems, the stiffness matrix can be positive definite, positive semidefinite, or indefinite. For an unsupported structure the stiffness matrix is indefinite. If the structure is stable (except for rigid motions), the stiffness matrix will be positive semidefinite. Also, some lumping procedures can produce mass matrices, which are positive semidefinite because they have zero mass elements on the diagonal. The mass matrix can be positive definite or semidefinite (if some of the diagonal mass elements are zero, due to the lumping procedure used).

For buckling problems, the stiffness matrix is positive definite, provided the deformation state is stable (which may be assessed by a buckling analysis). The geometric stiffness matrix may be indefinite.

The preferred eigenvalue extraction techniques in use to date are sampling techniques. They create a linear operator (or matrix) and apply it to a sequence of carefully constructed vectors. From these transformed vectors the dominant eigenvectors and their eigenvalues can be approximated. Examples of these techniques are subspace iteration (or simultaneous iteration) and Lanczos techniques. The details of these methods are described in Bathe [1996], Parlett [1987], and Hughes [1987].

The eigensolver algorithms typically generate a set of eigenpairs (eigenvalues and associated eigenvectors) for the lowest eigenstates of the system, i.e., for the smallest eigenvalues (in absolute order). Often, it is necessary to compute eigenpairs for cases other than the set of smallest eigenvalues. This may be performed by introducing a shift α , which defines the shifted eigenvalue

$$\lambda = \bar{\lambda} + \alpha$$

The shifted eigenvalue problem is

$$[[K] - \alpha[B]]\{\mathbf{X}\} = \bar{\lambda}[B]\{\mathbf{X}\} \quad (28.46)$$

Equation 28.46, with a nonzero α , can be used to compute the eigenvalues for an unsupported structure (one for which $[K]$ is singular).

28.5.6 Sensitivity Analysis

Sensitivity analysis refers to methods of calculating the rates of change of: (1) response quantities (e.g., displacements, stresses, vibration frequencies, and buckling loads) with respect to changes in the structure characteristics (e.g., geometric and material parameters of the structure) and (2) the optimum design variable values with respect to changes in the structure parameters (e.g., applied loads and allowable stresses). The two types of calculations are usually designated by response and optimum design sensitivity analysis, and the rates of change are referred to as sensitivity coefficients.

A number of techniques have been developed for evaluating the sensitivity coefficients of response quantities using either the governing discrete equations or continuum equations of the structure. The

techniques used with the discrete equations can be grouped into three categories: *analytical, direct differentiation methods; finite difference methods; and semianalytical or quasianalytical methods* (see Kleiber and Hisada [1993] and Hinton and Sieng [1994]).

Methods for computing sensitivity coefficients for linear structural response have been developed for over 20 years (see, for example, Haftka and Adelman [1989], Haber et al. [1993], and Choi [1993]). However, only recently have attempts been made to extend the domain of sensitivity analysis to (1) nonlinear structural response and to path-dependent problems, for which the sensitivity coefficients depend also on the deformation history (e.g., viscoplastic response and frictional contact — see, for example, Kleiber et al. [1994], Kulkarni and Noor [1995], and Karaoglan and Noor [1995]); and (2) structural systems exhibiting probabilistic uncertainties.

Because of the importance of its role in structural optimization and in assessing the effect of uncertainties in the input parameters on the structural response, some commercial software systems have incorporated response sensitivity analysis into their systems. Also, an automatic differentiation facility has been developed for evaluating the derivatives of functions defined by computer programs exactly to within machine precision. The facility, automatic differentiation of Fortran (ADIFOR), is described in Chinchalkar [1994] and Carle et al. [1994]. The use of ADIFOR to evaluate the sensitivity coefficients from incremental/iterative forms of three-dimensional fluid flow problems is discussed in Sherman et al. [1994], and the additional facilities needed for ADIFOR to become competitive with hand-differentiated codes are listed in Carle et al. [1994].

28.5.7 Strategies and Numerical Algorithms for New Computing Systems

In recent years, intense efforts have been devoted to the development of efficient computational strategies and numerical algorithms which exploit the capabilities of new computing systems (in particular, the vector and parallel processing of the powerful high-performance computers — see, for example, Onaté et al. [1992]). Efficient direct and iterative numerical algorithms have been developed for solution of large sparse linear systems of equations (see Wang and Bruch [1993], Law and Mackay [1993], Qin and Mackay [1993], Vaughan [1991], and Papadrakakis [1993]).

Most parallel strategies are related to the *divide-and-conquer* paradigm based on breaking a large problem into a number of smaller subproblems which may be solved separately on individual processors. The degree of independence of the subproblems is a measure of the effectiveness of the algorithm since it determines the amount and frequency of communication and synchronization. The numerical algorithms developed for structural analysis can be classified into three major categories: namely, *elementwise algorithms, nodewise algorithms, and domainwise algorithms*.

The elementwise parallel algorithms include element-by-element equation solvers and parallel frontal equation solvers. The nodewise parallel equation solvers include node-by-node iterative solvers as well as column-oriented direct solvers. The domainwise algorithms include nested dissection-based (substructuring) techniques and domain-decomposition methods. The first two categories of numerical algorithms allow only small granularity of the parallel tasks and require frequent communication among the processors. By contrast, the third category allows a larger granularity, which can result in improved performance for the algorithm.

Nested dissection ordering schemes have been found to be effective in reducing both the storage requirements and the total computational effort required of direct factorization [Noor et al. 1978]. The performance of nested dissection-based linear solvers depends on balancing the computational load across processors in a way that minimizes interprocessor communication. Several nested dissection ordering schemes have been developed which differ in the strategies used in partitioning the structure and selecting the separators. Among the proposed partitioning strategies are: recursive bisection strategies (e.g., spectral graph bisection, recursive coordinate bisection, and recursive graph bisection [Pothen et al. 1990, Hendrickson and Leland 1992]); combinatorial and design-optimization based strategies (e.g., simulated annealing algorithm, genetic algorithm and neural-network-based techniques [Khan and Topping 1993]); and heuristic strategies (e.g., methods based on geometric projections and mappings; and algorithms based

on embedding the problem in Euclidean space [Bui and Jones 1993]). For highly irregular and/or three-dimensional structures the effectiveness of nested dissection-based schemes may be reduced. However, this is also true for most other parallel numerical algorithms. Scalable parallel computational strategies for nonlinear, postbuckling, and dynamic contact/impact problems are presented in Watson and Noor [1996a, 1996b].

28.6 Brief History of the Development of Computational Structural Mechanics Software

Development of CSM software spans a period of less than 40 years, and may be divided into four stages, each stage lasting approximately 8–10 years. In the first stage (during the 1950s and 1960s), the aircraft industry pioneered development of in-house finite-element programs. These programs were generally based on the force method of analysis and were used to automate analysis of highly redundant structural components. Subsequent efforts in industry and academia led to development of simple two- and three-dimensional finite elements based on the displacement formulation. The variational process for formulating the elemental matrices was also introduced in this period.

In the second stage, general-purpose finite-element programs, such as NASTRAN, ASKA, ANSYS, STARDYNE, MARC, SAP, SESAM, and SAMCEF, were released for public use in the U.S. and Europe. These programs brought a significant technology base that led to development of numerous commercial finite-element software systems. This development included mixed and hybrid finite-element models with the fundamental unknowns consisting of stress and displacement parameters, efficient numerical algorithms for the solution of algebraic equations and extraction of eigenvalues, and substructuring and modal synthesis techniques for handling large problems. The finite-element method's success in linear static problems has encouraged bolder applications to nonlinear and transient response problems.

The third stage involved refining the commercial software codes and expanding their technology base. Design optimization techniques were also developed in this stage, as were pre- and postprocessing software and computer-aided design systems. The technology development included singular elements for fracture mechanics applications, boundary-element techniques, coupling of finite elements with other discretization techniques such as boundary elements, and quality assurance methods for both software and finite-element models.

The fourth stage included in the adaptation of CSM software to new computing systems (vector, multiprocessor, and massively parallel machines), development of efficient computational strategies and numerical algorithms for these machines, widespread availability of CSM software on personal computers and workstations, and the addition of substantial nonstructural modeling and analysis capabilities to CSM software systems such as MSC/NASTRAN and ANSYS. The latter capabilities were added because future flight vehicles and high-performance engineering systems (e.g., health monitoring aircraft and micro-sized spacecraft) will require significant interactions between CSM and other disciplines such as aerodynamics, controls, acoustics, electromagnetics, and optics.

Technology development in the fourth stage included introduction of advanced material models, development of stochastic models and probabilistic methods for structural analysis and design, and development of facilities for quality assessment and control of numerical simulations.

The four stages of CSM software development parallel the four stages of the computing environment's evolution: noncentralized mainframes, centralized mainframes, mainframe computing with timesharing, and distributed computing and networking. A summary of the major characteristics of currently used finite-element systems is given in Mackerle and Fredriksson [1988], and a guide to information sources on finite-element methods is given in Mackerle [1991]. Commercial finite-element programs for structural analysis have a rich variety of elements, and are widely used for performing structural calculations on large components and/or entire structures (see, for example, [Figure 28.7](#) to [Figure 28.9](#)).

28.7 Characteristics of Future Engineering Systems and Their Implications on Computational Structural Mechanics

The demands that future high-performance engineering systems place on CSM differ somewhat from those of current systems. The radically different and more unpredictable operational environments for many of the systems (e.g., future flight vehicles) are one reason for this difference. Another is the stringency

FIGURE 28.9 DYNA 3-D finite element car model used in crash simulation: 27,000 shell elements, 162,000 degrees of freedom. (Courtesy of Lawrence Livermore.)

of design requirements for high performance, light weight, and economy. The technical needs for future high-performance engineering systems include:

1. Development of new high-performance material systems, such as smart/intelligent material systems
2. Development of novel structural concepts, such as structural tailoring and smart/intelligent structures, with active and/or passive adaptive control of dynamic deformations
3. Investigation of more complex phenomena and interdisciplinary couplings such as fluid flow/acoustics/thermal/control/electromagnetic/optics, and structural couplings.

28.8 Primary Pacing Items and Research Issues

The primary pacing items for CSM are:

1. High-fidelity modeling of the structure and its components
2. Failure and life prediction methodologies
3. Hierarchical, integrated methods and adaptive modeling techniques
4. Nondeterministic analysis, modeling methods, and risk assessment
5. Validation of numerical simulations
6. Multidisciplinary analysis and design optimization

For each of the aforementioned items, attempts should be made to exploit the major characteristics of high-performance computing technologies, as well as the future computing environment. The six primary pacing items are described subsequently. Note that some of the tasks within the pacing items are of a generic nature. Others are specific to certain components of future engineering systems (e.g., propulsion systems or airframes).

28.8.1 High-Fidelity Modeling of the Structure

The reliability of the predictions of response, failure, and life of structures is critically dependent on: (1) the accurate characterization and modeling of material behavior and (2) high-fidelity modeling of the critical details of the structure and its components (e.g., joints, damping, and for large deformations, frictional contact between the different parts of the structure). The simple material models used to date are inadequate for many of the future applications, especially those involving severe environment (e.g., high temperatures). Needed work on material modeling can be grouped in two general areas: (1) modeling the response and damage of advanced material systems in the actual operating environment of future engineering systems and (2) numerical simulation of manufacturing (fabrication) processes.

Advanced material systems include new polymer composites, metal-matrix composites, ceramic composites, carbon/carbon, and advanced metallics. The length scale selected in the model must be adequate for capturing the response phenomena of interest (e.g., micromechanics, mesomechanics, and macromechanics). For materials used in high-temperature applications, work is needed on the modeling of damage accumulation and propagation to fracture; modeling of thermoviscoplastic response, thermal-mechanical cycling, and ratcheting; and prediction of long-term material behavior from short-term data, which are particularly important.

28.8.2 Failure and Life Prediction Methodologies

Practical numerical techniques are needed for predicting the life, as well as the failure initiation and propagation in structural components made of new, high-performance materials in terms of measurable and controllable parameters. Examples of these materials are high-temperature materials; piezoelectric composites; and electronic, optical, and smart materials. For some of the materials, accurate constitutive descriptions, failure criteria, damage theories, and fatigue data are needed, along with more realistic characterization of interface phenomena (such as contact and friction). The constitutive descriptions may require investigations at the microstructure level or even the atomic level, as well as carefully designed and conducted experiments. Failure and life prediction of structures made of these materials is difficult and numerical models often constructed under restricting assumptions may not capture the dominant and underlying physical failure mechanisms. Moreover, material failure and structural response (such as instability) often couple in the failure mechanism.

28.8.3 Hierarchical, Integrated Multiple Methods and Adaptive Modeling Techniques

The effective use of numerical simulations for predicting the response, life, performance, and failure of future engineering systems requires strategies for treating phenomena occurring at disparate spatial and time scales, using reasonable computer resources. The strategies are based on using multiple mathematical models in different regions of the structure to take advantage of efficiencies gained by matching the model to the expected response in each region. To achieve the full potential of hierarchical modeling, there should be minimal reliance on a priori assumptions about the response. This is accomplished by adding adaptivity to the strategy. The key tasks of the research in this area are: (1) simple design-oriented models for use in the early stages of the design process; (2) rational selection of a set of nested mathematical models for different regions, and discretization techniques for use in conjunction with the mathematical models, which in turn requires the availability of a capability for holistic modeling from micro to structural response with varying degrees of accuracy; (3) simulation of local phenomena through global/local methodologies; (4) automated (or semiautomated) coupling of different mathematical/discrete models; (5) error estimation and adaptive modeling strategies; (6) efficient methods for coupling different components (e.g., engine airframe and rotor/engine frame); and (7) sensitivity analysis to assess the sensitivity of the response to each of the parameters neglected in the current mathematical model.

28.8.4 Nondeterministic Analysis, Modeling, and Risk Assessment

The new methodology developed for treating different types of uncertainties in geometry, material properties, boundary conditions, loading, and operational environment in the structural analysis formulation of structural components needs to be extended to the design and risk assessment of engineering systems. The ability to quantify inherent uncertainties in the response of the structure is obviously of great advantage. However, the principal benefit of using any nondeterministic method consists of the insights into engineering, safety, and economics that are gained in the process of arriving at those quantitative results and carrying out reliability analyses. As future engineering structures become more complicated, modeling of failure mechanisms will account for uncertainties from the beginning of the design process, and potential design improvements will be evaluated to assess their effects on reducing overall risk. The results combined with economic considerations will be used in systematic cost-benefit analyses (perhaps also done on a non-deterministic basis) to determine the structural design with the most acceptable balance of cost and risk.

28.8.5 Validation of Numerical Simulations

In addition to selecting a benchmark set of structures for assessing new computational strategies and numerical algorithms, a high degree of interaction and communication is needed between computational modelers and experimentalists. This is done on four different levels, namely:

1. Laboratory tests on small specimens to obtain material data
2. Component tests to validate computational models
3. Full-scale tests to validate the modeling of details, and for flight vehicles
4. Flight tests to validate the entire modeling process

28.8.6 Multidisciplinary Analysis and Design Optimization

The realization of new complex engineering systems requires integration between the structures discipline and other traditionally separate disciplines such as aerodynamics, propulsion, and control. This is mandated by significant interdisciplinary interactions and couplings which need to be accounted for in predicting response, as well as in the optimal design of these structures. Examples are the couplings between the aerodynamic flow field, structural heat transfer, and structural response of high-speed aircraft and propulsion systems and the couplings between the control system and structural response in control-configured aircraft and spacecraft. This activity also includes design optimization with multiobjective functions (e.g., performance, durability, integrity, reliability, and cost), and multiscale structural tailoring (micro, local, and global levels). For propulsion systems, it also includes design with damping for high-cycle fatigue, low-cycle fatigue, and acoustic fatigue.

Typically, in the design process questions arise regarding influence of design variable changes on system behavior. Answers to these questions, quantified by the derivatives of behavior with respect to the design variables or by parametric studies, guide design improvements toward a better overall system. In large applications, this improvement process is executed by numerical optimization, combined with symbolic/artificial intelligence (AI) techniques, and human judgment aided by data visualization. Efficiency of the computations that provide data for such a process is decisive for the depth, breadth, and rate of progress achievable, and hence, ultimately, is critical for the final product quality.

28.8.7 Related Tasks

For CSM to impact the design process, the following tasks need to be addressed by the research community: (1) development of automated or semiautomated model (and mesh) generation facilities; (2) pre- and postdata processing and use of advanced visualization technology, including multimedia and virtual reality facilities; and (3) adaptation of object-oriented technology and AI tools (knowledge-based expert systems and neural networks) to CSM.

CSM's wide acceptance can affect the design and operation of future engineering systems and structures in three ways. It can provide a better understanding of the phenomena associated with response, failure, and life, thereby identifying desirable structural design attributes. CSM can verify and certify designs and also allow low-cost modifications to be made during the design process. Finally, it can improve the design team's productivity and allow major improvements and innovations during the design phase, enabling fully integrated design in an integrated product and process development (IPPD) environment. Such an environment allows computer simulation of the entire life cycle of the engineering system, including material selection and processing, multidisciplinary design, automated manufacturing and fabrication, quality assurance, certification, operation, health monitoring and control, retirement, and disposal.

Nomenclature

- B** = Magnetic flux density
- C** = Coefficient matrix of flux-vector formulation
- D** = Electric displacement
- E** = Electric field strength
- F** = Flux vector component
- H** = Magnetic flux intensity
- i, j, k = Index of discretization
- J** = Electric current density
- n = Index of temporal level of solution
- S** = Similar matrix of diagonalization
- t = Time
- U** = Dependent variables
- V** = Elementary-cell volume
- x, y, z = Cartesian coordinates
- Δ = Forward difference operator
- λ = Eigenvalue
- ξ, η, ζ = Transformed coordinates
- ∇ = Gradient, backward difference operator

29.1 Introduction

Computational electromagnetics (CEM) is a natural extension of the analytical approach in solving the Maxwell equations. In spite of the fundamental difference between representing the solution in a continuum and in a discretized space, both approaches satisfy all pertaining theorems rigorously. The analytic approach

to electromagnetics is elegant, and the results can describe the specific behavior as well as the general patterns of a physical phenomenon in a given regime. However, exact solutions to the Maxwell equations are usually unavailable. Some of the closed-form results that exist have restrictive underlying assumptions that limit their range of validity. Solutions of CEM generate only a point value for a specific simulation, but complexity of the physics or of the field configuration is no longer a limiting factor. The numerical accuracy of CEM is an issue to be addressed. Nevertheless, with the advent of high-performance computing systems, CEM is becoming a mainstay for engineering applications.

CEM in the present context is focused on simulation methods for solving the Maxwell equations in the time domain. First of all, time dependence is the most general form of the Maxwell equations, and the dynamic electromagnetic field is not confined to a time-harmonic phenomenon. Therefore, CEM in the time domain has the widest range of engineering applications. In addition, several new numerical algorithms for solving the first-order hyperbolic partial differential equations, as well as coordinate transformation techniques, were introduced recently to the CEM community. These finite-difference and finite-volume numerical algorithms were devised specifically to mimic the physics involving directional wave propagation. Meanwhile, very complex shapes associated with the field can be easily accommodated by incorporating a coordinate transformation technique. These methodologies have the potential to radically change future research in electromagnetics.

In order to use CEM effectively, it will be beneficial to understand the fundamentals of numerical simulation and its limitations. The inaccuracy incurred by a numerical simulation is attributable to the mathematical model for the physics, the numerical algorithm, and the computational accuracy. In general, differential equations in computational electromagnetics consist of two categories: the first-order divergence–curl equations and the second-order curl–curl equations [Elliott 1966, Harrington 1961, 1968]. In specific applications, further simplifications into the frequency-domain or the Helmholtz equations and the potential formulation have been accomplished. Poor numerical approximations to physical phenomena can result, however, from solving overly simplified governing equations. Under these circumstances, no meaningful quantification of errors for the numerical procedure can be achieved. Physically incorrect values and inappropriate implementation of initial and/or boundary conditions are another major source of error. The placement of the far-field boundary and the type of initial or boundary conditions have also played an important role. These concerns are easily appreciated in the light of the fact that the governing equations are identical, but the different initial/boundary conditions generate different solutions.

Numerical accuracy is also controlled by the algorithm and computing system adopted. The error induced by the discretization consists of the roundoff and the truncation error. The roundoff error is contributed by the computing system and is problem-size-dependent. Since this error is random, it is the most difficult to evaluate. One anticipates that this type of error will be a concern for solution procedures involving large-scale matrix manipulation such as the method of moments and the implicit numerical algorithm for finite-difference or finite-volume methods. The truncation error for time-dependent calculations appears as dissipation and dispersion, which can be assessed and alleviated by mesh-system refinements.

Finally, numerical error can be the consequence of a specific formulation. The error becomes pronounced when a special phenomenon is investigated or when a discontinuous and distinctive stratification of the field is encountered, such as a wave propagating through the interface between media of different characteristic impedances, for which the solution is piecewise continuous. Only in a strongly conservative formulation can the discontinuous phenomenon be adequately resolved. Another example is encountered in radar cross-section simulation, where the scattered-field formulation has been shown to be superior to the total-field formulation.

The Maxwell equations in the time domain consist of a first-order divergence–curl system and are difficult to solve by conventional numerical methods. Nevertheless, the pioneering efforts by Yee and others have attained impressive achievements [Yee 1966, Taflove 1992]. Recently, numerical techniques in CEM have been further enriched by development in the field of computational fluid dynamics (CFD). In CFD, the Euler equations, which are a subset of the Navier–Stokes equations, have the same partial-differential-system

classification as that of the time-dependent Maxwell equations. Both are hyperbolic systems and constitute initial-value problems [Sommerfeld 1949]. For hyperbolic partial differential equations, the solutions need not be analytic functions. More importantly, the initial values together with any possible discontinuities are continued along a time–space trajectory, which is commonly referred to as the characteristic. A series of numerical schemes have been devised in the CFD community to duplicate the directional information-propagation feature. These numerical procedures are collectively designated as the characteristic-based method, which in its most elementary form is identical to the Riemann problem [Roe 1986]. The characteristic-based method when applied to solve the Maxwell equations in the time domain has exhibited many attractive attributes. A synergism of the new numerical procedures and scalable parallel-computing capability will open up a new frontier in electromagnetics research. For this reason, a major portion of the present chapter will be focused on introducing the characteristic-based finite-volume and finite-difference methods [Shang 1993, Shang and Gaitonde 1993, Shang and Fithen 1994].

29.2 Governing Equations

The time-dependent Maxwell equations for the electromagnetic field can be written as [Elliott 1966, Harrington 1961]:

$$\frac{\partial \mathbf{B}}{\partial t} + \nabla \times \mathbf{E} = \mathbf{0} \quad (29.1)$$

$$\frac{\partial \mathbf{D}}{\partial t} - \nabla \times \mathbf{H} = -\mathbf{J} \quad (29.2)$$

$$\nabla \cdot \mathbf{B} = 0 \quad (29.3)$$

$$\nabla \cdot \mathbf{D} = \rho$$

The only conservation law for electric charge and current densities is

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \mathbf{J} = 0 \quad (29.4)$$

where ρ and \mathbf{J} are the charge and current density, respectively, and represent the source of the field. The constitutive relations between the magnetic flux density and intensity and between the electric displacement and field strength are $\mathbf{B} = \mu\mathbf{H}$ and $\mathbf{D} = \epsilon\mathbf{E}$. Equation 29.4 is regarded as a fundamental law of electromagnetics, derived from the generalized Ampere’s circuit law and Gauss’s law. Since Equation 29.1 and Equation 29.2 contain the information on the propagation of the electromagnetic field, they constitute the basic equations of CEM.

The above partial differential equations also can be expressed as a system of integral equations. The following expression is obtained by using Stoke’s law and the divergence theorem to reduce the surface and volume integrals to a circuital line and surface integrals, respectively [Elliott 1966]. These integral relationships hold only if the first derivatives of the electric displacement \mathbf{D} and the magnetic flux density \mathbf{B} are continuous throughout the control volume:

$$\oint \mathbf{E} \cdot d\mathbf{L} = - \iint \frac{\partial \mathbf{B}}{\partial t} \cdot d\mathbf{S} \quad (29.5)$$

$$\oint \mathbf{H} \cdot d\mathbf{L} = \iint \left(\mathbf{J} + \frac{\partial \mathbf{D}}{\partial t} \right) \cdot d\mathbf{S} \quad (29.6)$$

$$\iint \mathbf{D} \cdot d\mathbf{S} = \iiint \rho \, dV \quad (29.7)$$

$$\iint \mathbf{B} \cdot d\mathbf{S} = 0 \quad (29.8)$$

The integral form of the Maxwell equations is rarely used in CEM. They are, however, invaluable as a validation tool for checking the global behavior of field computations.

The second-order curl–curl form of the Maxwell equations is derived by applying the curl operator to get

$$\nabla \times \nabla \times \mathbf{E} + \frac{1}{c^2} \frac{\partial^2 \mathbf{E}}{\partial t^2} = -\frac{\partial(\mu \mathbf{J})}{\partial t} \quad (29.9)$$

$$\nabla \times \nabla \times \mathbf{B} + \frac{1}{c^2} \frac{\partial^2 \mathbf{B}}{\partial t^2} = \nabla \times (\mu \mathbf{J}) \quad (29.10)$$

The outstanding feature of the curl–curl formulation of the Maxwell equations is that the electric and magnetic fields are decoupled. The second-order equations can be further simplified for harmonic fields. If the time-dependent behavior can be represented by a harmonic function $e^{i\omega t}$, the separation-of-variables technique will transform the Maxwell equations into the frequency domain [Elliott 1966, Harrington 1961]. The resultant partial differential equations in spatial variables become elliptic:

$$\begin{aligned} \nabla \times \nabla \times \mathbf{E} - k^2 \mathbf{E} &= -i\omega(\mu \mathbf{J}) \\ \nabla \times \nabla \times \mathbf{B} - k^2 \mathbf{B} &= \nabla \times (\mu \mathbf{J}) \end{aligned} \quad (29.11)$$

where $k = \omega/c$ is called the propagation constant or the wave number, and ω is the angular frequency of a component of a Fourier series or a Fourier integral [Elliott 1966, Harrington 1961]. The above equations are frequently the basis for finite-element approaches [Rahman et al. 1991].

In order to complete the description of the differential system, initial and/or boundary values are required. For Maxwell equations, only the source of the field and a few physical boundary conditions at the media interfaces are pertinent [Elliott 1966, Harrington 1961]:

$$\begin{aligned} \mathbf{n} \times (\mathbf{E}_1 - \mathbf{E}_2) &= \mathbf{0} \\ \mathbf{n} \times (\mathbf{H}_1 - \mathbf{H}_2) &= \mathbf{J}_s \\ \mathbf{n} \cdot (\mathbf{D}_1 - \mathbf{D}_2) &= \rho_s \\ \mathbf{n} \cdot (\mathbf{B}_1 - \mathbf{B}_2) &= 0 \end{aligned} \quad (29.12)$$

where the subscripts 1 and 2 refer to media on two sides of the interface, and \mathbf{J}_s and ρ_s are the surface current and charge densities, respectively.

Since all computing systems have finite memory, all CEM computations in the time domain must be conducted on a truncated computational domain. This intrinsic constraint requires a numerical far-field condition at the truncated boundary to mimic the behavior of an unbounded field. This numerical boundary unavoidably induces a reflected wave to contaminate the simulated field. In the past, absorbing boundary conditions at the far-field boundary have been developed from the radiation condition [Sommerfeld 1949, Enquist and Majda 1977, Higdon 1986, Mur 1981]. In general, a progressive order-of-accuracy procedure can be used to implement the numerical boundary conditions with increasing accuracy [Enquist and Majda 1977, Higdon 1986]. On the other hand, the characteristic-based methods which satisfy the physical domain of influence requirement can specify the numerical boundary condition readily. For this formulation, the reflected wave can be suppressed by eliminating the undesirable incoming numerical data. Although the accuracy of the numerical far-field boundary condition depends on the coordinate system, in principle this formulation under ideal circumstances can effectively suppress artificial wave reflections.

29.3 Characteristic-Based Formulation

The fundamental idea of the characteristic-based method for solving the hyperbolic system of equations is derived from the eigenvalue–eigenvector analyses of the governing equations. For Maxwell equations in the time domain, every eigenvalue is real but not all of them are distinct [Shang 1993, Shang and Gaitonde 1993, Shang and Fithen 1994]. In a time–space plane, the eigenvalue actually defines the slope of the characteristic or the phase velocity of the wave motion. All dependent variables within the time–space domain bounded by two intersecting characteristics are completely determined by the values along these characteristics and by their compatibility relationship. The direction of information propagation is also clearly described by these two characteristics [Sommerfeld 1949]. In numerical simulation, the well-posedness requirement on initial or boundary conditions and the stability of a numerical approximation are also ultimately linked to the eigenvalues of the governing equation [Anderson et al. 1984, Richtmyer and Morton 1967]. Therefore, characteristic-based methods have demonstrated superior numerical stability and accuracy to other schemes [Roe 1986, Shang 1993]. However, characteristic-based algorithms also have an inherent limitation in that the governing equation can be diagonalized only in one spatial dimension at a time. The multidimensional equations are required to split into multiple one-dimensional formulations. This limitation is not unusual for numerical algorithms, such as the approximate factored and the fractional-step schemes [Shang 1993, Anderson et al. 1984]. A consequence of this restriction is that solutions of the characteristic-based procedure may exhibit some degree of sensitivity to the orientation of the coordinate selected. This numerical behavior is consistent with the concept of optimal coordinates.

In the characteristic formulation, data on the wave motion are first split according to the direction of phase velocity and then transmitted in each orientation. In each one-dimensional time–space domain, the direction of the phase velocity degenerates into either a positive or a negative orientation. They are commonly referred to as the right-running and the left-running wave components [Sommerfeld 1949, Roe 1986]. The sign of the eigenvalue is thus an indicator of the direction of signal transmission. The corresponding eigenvectors are the essential elements for diagonalizing the coefficient matrices and for formulating the approximate Riemann problem [Roe 1986]. In essence, knowledge of eigenvalues and eigenvectors of the Maxwell equations in the time domain becomes the first prerequisite of the present formulation.

The system of governing equations cast in the flux-vector form in the Cartesian frame becomes [Shang 1993, Shang and Gaitonde 1993, Shang and Fithen 1994]

$$\frac{\partial U}{\partial t} + \frac{\partial F_x}{\partial x} + \frac{\partial F_y}{\partial y} + \frac{\partial F_z}{\partial z} = -J \quad (29.13)$$

where U is the vector of dependent variables. The flux vectors are formed by the inner product of the coefficient matrix and the dependent variable: $F_x = C_x U$, $F_y = C_y U$, and $F_z = C_z U$, with

$$U = \{B_x, B_y, B_z, D_x, D_y, D_z\}^T \quad (29.14)$$

and

$$\begin{aligned} F_x &= \{0, -D_z/\epsilon, D_y/\epsilon, 0, B_z/\mu, -B_y/\mu\}^T \\ F_y &= \{D_z/\epsilon, 0, -D_x/\epsilon, -B_z/\mu, 0, B_x/\mu\}^T \\ F_z &= \{-D_y/\epsilon, D_x/\epsilon, 0, B_y/\mu, -B_x/\mu, 0\}^T \end{aligned} \quad (29.15)$$

The coefficient matrices, or the Jacobians of the flux vectors C_x , C_y , and C_z are [Shang 1993]:

$$C_x = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & -\frac{1}{\epsilon} \\ 0 & 0 & 0 & 0 & \frac{1}{\epsilon} & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & \frac{1}{\mu} & 0 & 0 & 0 \\ 0 & -\frac{1}{\mu} & 0 & 0 & 0 & 0 \end{bmatrix} \quad (29.16a)$$

$$C_y = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & \frac{1}{\epsilon} \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -\frac{1}{\epsilon} & 0 & 0 \\ 0 & 0 & -\frac{1}{\mu} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ \frac{1}{\mu} & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \quad (29.16b)$$

$$C_z = \begin{bmatrix} 0 & 0 & 0 & 0 & -\frac{1}{\epsilon} & 0 \\ 0 & 0 & 0 & \frac{1}{\epsilon} & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & \frac{1}{\mu} & 0 & 0 & 0 & 0 \\ -\frac{1}{\mu} & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \quad (29.16c)$$

where ϵ and μ are the permittivity and permeability, which relate the electric displacement to the electric field intensity and the magnetic flux density to the magnetic field intensity, respectively.

The eigenvalues of the coefficient matrices C_x , C_y , and C_z in the Cartesian frame are identical and contain multiplicities [Shang 1993, Shang and Gaitonde 1993]. Care must be exercised to ensure that all associated eigenvectors

$$\lambda = \left\{ +\frac{1}{\sqrt{\epsilon\mu}}, -\frac{1}{\sqrt{\epsilon\mu}}, 0, +\frac{1}{\sqrt{\epsilon\mu}}, -\frac{1}{\sqrt{\epsilon\mu}}, 0 \right\} \quad (29.17)$$

are linearly independent. The linearly independent eigenvectors associated with each eigenvalue are found by reducing the matrix equation, $(C - \bar{\lambda}I)U = 0$, to the Jordan normal form [Shang 1993, Shang and Fithen 1994].

Since the coefficient matrices C_x , C_y , and C_z can be diagonalized, there exist nonsingular similar matrices S_x , S_y , and S_z such that

$$\begin{aligned} \Lambda_x &= S_x^{-1} C_x S_x \\ \Lambda_y &= S_y^{-1} C_y S_y \\ \Lambda_z &= S_z^{-1} C_z S_z \end{aligned} \quad (29.18)$$

where the Λ s are the diagonalized coefficient matrices. The columns of the similar matrices S_x , S_y , and S_z are simply the linearly independent eigenvectors of the coefficient matrices C_x , C_y , and C_z , respectively.

The fundamental relationship between the characteristic-based formulation and the Riemann problem can be best demonstrated in the Cartesian frame of reference. For the Maxwell equations in this frame of reference and for an isotropic medium, all the similar matrices are invariant with respect to temporal and spatial independent variables. In each time-space plane ($x-t$, $y-t$, and $z-t$), the one-dimensional governing equation can be given just as in the $x-t$ plane:

$$\frac{\partial U}{\partial t} + C_x \frac{\partial U}{\partial x} = 0 \quad (29.19)$$

Substitute the diagonalized coefficient matrix to get

$$\frac{\partial U}{\partial t} + S_x \Lambda_x S_x^{-1} \frac{\partial U}{\partial x} = 0 \quad (29.20)$$

Since the similar matrix in the present consideration is invariant with respect to time and space, it can be brought into the differential operator. Multiplying the above equation by the left-hand inverse of S_x , S_x^{-1} , we have

$$\frac{\partial (S_x^{-1} U)}{\partial t} + \Lambda_x \frac{\partial (S_x^{-1} U)}{\partial x} = 0 \quad (29.21)$$

One immediately recognizes the group of variables $S_x^{-1} U$ as the characteristic, and the system of equations is decoupled [Shang 1993]. In scalar-variable form and with appropriate initial values, this is the Riemann problem [Sommerfeld 1949, Courant and Hilbert 1965]. This differential system is specialized to study the breakup of a single discontinuity. The piecewise continuous solutions separated by the singular point are also invariant along the characteristics. Equally important, stable numerical operators can now be easily devised to solve the split equations according to the sign of the eigenvalue. In practice it has been found if the multidimensional problem can be split into a sequence of one-dimensional equations, this numerical technique is applicable to those one-dimensional equations [Roe 1986, Shang 1993].

The gist of the characteristic-based formulation is also clearly revealed by the decomposition of the flux vector into positive and negative components corresponding to the sign of the eigenvalue:

$$\Lambda = \Lambda^+ + \Lambda^-, \quad F = F^+ + F^- \quad (29.22)$$

$$F^+ = S \Lambda^+ S^{-1}, \quad F^- = S \Lambda^- S^{-1} \quad (29.23)$$

where the superscripts + and – denote the split vectors associated with positive and negative eigenvalues, respectively.

The characteristic-based algorithms have a deep-rooted theoretical basis for describing the wave dynamics. They also have however an inherent limitation in that the diagonalized formulation is achievable only in one dimension at a time. All multidimensional equations are required to be split into multiple one-dimensional formulations. The approach yields accurate results so long as discontinuous waves remain aligned with the computational grid. This limitation is also the state-of-the-art constraint in solving partial differential equations [Roe 1986, Shang 1993, Anderson et al. 1984].

29.4 Maxwell Equations in a Curvilinear Frame

In order to develop a versatile numerical tool for computational electromagnetics in a wide range of applications, the Maxwell equations can be cast in a general curvilinear frame of reference [Shang and Gaitonde 1993, Shang and Fithen 1994]. For efficient simulation of complex electromagnetic field configurations, the adoption of a general curvilinear mesh system becomes necessary. The system of equations in general curvilinear coordinates is derived by a coordinate transformation [Anderson et al. 1984, Thompson 1982]. The mesh system in the transformed space can be obtained by numerous grid generation procedures [Thompson 1982]. Computational advantages in the transformed space are also realizable. For a body-oriented coordinate system, the interface between two different media is easily defined by one of the coordinate surfaces. Along this coordinate parametric plane, all discretized nodes on the interface are precisely prescribed without the need for an interpolating procedure. The outward normal to the interface, which is essential for boundary-value implementation, can be computed easily by $n = \nabla S / \|\nabla S\|$. In the transformed space, computations are performed on a uniform mesh space, but the corresponding physical spacing can be highly clustered to enhance the numerical resolution.

As an illustration of the numerical advantage of solving the Maxwell equations on nonorthogonal curvilinear, body-oriented coordinates, a simulation of the scattered electromagnetic field from a re-entry vehicle has been performed [Shang and Gaitonde 1994]. The aerospace vehicle, X24C-10D, has

FIGURE 29.1 Radar-wave fringes on X24C-10D, grid $181 \times 59 \times 162$, TE excitation, $L/\lambda = 9.2$.

a complex geometrical shape (Figure 29.1). In addition to a blunt leading-edge spherical nose and a relatively flat delta-shaped underbody, the aft portion of the vehicle consists of five control surfaces — a central fin, two middle fins, and two strakes. A body-oriented, single-block mesh system enveloping the configuration is adopted. The numerical grid system is generated by using a hyperbolic grid generator for the near-field mesh adjacent to the solid surface, and a transfinite technique for the far field. The two mesh systems are merged by the Poisson averaging technique [Thompson 1982, Shang and Gaitonde 1994]. In this manner, the composite grid system is orthogonal in the near field but less restrictive in the far field. All solid surfaces of the X24C-10D are mapped onto a parametric surface in the transformed space, defined by $\eta = 0$. The entire computational domain is supported by a $181 \times 59 \times 162$ grid system, where the first coordinate index denotes the number of cross sections in the numerical domain. The second index describes the number of cells between the body surface and the far-field boundary, while the third index gives the cells used to circumscribe each cross-sectional plane. The electromagnetic excitation is introduced by a harmonic incident wave traveling along the x -coordinate. The fringe pattern of the scattered electromagnetic waves on the X24C-10D is presented in Figure 29.1 for a characteristic-length-to-wavelength ratio $L/\lambda = 9.2$. A salient feature of the scattered field is brought out by the surface curvature: the smaller the radius of surface curvature, the broader the diffraction pattern. The numerical result exhibits highly concentrated contours at the chine (the line of intersection between upper and lower vehicle surfaces) of the forebody and the leading edges of strakes and fins.

For the most general coordinate transformation of the Maxwell equations in the time domain, a one-to-one relationship between two sets of temporal and spatial independent variables is required. However, for most practical applications, the spatial coordinate transformation is sufficient:

$$\begin{aligned}
 \xi &= \xi(x, y, z) \\
 \eta &= \eta(x, y, z) \\
 \zeta &= \zeta(x, y, z)
 \end{aligned}
 \tag{29.24}$$

The governing equation in the strong conservation form is obtained by dividing the chain-rule-differentiated equations by the Jacobian of coordinate transformation and by invoking metric identities [Shang and Gaitonde 1993, Anderson et al. 1984]. The time-dependent Maxwell equations on a general

curvilinear frame of reference and in the strong conservative form are

$$\frac{\partial U}{\partial t} + \frac{\partial F_\xi}{\partial \xi} + \frac{\partial F_\eta}{\partial \eta} + \frac{\partial F_\zeta}{\partial \zeta} = -J \quad (29.25)$$

where the dependent variables are now defined as

$$U = U(B_x V, B_y V, B_z V, D_x V, D_y V, D_z V) \quad (29.26)$$

Here V is the Jacobian of the coordinate transformation and is also the inverse local cell volume. If the Jacobian has nonzero values in the computational domain, the correspondence between the physical and the transformed space is uniquely defined [Anderson et al. 1984, Thompson 1982]. Since systematic procedures have been developed to ensure this property of coordinate transformations, detailed information on this point is not repeated here [Anderson et al. 1984, Thompson 1982]. We have

$$V = \begin{bmatrix} \xi_x & \eta_x & \zeta_x \\ \xi_y & \eta_y & \zeta_y \\ \xi_z & \eta_z & \zeta_z \end{bmatrix} \quad (29.27)$$

and ξ_x, η_x, ζ_x , etc. are the metrics of coordinate transformation and can be computed easily from the definition given by Equation 29.24. The flux-vector components in the transformed space have the following form:

$$F_\xi = \begin{bmatrix} 0 & 0 & 0 & 0 & -\frac{\xi_z}{\epsilon V} & \frac{\xi_y}{\epsilon V} \\ 0 & 0 & 0 & \frac{\xi_z}{\epsilon V} & 0 & -\frac{\xi_x}{\epsilon V} \\ 0 & 0 & 0 & -\frac{\xi_y}{\epsilon V} & \frac{\xi_x}{\epsilon V} & 0 \\ 0 & \frac{\xi_z}{V\mu} & -\frac{\xi_y}{V\mu} & 0 & 0 & 0 \\ -\frac{\xi_z}{V\mu} & 0 & \frac{\xi_x}{V\mu} & 0 & 0 & 0 \\ \frac{\xi_y}{V\mu} & -\frac{\xi_x}{V\mu} & 0 & 0 & 0 & 0 \end{bmatrix} \begin{Bmatrix} B_x \\ B_y \\ B_z \\ D_x \\ D_y \\ D_z \end{Bmatrix} \quad (29.28)$$

$$F_\eta = \begin{bmatrix} 0 & 0 & 0 & 0 & -\frac{\eta_z}{\epsilon V} & \frac{\eta_y}{\epsilon V} \\ 0 & 0 & 0 & \frac{\eta_z}{\epsilon V} & 0 & -\frac{\eta_x}{\epsilon V} \\ 0 & 0 & 0 & -\frac{\eta_y}{\epsilon V} & \frac{\eta_x}{\epsilon V} & 0 \\ 0 & \frac{\eta_z}{V\mu} & -\frac{\eta_y}{V\mu} & 0 & 0 & 0 \\ -\frac{\eta_z}{V\mu} & 0 & \frac{\eta_x}{V\mu} & 0 & 0 & 0 \\ \frac{\eta_y}{V\mu} & -\frac{\eta_x}{V\mu} & 0 & 0 & 0 & 0 \end{bmatrix} \begin{Bmatrix} B_x \\ B_y \\ B_z \\ D_x \\ D_y \\ D_z \end{Bmatrix} \quad (29.29)$$

$$F_\zeta = \begin{bmatrix} 0 & 0 & 0 & 0 & -\frac{\zeta_z}{\epsilon V} & \frac{\zeta_y}{\epsilon V} \\ 0 & 0 & 0 & \frac{\zeta_z}{\epsilon V} & 0 & -\frac{\zeta_x}{\epsilon V} \\ 0 & 0 & 0 & -\frac{\zeta_y}{\epsilon V} & \frac{\zeta_x}{\epsilon V} & 0 \\ 0 & \frac{\zeta_z}{V\mu} & -\frac{\zeta_y}{V\mu} & 0 & 0 & 0 \\ -\frac{\zeta_z}{V\mu} & 0 & \frac{\zeta_x}{V\mu} & 0 & 0 & 0 \\ \frac{\zeta_y}{V\mu} & -\frac{\zeta_x}{V\mu} & 0 & 0 & 0 & 0 \end{bmatrix} \begin{Bmatrix} B_x \\ B_y \\ B_z \\ D_x \\ D_y \\ D_z \end{Bmatrix} \quad (29.30)$$

After the coordinate transformation, all coefficient matrices now contain metrics which are position-dependent, and the system of equations in the most general frame of reference possesses variable coefficients. This added complexity of the characteristic formulation of the Maxwell equations no longer permits the system of one-dimensional equations to be decoupled into six scalar equations and reduced to the true Riemann problem [Shang 1993, Shang and Gaitonde 1993, Shang and Fithen 1994] like that on the Cartesian form.

29.5 Eigenvalues and Eigenvectors

As previously mentioned, eigenvalue and the eigenvector analyses are the prerequisites for characteristic-based algorithms. The analytic process to obtain the eigenvalues and the corresponding eigenvectors of the Maxwell equations in general curvilinear coordinates is identical to that in the Cartesian frame. In each of the temporal–spatial planes t – ξ , t – η , and t – ζ , the eigenvalues are easily found by solving the sixth-degree characteristic equation associated with the coefficient matrices [Sommerfeld 1949, Courant and Hilbert 1965]

$$\lambda_\xi = \left\{ -\frac{\alpha}{V\sqrt{\epsilon\mu}}, -\frac{\alpha}{V\sqrt{\epsilon\mu}}, \frac{\alpha}{V\sqrt{\epsilon\mu}}, \frac{\alpha}{V\sqrt{\epsilon\mu}}, 0, 0 \right\} \quad (29.31)$$

$$\lambda_\eta = \left\{ -\frac{\beta}{V\sqrt{\epsilon\mu}}, -\frac{\beta}{V\sqrt{\epsilon\mu}}, \frac{\beta}{V\sqrt{\epsilon\mu}}, \frac{\beta}{V\sqrt{\epsilon\mu}}, 0, 0 \right\} \quad (29.32)$$

$$\lambda_\zeta = \left\{ -\frac{\gamma}{V\sqrt{\epsilon\mu}}, -\frac{\gamma}{V\sqrt{\epsilon\mu}}, \frac{\gamma}{V\sqrt{\epsilon\mu}}, \frac{\gamma}{V\sqrt{\epsilon\mu}}, 0, 0 \right\} \quad (29.33)$$

where $\alpha = \sqrt{\xi_z^2 + \xi_y^2 + \xi_x^2}$, $\beta = \sqrt{\eta_z^2 + \eta_y^2 + \eta_x^2}$, and $\gamma = \sqrt{\zeta_z^2 + \zeta_y^2 + \zeta_x^2}$.

One recognizes that the eigenvalues in each one-dimensional time–space plane contain multiplicities, and hence the eigenvectors do not necessarily have unique elements [Shang 1993, Courant and Hilbert 1965]. Nevertheless, linearly independent eigenvectors associated with each eigenvalue still have been found by reducing the coefficient matrix to the Jordan normal form [Shang 1993, Shang and Fithen 1994]. For reasons of wide applicability and internal consistency, the eigenvectors are selected in such a fashion that the similar matrices of diagonalization reduce to the same form as in the Cartesian frame. Furthermore, in order to accommodate a wide range of electromagnetic field configurations such as antennas, wave guides, and scatterers, the eigenvalues are no longer identical in the three time–space planes. This complexity of formulation is essential to facilitate boundary-condition implementation on the interfaces of media with different characteristic impedances.

From the eigenvector analysis, the similarity transformation matrices for diagonalization in each time–space plane are formed by using eigenvectors as the column arrays as shown in the following equations. For an example, the first column of the similar matrix of diagonalization,

$$\left[-\frac{\sqrt{\mu}\xi_y}{\sqrt{\epsilon\alpha}}, \frac{\sqrt{\mu}(\xi_x^2 + \xi_z^2)}{\sqrt{\epsilon\xi_x\alpha}}, \frac{\sqrt{\mu}\xi_y\xi_z}{\sqrt{\epsilon\xi_x\alpha}}, \frac{\xi_y}{\xi_x}, 0, 1 \right]$$

in the t – ξ plane is the eigenvector corresponding to the eigenvalue $\lambda_\xi = -\alpha/V\sqrt{\epsilon\mu}$. We have

$$S_\xi = \begin{bmatrix} -\frac{\sqrt{\mu}\xi_y}{\sqrt{\epsilon\alpha}} & \frac{\sqrt{\mu}\xi_z}{\sqrt{\epsilon\alpha}} & \frac{\sqrt{\mu}\xi_y}{\sqrt{\epsilon\alpha}} & -\frac{\sqrt{\mu}\xi_z}{\sqrt{\epsilon\alpha}} & 1 & 0 \\ \frac{\sqrt{\mu}(\xi_x^2 + \xi_z^2)}{\sqrt{\epsilon\xi_x\alpha}} & \frac{\sqrt{\mu}\xi_y\xi_z}{\sqrt{\epsilon\xi_x\alpha}} & -\frac{\sqrt{\mu}(\xi_x^2 + \xi_z^2)}{\sqrt{\epsilon\xi_x\alpha}} & -\frac{\sqrt{\mu}\xi_y\xi_z}{\sqrt{\epsilon\xi_x\alpha}} & \frac{\xi_y}{\xi_x} & 0 \\ -\frac{\sqrt{\mu}\xi_y\xi_z}{\sqrt{\epsilon\xi_x\alpha}} & -\frac{\sqrt{\mu}(\xi_x^2 + \xi_z^2)}{\sqrt{\epsilon\xi_x\alpha}} & \frac{\sqrt{\mu}\xi_y\xi_z}{\sqrt{\epsilon\xi_x\alpha}} & \frac{\sqrt{\mu}(\xi_x^2 + \xi_z^2)}{\sqrt{\epsilon\xi_x\alpha}} & \frac{\xi_x}{\xi_x} & 0 \\ -\frac{\xi_x}{\xi_x} & -\frac{\xi_y}{\xi_x} & -\frac{\xi_x}{\xi_x} & -\frac{\xi_y}{\xi_x} & 0 & 1 \\ 0 & 1 & 0 & 1 & 0 & \frac{\xi_y}{\xi_x} \\ 1 & 0 & 1 & 0 & 0 & \frac{\xi_x}{\xi_x} \end{bmatrix} \quad (29.34)$$

$$S_{\eta} = \begin{bmatrix} -\frac{(\eta_y^2 + \eta_z^2)\sqrt{\mu}}{\sqrt{\epsilon}\eta_y\beta} & -\frac{\eta_x\eta_z\sqrt{\mu}}{\sqrt{\epsilon}\eta_y\beta} & \frac{(\eta_y^2 + \eta_z^2)\sqrt{\mu}}{\sqrt{\epsilon}\eta_y\beta} & \frac{\eta_x\eta_z\sqrt{\mu}}{\sqrt{\epsilon}\eta_y\beta} & \frac{\eta_x}{\eta_y} & 0 \\ \frac{\eta_x\sqrt{\mu}}{\sqrt{\epsilon}\beta} & -\frac{\eta_z\sqrt{\mu}}{\sqrt{\epsilon}\beta} & -\frac{\eta_x\sqrt{\mu}}{\sqrt{\epsilon}\beta} & \frac{\eta_z\sqrt{\mu}}{\sqrt{\epsilon}\beta} & 1 & 0 \\ \frac{\eta_x\eta_z\sqrt{\mu}}{\sqrt{\epsilon}\eta_y\beta} & \frac{(\eta_x^2 + \eta_y^2)\sqrt{\mu}}{\sqrt{\epsilon}\eta_y\beta} & -\frac{\eta_x\eta_z\sqrt{\mu}}{\sqrt{\epsilon}\eta_y\beta} & -\frac{(\eta_x^2 + \eta_y^2)\sqrt{\mu}}{\sqrt{\epsilon}\eta_y\beta} & \frac{\eta_x}{\eta_y} & 0 \\ 0 & 1 & 0 & 1 & 0 & \frac{\eta_x}{\eta_y} \\ -\frac{\eta_z}{\eta_y} & -\frac{\eta_x}{\eta_y} & -\frac{\eta_z}{\eta_y} & -\frac{\eta_x}{\eta_y} & 0 & 1 \\ 1 & 0 & 1 & 0 & 0 & \frac{\eta_z}{\eta_y} \end{bmatrix} \quad (29.35)$$

$$S_{\zeta} = \begin{bmatrix} \frac{\sqrt{\mu}(\zeta_y^2 + \zeta_z^2)}{\sqrt{\epsilon}\zeta_x\gamma} & \frac{\sqrt{\mu}\zeta_x\zeta_y}{\sqrt{\epsilon}\zeta_x\gamma} & -\frac{\sqrt{\mu}(\zeta_y^2 + \zeta_z^2)}{\sqrt{\epsilon}\zeta_x\gamma} & -\frac{\sqrt{\mu}\zeta_x\zeta_y}{\sqrt{\epsilon}\zeta_x\gamma} & \frac{\zeta_x}{\zeta_x} & 0 \\ -\frac{\sqrt{\mu}\zeta_x\zeta_y}{\sqrt{\epsilon}\zeta_x\gamma} & -\frac{\sqrt{\mu}(\zeta_x^2 + \zeta_z^2)}{\sqrt{\epsilon}\zeta_x\gamma} & \frac{\sqrt{\mu}\zeta_x\zeta_y}{\sqrt{\epsilon}\zeta_x\gamma} & \frac{\sqrt{\mu}(\zeta_x^2 + \zeta_z^2)}{\sqrt{\epsilon}\zeta_x\gamma} & \frac{\zeta_y}{\zeta_x} & 0 \\ -\frac{\sqrt{\mu}\zeta_x}{\sqrt{\epsilon}\gamma} & \frac{\sqrt{\mu}\zeta_y}{\sqrt{\epsilon}\gamma} & \frac{\sqrt{\mu}\zeta_x}{\sqrt{\epsilon}\gamma} & -\frac{\sqrt{\mu}\zeta_y}{\sqrt{\epsilon}\gamma} & 1 & 0 \\ 0 & 1 & 0 & 1 & 0 & \frac{\zeta_x}{\zeta_x} \\ 1 & 0 & 1 & 0 & 0 & \frac{\zeta_y}{\zeta_x} \\ -\frac{\zeta_y}{\zeta_x} & -\frac{\zeta_x}{\zeta_x} & -\frac{\zeta_y}{\zeta_x} & -\frac{\zeta_x}{\zeta_x} & 0 & 1 \end{bmatrix} \quad (29.36)$$

Since the similar matrices of diagonalization, S_{ξ} , S_{η} , and S_{ζ} , are nonsingular, the left-hand inverse matrices S_{ξ}^{-1} , S_{η}^{-1} , and S_{ζ}^{-1} are easily found. Although these left-hand inverse matrices are essential to the diagonalization process, they provide little insight for the following flux-vector splitting procedure. The rather involved results are omitted here, but they can be found in Shang and Fithen [1994].

29.6 Flux-Vector Splitting

An efficient flux-vector splitting algorithm for solving the Euler equations was developed by Steger and Warming [1987]. The basic concept is equally applicable to any hyperbolic differential system for which the solution need not be analytic [Sommerfeld 1949, Courant and Hilbert 1965]. In most CEM applications, discontinuous behavior of the solution is associated only with the wave across an interface between different media, a piecewise continuous solution. Even if a jump condition exists, the magnitude of the finite jump across the interface is much less drastic than the shock waves encountered in supersonic flows. Nevertheless, the salient feature of the piecewise continuous solution domains of the hyperbolic partial differential equation stands out: The coefficient matrices of the time-dependent, three-dimensional Maxwell equations cast in the general curvilinear frame of reference contain metrics of coordinate transformation. Therefore, the equation system no longer has constant coefficients even in an isotropic and homogeneous medium. Under this circumstance, eigenvalues can change sign at any given field location due to the metric variations of the coordinate transformation. Numerical oscillations have appeared in results calculated using the flux-vector splitting technique when eigenvalues change sign. A refined flux-difference splitting algorithm has been developed to resolve fields with jump conditions [Van Leer 1982, Anderson et al. 1985]. The newer flux-difference splitting algorithm is particularly effective at locations where the eigenvalues vanish. Perhaps more crucial for electromagnetics, the polarization of the medium, making the basic equations become nonlinear, occurs only in the extremely high-frequency range [Elliott 1966, Harrington 1961]. In general the governing equations are linear; at most, the coefficients of the differential system are dependent on physical location and phase velocity. For this reason, the difference between the flux-vector splitting [Steger and Warming 1987] and flux-difference splitting [Van Leer 1982, Anderson et al. 1985] schemes, when applied to the time-dependent Maxwell equations, is not of great importance.

The basic idea of the flux-vector splitting of Steger and Warming is to process data according to the direction of information propagation. Since diagonalization is achievable only in each time-space plane,

the direction of wave propagation degenerates into either the positive or the negative orientation. This designation is consistent with the notion of the right-running and the left-running wave components. The flux vectors are computed from the point value, including the metrics at the node of interest. This formulation for solving hyperbolic partial differential equations not only ensures the well-posedness of the differential system but also enhances the stability of the numerical procedure [Roe 1986, Shang 1993, Anderson et al. 1984, Richtmyer and Morton 1967]. Specifically, the flux vectors F_ξ , F_η , and F_ζ will be split according to the sign of their corresponding eigenvalues. The split fluxes are differenced by an upwind algorithm to allow for the zone of dependence of an initial-value problem [Roe 1986, Shang 1993, Shang and Gaitonde 1993, Shang and Fithen 1994].

From the previous analysis, it is clear that the eigenvalues contain multiplicities, and hence the split flux of the three-dimensional Maxwell equations is not unique [Shang and Gaitonde 1993, Shang and Fithen 1994]. All flux vectors in each time-space plane are split according to the signs of the local eigenvalues:

$$\begin{aligned} F_\xi &= F_\xi^+ + F_\xi^- \\ F_\eta &= F_\eta^+ + F_\eta^- \\ F_\zeta &= F_\zeta^+ + F_\zeta^- \end{aligned} \quad (29.37)$$

The flux-vector components associated with the positive and negative eigenvalues are obtainable by a straightforward matrix multiplication:

$$\begin{aligned} F_\xi^+ &= S_\xi \lambda_\xi^+ S_\xi^{-1} U \\ F_\xi^- &= S_\xi \lambda_\xi^- S_\xi^{-1} U \\ F_\eta^+ &= S_\eta \lambda_\eta^+ S_\eta^{-1} U \\ F_\eta^- &= S_\eta \lambda_\eta^- S_\eta^{-1} U \\ F_\zeta^+ &= S_\zeta \lambda_\zeta^+ S_\zeta^{-1} U \\ F_\zeta^- &= S_\zeta \lambda_\zeta^- S_\zeta^{-1} U \end{aligned} \quad (29.38)$$

It is also important to recognize that even if the split flux vectors in each time-space plane are non-unique, the sum of the split components must be unambiguously identical to the flux vector of the governing Equation 29.25. This fact is easily verifiable by performing the addition of the split matrices to reach the identities in Equation 29.28, Equation 29.29, and Equation 29.30. In addition, if one sets the diagonal elements of metrics, ξ_x , η_y , and ζ_z equal to unity and the off-diagonal elements equal to zero, the coefficient matrices will recover the Cartesian form:

$$F_\xi^+ = \begin{bmatrix} \frac{\xi_y^2 + \xi_z^2}{2\sqrt{\epsilon\mu}V\alpha} & \frac{-\xi_x\xi_y}{2\sqrt{\epsilon\mu}V\alpha} & \frac{-\xi_x\xi_z}{2\sqrt{\epsilon\mu}V\alpha} & 0 & \frac{-\xi_x}{2\epsilon V} & \frac{\xi_y}{2\epsilon V} \\ \frac{-\xi_x\xi_y}{2\sqrt{\epsilon\mu}V\alpha} & \frac{\xi_x^2 + \xi_z^2}{2\sqrt{\epsilon\mu}V\alpha} & \frac{-\xi_y\xi_z}{2\sqrt{\epsilon\mu}V\alpha} & \frac{\xi_z}{2\epsilon V} & 0 & \frac{-\xi_x}{2\epsilon V} \\ \frac{-\xi_x\xi_z}{2\sqrt{\epsilon\mu}V\alpha} & \frac{-\xi_y\xi_z}{2\sqrt{\epsilon\mu}V\alpha} & \frac{\xi_x^2 + \xi_y^2}{2\sqrt{\epsilon\mu}V\alpha} & \frac{-\xi_y}{2\epsilon V} & \frac{\xi_x}{2\epsilon V} & 0 \\ 0 & \frac{\xi_z}{2V\mu} & \frac{-\xi_y}{2V\mu} & \frac{\xi_y^2 + \xi_z^2}{2\sqrt{\epsilon\mu}V\alpha} & \frac{-\xi_x\xi_y}{2\sqrt{\epsilon\mu}V\alpha} & \frac{-\xi_x\xi_z}{2\sqrt{\epsilon\mu}V\alpha} \\ \frac{-\xi_x}{2V\mu} & 0 & \frac{\xi_x}{2V\mu} & \frac{-\xi_x\xi_y}{2\sqrt{\epsilon\mu}V\alpha} & \frac{\xi_x^2 + \xi_z^2}{2\sqrt{\epsilon\mu}V\alpha} & \frac{-\xi_y\xi_z}{2\sqrt{\epsilon\mu}V\alpha} \\ \frac{\xi_y}{2V\mu} & \frac{-\xi_x}{2V\mu} & 0 & \frac{-\xi_x\xi_z}{2\sqrt{\epsilon\mu}V\alpha} & \frac{-\xi_y\xi_z}{2\sqrt{\epsilon\mu}V\alpha} & \frac{\xi_x^2 + \xi_y^2}{2\sqrt{\epsilon\mu}V\alpha} \end{bmatrix} \begin{Bmatrix} B_x \\ B_y \\ B_z \\ D_x \\ D_y \\ D_z \end{Bmatrix} \quad (29.39)$$

$$F_{\xi}^{-} = \begin{bmatrix} -\frac{(\xi_y^2 + \xi_z^2)}{2\sqrt{\epsilon\mu}V\alpha} & \frac{\xi_x \xi_y}{2\sqrt{\epsilon\mu}V\alpha} & \frac{\xi_x \xi_z}{2\sqrt{\epsilon\mu}V\alpha} & 0 & \frac{-\xi_z}{2\epsilon V} & \frac{\xi_y}{2\epsilon V} \\ \frac{\xi_x \xi_y}{2\sqrt{\epsilon\mu}V\alpha} & -\frac{(\xi_x^2 + \xi_z^2)}{2\sqrt{\epsilon\mu}V\alpha} & \frac{\xi_y \xi_z}{2\sqrt{\epsilon\mu}V\alpha} & \frac{\xi_z}{2\epsilon V} & 0 & \frac{-\xi_x}{2\epsilon V} \\ \frac{\xi_x \xi_z}{2\sqrt{\epsilon\mu}V\alpha} & \frac{\xi_y \xi_z}{2\sqrt{\epsilon\mu}V\alpha} & -\frac{(\xi_x^2 + \xi_y^2)}{2\sqrt{\epsilon\mu}V\alpha} & \frac{-\xi_y}{2\epsilon V} & \frac{\xi_x}{2\epsilon V} & 0 \\ 0 & \frac{\xi_z}{2V\mu} & \frac{-\xi_y}{2V\mu} & \frac{-(\xi_y^2 + \xi_z^2)}{2\sqrt{\epsilon\mu}V\alpha} & \frac{\xi_x \xi_y}{2\sqrt{\epsilon\mu}V\alpha} & \frac{\xi_x \xi_z}{2\sqrt{\epsilon\mu}V\alpha} \\ \frac{-\xi_z}{2V\mu} & 0 & \frac{\xi_x}{2V\mu} & \frac{\xi_x \xi_y}{2\sqrt{\epsilon\mu}V\alpha} & \frac{-(\xi_x^2 + \xi_z^2)}{2\sqrt{\epsilon\mu}V\alpha} & \frac{\xi_y \xi_z}{2\sqrt{\epsilon\mu}V\alpha} \\ \frac{\xi_y}{2V\mu} & \frac{-\xi_x}{2V\mu} & 0 & \frac{\xi_x \xi_z}{2\sqrt{\epsilon\mu}V\alpha} & \frac{\xi_y \xi_z}{2\sqrt{\epsilon\mu}V\alpha} & \frac{-(\xi_x^2 + \xi_y^2)}{2\sqrt{\epsilon\mu}V\alpha} \end{bmatrix} \begin{Bmatrix} B_x \\ B_y \\ B_z \\ D_x \\ D_y \\ D_z \end{Bmatrix} \quad (29.40)$$

$$F_{\eta}^{+} = \begin{bmatrix} \frac{\eta_y^2 + \eta_z^2}{2\sqrt{\epsilon\mu}\beta V} & \frac{-\eta_x \eta_y}{2\sqrt{\epsilon\mu}\beta V} & \frac{-\eta_x \eta_z}{2\sqrt{\epsilon\mu}\beta V} & 0 & \frac{-\eta_x}{2\epsilon V} & \frac{\eta_y}{2\epsilon V} \\ \frac{-\eta_x \eta_y}{2\sqrt{\epsilon\mu}\beta V} & \frac{\eta_x^2 + \eta_z^2}{2\sqrt{\epsilon\mu}\beta V} & \frac{-\eta_y \eta_z}{2\sqrt{\epsilon\mu}\beta V} & \frac{\eta_z}{2\epsilon V} & 0 & \frac{-\eta_x}{2\epsilon V} \\ \frac{-\eta_x \eta_z}{2\sqrt{\epsilon\mu}\beta V} & \frac{-\eta_y \eta_z}{2\sqrt{\epsilon\mu}\beta V} & \frac{\eta_x^2 + \eta_y^2}{2\sqrt{\epsilon\mu}\beta V} & \frac{-\eta_y}{2\epsilon V} & \frac{\eta_x}{2\epsilon V} & 0 \\ 0 & \frac{\eta_z}{2V\mu} & \frac{-\eta_y}{2V\mu} & \frac{\eta_y^2 + \eta_z^2}{2\sqrt{\epsilon\mu}\beta V} & \frac{-\eta_x \eta_y}{2\sqrt{\epsilon\mu}\beta V} & \frac{-\eta_x \eta_z}{2\sqrt{\epsilon\mu}\beta V} \\ \frac{-\eta_z}{2V\mu} & 0 & \frac{\eta_x}{2V\mu} & \frac{-\eta_x \eta_y}{2\sqrt{\epsilon\mu}\beta V} & \frac{\eta_x^2 + \eta_z^2}{2\sqrt{\epsilon\mu}\beta V} & \frac{-\eta_y \eta_z}{2\sqrt{\epsilon\mu}\beta V} \\ \frac{\eta_y}{2V\mu} & \frac{-\eta_x}{2V\mu} & 0 & \frac{-\eta_x \eta_z}{2\sqrt{\epsilon\mu}\beta V} & \frac{-\eta_y \eta_z}{2\sqrt{\epsilon\mu}\beta V} & \frac{\eta_x^2 + \eta_y^2}{2\sqrt{\epsilon\mu}\beta V} \end{bmatrix} \begin{Bmatrix} B_x \\ B_y \\ B_z \\ D_x \\ D_y \\ D_z \end{Bmatrix} \quad (29.41)$$

$$F_{\eta}^{-} = \begin{bmatrix} -\frac{(\eta_y^2 + \eta_z^2)}{2\sqrt{\epsilon\mu}\beta V} & \frac{\eta_x \eta_y}{2\sqrt{\epsilon\mu}\beta V} & \frac{\eta_x \eta_z}{2\sqrt{\epsilon\mu}\beta V} & 0 & \frac{-\eta_x}{2\epsilon V} & \frac{\eta_y}{2\epsilon V} \\ \frac{\eta_x \eta_y}{2\sqrt{\epsilon\mu}\beta V} & -\frac{(\eta_x^2 + \eta_z^2)}{2\sqrt{\epsilon\mu}\beta V} & \frac{\eta_y \eta_z}{2\sqrt{\epsilon\mu}\beta V} & \frac{\eta_z}{2\epsilon V} & 0 & \frac{-\eta_x}{2\epsilon V} \\ \frac{\eta_x \eta_z}{2\sqrt{\epsilon\mu}\beta V} & \frac{\eta_y \eta_z}{2\sqrt{\epsilon\mu}\beta V} & -\frac{(\eta_x^2 + \eta_y^2)}{2\sqrt{\epsilon\mu}\beta V} & \frac{-\eta_y}{2\epsilon V} & \frac{\eta_x}{2\epsilon V} & 0 \\ 0 & \frac{\eta_z}{2V\mu} & \frac{-\eta_y}{2V\mu} & \frac{-(\eta_y^2 + \eta_z^2)}{2\sqrt{\epsilon\mu}\beta V} & \frac{\eta_x \eta_y}{2\sqrt{\epsilon\mu}\beta V} & \frac{\eta_x \eta_z}{2\sqrt{\epsilon\mu}\beta V} \\ \frac{-\eta_z}{2V\mu} & 0 & \frac{\eta_x}{2V\mu} & \frac{\eta_x \eta_y}{2\sqrt{\epsilon\mu}\beta V} & \frac{-(\eta_x^2 + \eta_z^2)}{2\sqrt{\epsilon\mu}\beta V} & \frac{\eta_y \eta_z}{2\sqrt{\epsilon\mu}\beta V} \\ \frac{\eta_y}{2V\mu} & \frac{-\eta_x}{2V\mu} & 0 & \frac{\eta_x \eta_z}{2\sqrt{\epsilon\mu}\beta V} & \frac{\eta_y \eta_z}{2\sqrt{\epsilon\mu}\beta V} & \frac{-(\eta_x^2 + \eta_y^2)}{2\sqrt{\epsilon\mu}\beta V} \end{bmatrix} \begin{Bmatrix} B_x \\ B_y \\ B_z \\ D_x \\ D_y \\ D_z \end{Bmatrix} \quad (29.42)$$

$$F_{\zeta}^{+} = \begin{bmatrix} \frac{\zeta_y^2 + \zeta_z^2}{2\sqrt{\epsilon\mu}V\gamma} & \frac{-\zeta_x \zeta_y}{2\sqrt{\epsilon\mu}V\gamma} & \frac{-\zeta_x \zeta_z}{2\sqrt{\epsilon\mu}V\gamma} & 0 & \frac{-\zeta_z}{2\epsilon V} & \frac{\zeta_y}{2\epsilon V} \\ \frac{-\zeta_x \zeta_y}{2\sqrt{\epsilon\mu}V\gamma} & \frac{\zeta_x^2 + \zeta_z^2}{2\sqrt{\epsilon\mu}V\gamma} & \frac{-\zeta_y \zeta_z}{2\sqrt{\epsilon\mu}V\gamma} & \frac{\zeta_z}{2\epsilon V} & 0 & \frac{-\zeta_x}{2\epsilon V} \\ \frac{-\zeta_x \zeta_z}{2\sqrt{\epsilon\mu}V\gamma} & \frac{-\zeta_y \zeta_z}{2\sqrt{\epsilon\mu}V\gamma} & \frac{\zeta_x^2 + \zeta_y^2}{2\sqrt{\epsilon\mu}V\gamma} & \frac{-\xi_y}{2\epsilon V} & \frac{\zeta_x}{2\epsilon V} & 0 \\ 0 & \frac{\zeta_z}{2V\mu} & \frac{-\zeta_y}{2V\mu} & \frac{\zeta_y^2 + \zeta_z^2}{2\sqrt{\epsilon\mu}V\gamma} & \frac{-\zeta_x \zeta_y}{2\sqrt{\epsilon\mu}V\gamma} & \frac{-\zeta_x \zeta_z}{2\sqrt{\epsilon\mu}V\gamma} \\ \frac{-\zeta_z}{2V\mu} & 0 & \frac{\zeta_x}{2V\mu} & \frac{-\zeta_x \zeta_y}{2\sqrt{\epsilon\mu}V\gamma} & \frac{\zeta_x^2 + \zeta_z^2}{2\sqrt{\epsilon\mu}V\gamma} & \frac{-\zeta_y \zeta_z}{2\sqrt{\epsilon\mu}V\gamma} \\ \frac{\zeta_y}{2V\mu} & \frac{-\zeta_x}{2V\mu} & 0 & \frac{-\zeta_x \zeta_z}{2\sqrt{\epsilon\mu}V\gamma} & \frac{-\zeta_y \zeta_z}{2\sqrt{\epsilon\mu}V\gamma} & \frac{\zeta_x^2 + \zeta_y^2}{2\sqrt{\epsilon\mu}V\gamma} \end{bmatrix} \begin{Bmatrix} B_x \\ B_y \\ B_z \\ D_x \\ D_y \\ D_z \end{Bmatrix} \quad (29.43)$$

$$F_{\zeta}^{-} = \begin{bmatrix} \frac{-(\zeta_y^2 + \zeta_z^2)}{2\sqrt{\epsilon\mu}V\gamma} & \frac{\zeta_x\zeta_y}{2\sqrt{\epsilon\mu}V\gamma} & \frac{\zeta_x\zeta_z}{2\sqrt{\epsilon\mu}V\gamma} & 0 & \frac{-\zeta_z}{2\epsilon V} & \frac{\zeta_y}{2\epsilon V} \\ \frac{\zeta_x\zeta_y}{2\sqrt{\epsilon\mu}V\gamma} & \frac{-(\zeta_x^2 + \zeta_z^2)}{2\sqrt{\epsilon\mu}V\gamma} & \frac{\zeta_y\zeta_z}{2\sqrt{\epsilon\mu}V\gamma} & \frac{\zeta_x}{2\epsilon V} & 0 & \frac{-\zeta_x}{2\epsilon V} \\ \frac{\zeta_x\zeta_z}{2\sqrt{\epsilon\mu}V\gamma} & \frac{\zeta_y\zeta_z}{2\sqrt{\epsilon\mu}V\gamma} & \frac{-(\zeta_x^2 + \zeta_y^2)}{2\sqrt{\epsilon\mu}V\gamma} & \frac{-\zeta_y}{2\epsilon V} & \frac{\zeta_x}{2\epsilon V} & 0 \\ 0 & \frac{\zeta_z}{2V\mu} & \frac{-\zeta_y}{2V\mu} & \frac{-(\zeta_y^2 + \zeta_z^2)}{2\sqrt{\epsilon\mu}V\gamma} & \frac{\zeta_x\zeta_y}{2\sqrt{\epsilon\mu}V\gamma} & \frac{\zeta_x\zeta_z}{2\sqrt{\epsilon\mu}V\gamma} \\ \frac{-\zeta_z}{2V\mu} & 0 & \frac{\zeta_x}{2V\mu} & \frac{\zeta_x\zeta_y}{2\sqrt{\epsilon\mu}V\gamma} & \frac{-(\zeta_x^2 + \zeta_z^2)}{2\sqrt{\epsilon\mu}V\gamma} & \frac{\zeta_y\zeta_z}{2\sqrt{\epsilon\mu}V\gamma} \\ \frac{\zeta_y}{2V\mu} & \frac{-\zeta_x}{2V\mu} & 0 & \frac{\zeta_x\zeta_z}{2\sqrt{\epsilon\mu}V\gamma} & \frac{\zeta_y\zeta_z}{2\sqrt{\epsilon\mu}V\gamma} & \frac{-(\zeta_x^2 + \zeta_y^2)}{2\sqrt{\epsilon\mu}V\gamma} \end{bmatrix} \begin{Bmatrix} B_x \\ B_y \\ B_z \\ D_x \\ D_y \\ D_z \end{Bmatrix} \quad (29.44)$$

29.7 Finite-Difference Approximation

Once the detailed split fluxes are known, formulation of the finite-difference approximation is straightforward. From the sign of an eigenvalue, the stencil of a spatially second- or higher-order-accurate windward differencing can be easily constructed to form multiple one-dimensional difference operators [Shang 1993, Anderson et al. 1984, Richtmyer and Morton 1967]. In this regard, the forward difference and the backward difference approximations are used for the negative and the positive eigenvalues, respectively. The split flux vectors are evaluated at each discretized point of the field according to the signs of the eigenvalues. For the present purpose, a second-order accurate procedure is given:

$$\begin{aligned} \text{If } \lambda < 0, \quad \Delta U_i &= [-3U_i + 4U_{i+1} - U_{i+2}] / 2 \\ \text{If } \lambda > 0, \quad \nabla U_i &= [3U_i - 4U_{i-1} + U_{i-2}] / 2 \end{aligned} \quad (29.45)$$

The necessary metrics of the coordinate transformation are calculated by central-differencing, except at the edges of computational domain, where one-sided differences are used. Although the fractional-step or the time-splitting algorithm [Shang 1993, Anderson et al. 1984, Richtmyer and Morton 1967] has demonstrated greater efficiency in data storage and a higher data-processing rate than predictor–corrector time integration procedures [Shang 1993, Shang and Gaitonde 1993, Shang and Fithen 1994], it is limited to second-order accuracy in time. With respect to the fractional-step method, the temporal second-order result is obtained by a sequence of symmetrically cyclic operators [Shang 1993, Richtmyer and Morton 1967]:

$$U^{n+2} = L_{\xi} L_{\eta} L_{\zeta} L_{\xi} L_{\eta} L_{\zeta} U^n \quad (29.46)$$

where L_{ξ} , L_{η} , and L_{ζ} are the difference operators for one-dimensional equations in the ξ , η , and ζ coordinates, respectively.

In general, second-order and higher temporal resolution is achievable through multiple-time-step schemes [Anderson et al. 1984, Richtmyer and Morton 1967]. However, one-step schemes are more attractive because they have less memory requirements and don't need special startup procedures [Shang and Gaitonde 1993, Shang and Fithen 1994]. For future higher-order accurate solution development potential, the Runge–Kutta family of single-step, multistage procedures is recommended. This choice is also consistent with the accompanying characteristic-based finite-volume method [Shang and Gaitonde 1993].

In the present effort, the two-stage, formally second-order accurate scheme is used:

$$\begin{aligned}
 U_0 &= U_n \\
 U_1 &= U_0 - \Delta U (U_0) \\
 U_2 &= U_0 - 0.5 (\Delta U (U_1) + \Delta U (U_0)) \\
 U_{n+1} &= U_2
 \end{aligned}
 \tag{29.47}$$

where ΔU comprises the incremental values of dependent variables during each temporal sweep. The resultant characteristic-based finite-difference scheme for solving the three-dimensional Maxwell equations in the time domain is second-order accurate in both time and space.

The most significant feature of the flux-vector splitting scheme lies in its ability to easily suppress reflected waves from the truncated computational domain. In wave motion, the compatibility condition at any point in space is described by the split flux vector [Shang 1993, Shang and Gaitonde 1993, Shang and Fithen 1994]. In the present formulation, an approximated no-reflection condition can be achieved by setting the incoming flux component equal to zero:

$$\text{either } \lim_{r \rightarrow \infty} F^+(\xi, \eta, \zeta) = 0 \quad \text{or} \quad \lim_{r \rightarrow \infty} F^-(\xi, \eta, \zeta) = 0
 \tag{29.48}$$

The one-dimensional compatibility condition is exact when the wave motion is aligned with one of the coordinates [Shang 1993]. This unique attribute of the characteristic-based numerical procedure in removing a fundamental dilemma in computational electromagnetics will be demonstrated in detail later.

29.8 Finite-Volume Approximation

The finite-volume approximation solves the governing equation by discretizing the physical space into contiguous cells and balancing the flux-vectors on the cell surfaces. Thus in discretized form, the integration procedure reduces to evaluation of the sum of all fluxes aligned with surface-area vectors

$$\frac{\Delta U}{\Delta t} + \frac{\Delta F}{\Delta \xi} + \frac{\Delta G}{\Delta \eta} + \frac{\Delta H}{\Delta \zeta} - J = 0
 \tag{29.49}$$

In the present approach, the continuous differential operators have been replaced by discrete operators. In essence, the numerical procedure needs only to evaluate the sum of all flux vectors aligned with surface-area vectors [Shang and Gaitonde 1993, Shang and Fithen 1994, Van Leer 1982, Anderson et al. 1985]. Only one of the vectors is required to coincide with the outward normal to the cell surface, and the rest of the orthogonal triad can be made to lie on the same surface. The metrics, or more appropriately the direction cosines, on the cell surface are uniquely determined by the nodes and edges of the elementary volume. This feature is distinct from the finite-difference approximation. The shape of the cell under consideration and the stretching ratio of neighbor cells can lead to a significant deterioration of the accuracy of finite-volume schemes [Leonard 1988].

The most outstanding aspect of finite-volume schemes is the elegance of its flux-splitting process. The flux-difference splitting for Equation 29.25 is greatly facilitated by a locally orthogonal system in the transformed space [Van Leer 1982, Anderson et al. 1985]. In this new frame of reference, eigenvalues and eigenvectors as well as metrics of the coordinate transformation between two orthogonal systems are well known [Shang 1993, Shang and Gaitonde 1993]. The inverse transformation is simply the transpose of the forward mapping. In particular, the flux vectors in the transformed space have the same functional form as that in the Cartesian frame. The difference between the flux vectors in the transformed and the Cartesian coordinates is a known quantity and is given by the product of the surface outward normal and the cell volume, $V(\nabla S / \|\nabla S\|)$ [Shang and Gaitonde 1993]. Therefore, the flux vectors can be split in the transformed space according to the signs of the eigenvalues but without detailed knowledge of the associated eigenvectors in the transformed space. This feature of the finite-volume approach

provides a tremendous advantage over the finite-difference approximation in solving complex problems in physics.

The present formulation adopts Van Leer's kappa scheme in which solution vectors are reconstructed on the cell surface from the piecewise data of neighboring cells [Van Leer 1982, Anderson et al. 1985]. The spatial accuracy of this scheme spans a range from first-order to third-order upwind biased approximations,

$$\begin{aligned} U_{i+\frac{1}{2}}^+ &= U_i + \frac{\phi}{4} [(1 - \kappa)\nabla + (1 + \kappa)\Delta] U_i \\ U_{i+\frac{1}{2}}^- &= U_i - \frac{\phi}{4} [(1 + \kappa)\nabla + (1 - \kappa)\Delta] U_{i+1} \end{aligned} \quad (29.50)$$

where $\Delta U_i = U_i - U_{i-1}$ and $\nabla U_i = U_{i+1} - U_i$ are the forward and backward differencing discretizations. The parameters ϕ and κ control the accuracy of the numerical results. For $\phi = 1$, $\kappa = -1$ a two-point windward scheme is obtained. This method has an odd-order leading truncation-error term; the dispersive error is expected to dominate. If $\kappa = \frac{1}{3}$, a third-order upwind-biased scheme will emerge. In fact both upwind procedures have discernible leading phase error. This behavior is a consequence of using the two-stage time integration algorithm, and the dispersive error can be alleviated by increasing the temporal resolution. For $\phi = 1$, $\kappa = 0$ the formulation recovers the Fromm scheme [Van Leer 1982, Anderson et al. 1985]. If $\kappa = 1$, the formulation yields the spatially central scheme. Since the fourth-order dissipative term is suppressed, the central scheme is susceptible to parasitic odd-even point decoupling [Anderson et al. 1984, 1985].

The time integration is carried out by the same two-stage Runge–Kutta method as in the present finite-difference procedure [Shang 1993, Shang and Gaitonde 1993]. The finite-volume procedure is therefore second-order accurate in time and up to third-order accurate in space [Shang and Gaitonde 1993, Shang and Fithen 1994]. For the present purpose, only the second-order upwinding and the third-order upwind biased options are exercised. The second-order windward schemes in the form of the flux-vector splitting finite-difference and the flux-difference splitting finite-volume scheme are formally equivalent [Shang and Gaitonde 1993, Shang and Fithen 1994, Van Leer 1982, Anderson et al. 1985, Leonard 1988].

29.9 Summary and Research Issues

The technical merits of the characteristic-based methods for solving the time-dependent, three-dimensional Maxwell equations can best be illustrated by the following two illustrations. In [Figure 29.2](#), the exact electrical field of a traveling wave is compared with numerical results. The numerical results were generated at the maximum allowable time-step size defined by the Courant–Friedrichs–Lewy (CFL) number of 2 ($\lambda \Delta x / \Delta t = 2$) [Anderson et al. 1984, Richtmyer and Morton 1967]. The numerical solutions presented are at instants when a right-running wave reaches the midpoint of the computational domain and exits the numerical boundary respectively. For this one-dimensional simulation, the characteristic-based scheme using the single-step upwind explicit algorithm exhibits the shift property, which indicates a perfect translation of the initial value in space [Anderson et al. 1984]. As the impulse wave moves through the initially quiescent environment, the numerical result duplicates the exact solution at each and every discretized point, including the discontinuous incoming wavefront. Although this highly desirable property of a numerical solution is achievable only under very restrictive conditions and is not preserved for multidimensional problems [Anderson et al. 1984, Richtmyer and Morton 1967], the ability to simulate the nonanalytic solution behavior in the limit is clearly illustrated.

In [Figure 29.3](#), another outstanding feature of the characteristic-based method is highlighted by simulating the oscillating electric dipole. For the radiating electric dipole, the depicted temporal calculations are sampled at the instant when the initial pulse has traveled a distance of 2.24 wavelengths from the dipole. The numerical results are generated on a $48 \times 48 \times 96$ mesh system with the second-order scheme. Under that condition each wavelength is resolved by 15 mesh points and the difference between numerical results by the finite-volume and the finite-difference method is negligible. However, on an irregular

FIGURE 29.2 Perfect-shift property of a one-dimensional wave computation, CFL = 2.

FIGURE 29.3 Instantaneous distributions of oscillating-dipole electric field.

mesh like the present spherical polar system, the finite-volume procedure has shown a greater numerical error than the finite-difference procedure on highly stretched grid systems [Shang and Fithen 1994, Anderson et al. 1985]. Under the present computational conditions, both numerical procedures yield uniformly excellent comparison with the theoretical result. Significant error appeared only in the immediate region of the coordinate origin. At that location, the solution has a singularity that behaves as the inverse cube of the radial distance. The most interesting numerical behavior, however, is revealed in the truncated far field. The no-reflection condition at the numerical boundary is observed to be satisfied

FIGURE 29.4 Instantaneous distributions of oscillating-dipole magnetic field.

within the order of the truncation error. For a spherically symmetric radiating field, the orientation of the wave is aligned with the radial coordinate, and the suppression of the reflected wave within the numerical domain is the best achievable by the characteristic formulation.

The corresponding magnetic field intensity computed by both the second-order accurate finite-difference and the finite-volume procedure is given in Figure 29.4. Again the difference in solution between the two distinct numerical procedures is indiscernible. For the oscillating electric dipole, only the x and y components of the magnetic field exist. Numerical results attain excellent agreement with theoretical values [Shang and Gaitonde 1993, Shang and Fithen 1994]. The third-order accurate finite-volume scheme also produces a similar result on the same mesh but at a greater allowable time-step size (a CFL value of 0.87 is used vs. 0.5 for the second-order method). A numerically more efficient and higher-order accurate simulation is obtainable in theory. However, at the present, the third-order windward biased algorithm cannot reinforce rigorously the zone-of-dependence requirement; therefore the reflected-wave suppression is incomplete in the truncated numerical domain. For this reason, the third-order accurate results are not included here.

Numerical accuracy and efficiency are closely related issues in computational electromagnetics. A high-accuracy requirement of a simulation is supportable only by efficient numerical procedures. The inaccuracies incurred by numerical simulations are attributable to the mathematical formulation of the problem, to the algorithm, to the numerical procedure, and to computational inaccuracy. A basic approach to relieve the accuracy limitation must be derived from using high-order schemes or spectral methods. The numerical efficiency of CEM can be enhanced substantially by using scalable multicomputers [Shang et al. 1993]. The effective use of a distributed-memory, message-passing homogeneous multicomputer still requires a judicious tradeoff between a balanced work load and interprocessor communication. A characteristic-based finite-volume computer program has been successfully mapped onto distributed-memory systems by a rudimentary domain decomposition strategy [Shang et al. 1993]. For example, a square waveguide, at five different frequencies up to the cutoff, was simulated.

Figure 29.5 displays the x -component of the magnetic field intensity within the waveguide. The simulated transverse electric mode, $TE_{1,1}$, $E_x = 0$, which has a half period of π along the x and y coordinates, is generated on a $24 \times 24 \times 128$ mesh system. Since the entire field is described by simple harmonic functions, the remaining field components are similar and only half the solution domain along the z -coordinate is

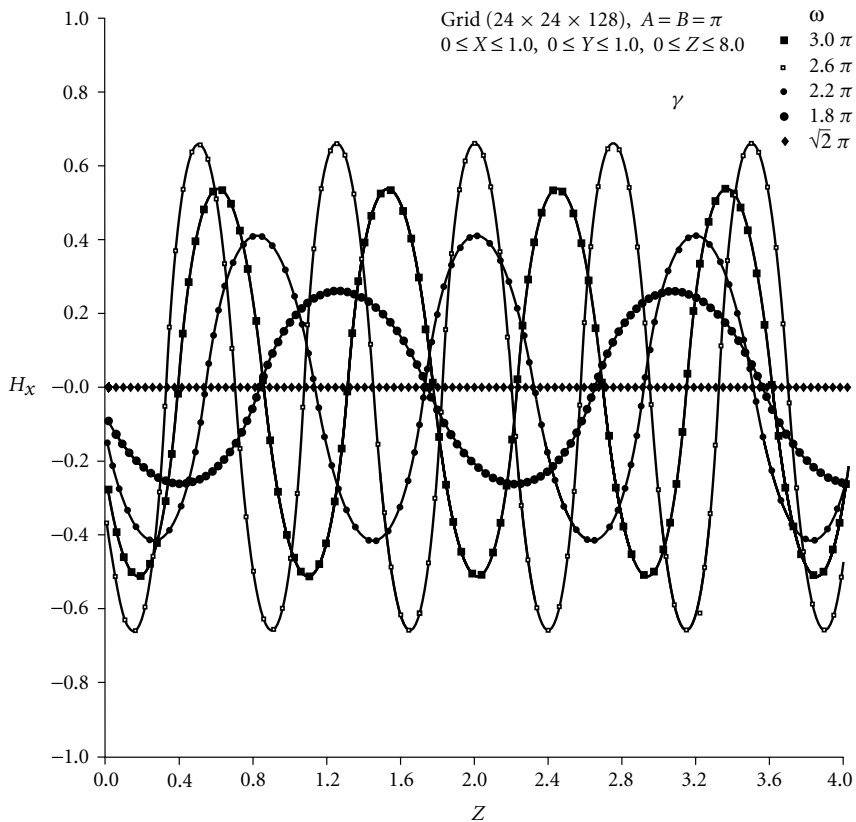

FIGURE 29.5 Cutoff frequency of a square waveguide, $TE_{1,1}$.

presented to minimize repetition. In short, the agreement between the closed-form and numerical solutions is excellent at each frequency. In addition, the numerical simulations duplicate the physical phenomenon at the cutoff frequency, below which there is no phase shift along the waveguide and the wave motion ceases [Elliott 1966, Harrington 1961]. For simple harmonic wave motion in an isotropic medium, the numerical accuracy can be quantified. At a grid-point density of 12 nodes per wavelength, the L2 norm [Richtmyer and Morton 1967] has a nearly uniform magnitude of order 10^{-4} . The numerical results are fully validated by comparison with theory. However, further efforts are still required to substantially improve the parallel and scalable numerical efficiency. In fact, this is the most promising area in CEM research.

The pioneering efforts in CEM usually employed the total-field formulation on staggered-mesh systems [Yee 1966, Taflove 1992]. That particular combination of numerical algorithm and procedure has been proven to be very effective. In earlier RCS calculations using the present numerical procedure, the total-field formulation was also utilized [Shang and Gaitonde 1994, Shang et al. 1993]. However, for three-dimensional scatterer simulation, the numerical accuracy requirement for RCS evaluations becomes extremely stringent. In the total-field formulation, the dynamic range of the field variables has a substantial difference from the exposed and the shadow region, and the incident wave must also traverse the entire computation domain. Both requirements impose severe demands on the numerical accuracy of simulation. In addition, the total field often contains only the residual of partial cancellations of the incident and the diffracted waves. The far-field electromagnetic energy distribution becomes a secular problem — a small difference between two variables of large magnitude. An alternative approach via the scattered-field formulation for RCS calculations appears to be very attractive. Particularly in this formulation, the numerical dissipation of the

FIGURE 29.6 Comparison of total-field and scattered-field RCS calculations of $\sigma(\theta, 0^\circ)$, $ka = 5.3$.

incident wave that must propagate from the far-field boundary to the scatterer is completely eliminated from the computations. In short, the incident field can be directly specified on the scatterer's surface. The numerical advantage over the total-field formulation is substantial.

The total-field formulation can be cast in the scattered-field form by replacing the total field with scattered field variables [Elliott 1966, Harrington 1961]:

$$U_s = U_t - U_i \quad (29.51)$$

Since the incident field U_i must satisfy the Maxwell equations identically, the equations of the scattered field remain unaltered from the total-field formulation. Thus, the scattered-field formulation can be considered as a dependent-variable transform of the total-field equations. In the present approach, both formulations are solved by a characteristic-based finite-volume scheme.

The comparison of horizontal polarized RCS of a perfect electrically conducting (PEC) sphere, $\sigma(\theta, 0.0)$, from the total-field and scattered-field formulations at $ka = 5.3$ (where $k =$ wave number and $a =$ diameter of the sphere) is presented in Figure 29.6. The validating datum is the exact solution for the scattering of a plane electromagnetic wave by a PEC sphere, which is commonly referred to as the Mie series [Elliott 1966]. Both numerical results are generated under identical computational conditions. The location of the truncated far-field boundary is prescribed at 2.5 wavelengths from the center of the PEC sphere. Numerical results of the total-field formulation reveal far greater error than for the scattered-field formulation. The additional source of error is incurred when the incident wave must propagate from the far-field boundary to the scatterer. In the scattered-field formulation, the incident field data are described precisely by the boundary condition on the scatterer surface. Since the far-field electromagnetic energy distribution is derived from the near-field parameters [Taflove 1992, Sommerfeld 1949, Shang and Gaitonde 1993], the advantage of describing the data incident on a scatterer without error is tremendous. Numerical errors of the total-field calculations are evident in the exaggerated peaks and troughs over the entire viewing-angle displacement.

In Figure 29.7, the vertically polarized RCS $\sigma(\theta, 90.0^\circ)$ of the $ka = 5.3$ case substantiates the previous observation. In fact, the numerical error of the total-field calculation is excessive in comparison with the result of the scattered-field formulation. Since the results are not obtained for the optimal far-field placement for RCS computation, the results of the scattered-field formulation overpredict the theoretical values by 2.7 percent. The deviation of the total-field result from the theory, however, exceeds

FIGURE 29.7 Comparison of total-field and scattered-field RCS calculations of $\sigma(\theta, 90^\circ)$, $ka = 5.3$.

25.6 percent and becomes unacceptable. In addition, computations by the total-field formulation exhibit a strong sensitivity to placement of the far-field boundary. A small perturbation of the far-field boundary placement leads to a drastic change in the RCS prediction: a feature resembling the ill-posedness condition, which is highly undesirable for numerical simulation. Since there is very little difference in computer coding for the two formulations, the difference in computing time required for an identical simulation is insignificant. On the Cray C90, 1,505.3 s at a data-processing rate of 528.8 Mflops and an average vector length of 62.9 is needed to complete a sampling period. At the present, the most efficient calculation on a distributed memory system, Cray T3-D, has reduced the processing time to 1,204.2 s using 76 computing nodes.

In summary, recent progress in solving the three-dimensional Maxwell equations in the time domain has opened a new frontier in electromagnetics, plasmadynamics, and optics, as well as the interface between electrodynamics and quantum mechanics [Taflove 1992]. The progress in microchip and interconnect network technology has led to a host of high-performance distributed memory, message-passing parallel computer systems. The synergism of efficient and accurate numerical algorithms for solving the Maxwell equations in the time domain with high-performance multicomputers will propel the new interdisciplinary simulation technique to practical and productive applications.

30.1 Introduction

The use of computer-based methods for the prediction of fluid flows has seen tremendous growth in the past several decades. Fluid dynamics has been one of the earliest, and most active fields for the application of numerical techniques. This is due to the essential nonlinearity of most fluid flow problems of practical interest — which makes analytical, or closed-form, solutions virtually impossible to obtain — combined with the geometrical complexity of these problems. In fact, the history of computational fluid dynamics can be traced back virtually to the birth of the digital computer itself, with the pioneering work of John von Neumann and others in this area. Von Neumann was interested in using the computer not only to solve engineering problems, but to understand the fundamental nature of fluid flows themselves. This is possible because the complexity of fluid flows arises, in many instances, not from complicated or poorly understood formulations, but from the nonlinearity of partial differential equations that have been known for more than a century. A famous paragraph written by von Neumann in 1946 serves to illustrate this point. He wrote [Goldstine and von Neumann 1963]:

Indeed, to a great extent, experimentation in fluid mechanics is carried out under conditions where the underlying physical principles are not in doubt, where the quantities to be observed are completely determined by known equations. The purpose of the experiment is not to verify a proposed theory but to replace a computation from an unquestioned theory by direct measurements. Thus, wind tunnels are, for example, used at present, at least in part, as computing devices of the so-called analogy type . . . to integrate the nonlinear partial differential equations of fluid dynamics.

The present article provides some of the basic background in fluid dynamics required to understand the issues involved in numerical solution of fluid flow problems, then outlines the approaches that have been successful in attacking problems of practical interest.

30.2 Underlying Principles

In this section, we will provide the background in fluid dynamics required to understand the principles involved in the numerical solution of the governing equations. The formulation of the equations in generalized, curvilinear coordinates and the geometrical issues involved in the construction of suitable grids also will be discussed.

30.2.1 Fluid-Dynamical Background

As can be inferred from the quotation of von Neumann presented in the introduction, fluid dynamics is fortunate to have a generally accepted mathematical framework for describing most problems of practical interest. Such diverse problems as the high-speed flow past an aircraft wing, the motions of the atmosphere responsible for our weather, and the unsteady air currents produced by the flapping wings of a housefly all can be described as solutions to a set of partial differential equations known as the Navier–Stokes equations. These equations express the physical laws corresponding to conservation of mass, Newton’s second law of motion relating the acceleration of fluid elements to the imposed forces, and conservation of energy, under the assumption that the stresses in the fluid are linearly related to the local rates of strain of the fluid elements. This latter assumption is generally regarded as an excellent approximation for everyday fluids such as water and air — the two most common fluids of engineering and scientific interest.

We will describe the equations for problems in two space dimensions, for the sake of economy of notation; here, and elsewhere, the extension to problems in three dimensions will be straightforward unless otherwise noted. The Navier–Stokes equations can be written in the form

$$\frac{\partial \mathbf{w}}{\partial t} + \frac{\partial \mathbf{f}}{\partial x} + \frac{\partial \mathbf{g}}{\partial y} = \frac{\partial \mathbf{R}}{\partial x} + \frac{\partial \mathbf{S}}{\partial y} \quad (30.1)$$

where \mathbf{w} is the vector of conserved quantities

$$\mathbf{w} = \{\rho, \rho u, \rho v, e\}^T \quad (30.2)$$

where ρ is the fluid density, u and v are the fluid velocity components in the x and y directions, respectively, and e is the total energy per unit volume. The inviscid flux vectors \mathbf{f} and \mathbf{g} are given by

$$\mathbf{f} = \{\rho u, \rho u^2 + p, \rho uv, (e + p)u\}^T \quad (30.3)$$

$$\mathbf{g} = \{\rho v, \rho uv, \rho v^2 + p, (e + p)v\}^T \quad (30.4)$$

where p is the fluid pressure, and the flux vectors describing the effects of viscosity are

$$\mathbf{R} = \{0, \tau_{xx}, \tau_{xy}, u\tau_{xx} + v\tau_{xy} - q_x\}^T \quad (30.5)$$

$$\mathbf{S} = \{0, \tau_{xy}, \tau_{yy}, u\tau_{xy} + v\tau_{yy} - q_y\}^T \quad (30.6)$$

The viscous stresses appearing in these terms are related to the derivatives of the components of the velocity vector by

$$\tau_{xx} = 2\mu \frac{\partial u}{\partial x} - \frac{2}{3}\mu \left\{ \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} \right\} \quad (30.7)$$

$$\tau_{xy} = \mu \left\{ \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \right\} \quad (30.8)$$

$$\tau_{yy} = 2\mu \frac{\partial v}{\partial y} - \frac{2}{3}\mu \left\{ \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} \right\} \quad (30.9)$$

and

$$q_x = -k \frac{\partial T}{\partial x} \quad (30.10)$$

$$q_y = -k \frac{\partial T}{\partial y} \quad (30.11)$$

represent the x and y components of the heat flux vector, according to Fourier's law. In these equations μ and k represent the coefficients of viscosity and thermal conductivity, respectively.

If the Navier–Stokes equations are nondimensionalized by normalizing lengths with respect to a representative length L and velocities by a representative velocity V_∞ , and normalizing the fluid properties (such as density and coefficient of viscosity) by their values in the freestream, an important nondimensional parameter, the *Reynolds number*

$$\mathbf{Re} = \frac{\rho_\infty V_\infty L}{\mu_\infty} \quad (30.12)$$

appears as a parameter in the equations. In particular, the viscous stress terms on the right-hand side of Equation 30.1 are multiplied by the reciprocal of the Reynolds number. Physically, the Reynolds number can be interpreted as an inverse measure of the relative importance of the contributions of the viscous stresses to the dynamics of the flow; i.e., when the Reynolds number is large, the viscous stresses are small almost everywhere in the flowfield.

The computational resources required to solve the complete Navier–Stokes equations are enormous, particularly when the Reynolds number is large and regions of **turbulent flow** must be resolved. In 1970 Howard Emmons of Harvard University estimated the computer time required to solve a simple turbulent pipe-flow problem, including direct computation of all turbulent eddies containing significant energy [Emmons 1970]. For a computational domain consisting of approximately 12 diameters of a pipe of circular cross section, the computation of the solution at a Reynolds number based on the pipe diameter of $\mathbf{Re}_d = 10^7$ would require approximately 10^{17} seconds on a 1970s mainframe computer. Of course, much faster computers are now available, but even at a computational speed of 100 gigaflops — i.e., 10^{11} floating-point operations per second — such a calculation would require more than 3000 *years* to complete.

Because the resources required to solve the complete Navier–Stokes equations are so large, it is common to make approximations to bring the required computational resources to a more modest level for problems of practical interest. Expanding slightly on a classification introduced by Chapman [1979], the sequence of fluid-mechanical equations can be organized into the hierarchy shown in Table 30.1.

Table 30.1 summarizes the physical assumptions and time periods of most intense development for each of the stages in the fluid-mechanical hierarchy. Stage IV represents an approximation to the Navier–Stokes equations in which only the largest, presumably least isotropic scales of turbulence are resolved; the subgrid scales are modeled. Stage III represents an approximation in which the solution is decomposed into time-averaged or ensemble-averaged and fluctuating components for each variable. For example, the

TABLE 30.1 The Hierarchy of Fluid-Mechanical Approximations, Following Chapman [1979]

Stage	Model	Equations	Time Frame
I	Linear potential	Laplace's equation	1960s
IIa	Nonlinear potential	Full potential equation	1970s
IIb	Nonlinear inviscid	Euler equations	1980s
III	Modeled turbulence	Reynolds-averaged Navier–Stokes equations	1990s
IV	Large-eddy simulation (LES)	Navier–Stokes equations with subgrid turbulence model	1980s–1990s
V	Direct numerical simulation (DNS)	Fully resolved Navier–Stokes equations	1980s–1990s

velocity components and pressure can be decomposed into

$$u = U + u' \quad (30.13)$$

$$v = V + v' \quad (30.14)$$

$$p = P + p' \quad (30.15)$$

where U , V , and P are the average values of u , v , and p , respectively, taken over a time interval that is long compared to the turbulence time scales, but short compared to the time scales of any nonsteadiness of the averaged flowfield. If we let $\langle u \rangle$ denote such a time average of the u -component of the velocity, then, e.g.,

$$\langle u \rangle = U \quad (30.16)$$

When a decomposition of the form of Equation 30.13 to Equation 30.15 is substituted into the Navier–Stokes equations and the equations are averaged as described above, the resulting equations describe the evolution of the mean-flow quantities (such as U , V , P , etc.). These equations, called the **Reynolds-averaged Navier–Stokes equations**, are nearly identical to the original Navier–Stokes equations written for the mean-flow variables because terms that are linear in $\langle u' \rangle$, $\langle v' \rangle$, $\langle p' \rangle$, etc., are identically zero. The nonlinearity of the equations, however, introduces terms that depend upon the fluctuating components. In particular, terms proportional to $\langle \rho u' v' \rangle$, $\langle \rho u'^2 \rangle$, and $\langle \rho v'^2 \rangle$ appear in the averaged equations. Dimensionally, these terms are equivalent to stresses; in fact, these quantities are called the Reynolds stresses. Physically, the Reynolds stresses are the turbulent counterparts of the molecular viscous stresses, and appear as a result of the transport of momentum by the turbulent fluctuations. The appearance of these terms in the equations describing the mean flow means that the mean flow cannot be determined without some knowledge of these fluctuating components.

In order to solve the Reynolds-averaged Navier–Stokes equations, the Reynolds stresses must be related to the mean flow at some level of approximation using a phenomenological model. The simplest procedure is to try to relate the Reynolds stresses to the local mean-flow properties. Since the turbulence that is responsible for these stresses is a function not only of the local mean-flow state, but also of the flow history as well, such an approximation cannot have broad generality, but such local, or algebraic, turbulence models, based on the analogy of the mixing length from the kinetic theory of gases, are useful for many flows of engineering interest, especially for flows in which boundary-layer separation does not occur.

A more general procedure is to develop partial differential equations for the Reynolds stresses themselves, or for quantities that can be used to determine the scales of the turbulence, such as the turbulent kinetic energy k and the dissipation rate ϵ . The latter, so-called k – ϵ model is widely used in engineering analyses of turbulent flows. These differential equations can be derived by taking higher-order moments of the Navier–Stokes equations. For example, if the x -momentum equation is multiplied by v and then averaged, the result will be an equation for the Reynolds-stress component $\langle \rho u' v' \rangle$. Again because of the nonlinearity of the equations, however, yet higher moments of the fluctuating components (e.g., terms proportional to $\langle \rho u'^2 v' \rangle$, $\langle \rho u' v'^2 \rangle$, etc.) will appear in the equations for the Reynolds stresses. This is an example of the problem of closure of the equations for the Reynolds stresses; i.e., to solve the equations for the Reynolds stresses, these third-order quantities must be known. Equations for the third-order quantities can be derived by taking yet higher-order moments of the Navier–Stokes equations, but these equations will involve fourth-order moments. Thus, at some point the taking of moments must be terminated and models must be developed for the unknown higher-order quantities. It is hoped that more nearly universal models may be developed for these higher-order quantities, but the superiority of second-order models, in which the equations for the Reynolds-stress components are solved, subject to modeling assumptions for the required third-order quantities, has yet to be established for most practical problems.

For many design purposes, especially in aerodynamics, it is sufficient to represent the flow as that of an inviscid, or ideal, fluid. This is appropriate for flows at high Reynolds numbers that contain only negligibly small regions of separated flow. The equations describing inviscid flows can be obtained as a simplification of the Navier–Stokes equations in which the viscous terms are neglected altogether. This results in the

Euler equations of inviscid, compressible flow,

$$\frac{\partial \mathbf{w}}{\partial t} + \frac{\partial \mathbf{f}}{\partial x} + \frac{\partial \mathbf{g}}{\partial y} = 0 \quad (30.17)$$

This approximation corresponds to stage IIb in the hierarchy described in [Table 30.1](#).

The Euler equations constitute a hyperbolic system of partial differential equations, and their solutions contain features that are absent from the Navier–Stokes equations. In particular, while the viscous diffusion terms appearing in the Navier–Stokes equations guarantee that solutions will remain smooth, the absence of these dissipative terms from the Euler equations allows them to have solutions that are discontinuous across surfaces in the flow. Solutions to the Euler equations must be interpreted within the context of generalized (or weak) solutions, and this theory provides the mathematical framework for developing the properties of any discontinuities that may appear. In particular, jumps in dependent variables (such as density, pressure, and velocity) across such surfaces must be consistent with the original conservation laws upon which the differential equations are based. For the Euler equations, these jump conditions are called the Rankine–Hugoniot conditions.

Solutions of the Euler equations for flows containing shock waves can be computed using either **shock fitting** or **shock capturing** methods. In the former, the shock surfaces must be located and the Rankine–Hugoniot jump conditions enforced explicitly. In shock capturing methods, **artificial viscosity** terms are added in the numerical approximation to provide enough dissipation to allow the shocks to be captured automatically by the scheme, with no special treatment in the vicinity of the shock waves. The numerical viscosity terms usually act to smear out the discontinuity over several grid cells. Numerical viscosity also is used when solving the Navier–Stokes equations for flows containing shock waves, because usually it is impractical to resolve the shock structure defined by the physical dissipative mechanisms.

In many cases, the flow can further be approximated as steady and irrotational. In these cases, it is possible to define a velocity potential Φ such that the velocity vector \mathbf{V} is given by

$$\mathbf{V} = \nabla \Phi \quad (30.18)$$

and the fluid density is given by the isentropic relation

$$\rho = \left(1 + \frac{\gamma - 1}{2} \mathbf{M}_\infty^2 [1 - (u^2 + v^2)] \right)^{\frac{1}{\gamma - 1}} \quad (30.19)$$

where

$$u = \frac{\partial \Phi}{\partial x} \quad (30.20)$$

$$v = \frac{\partial \Phi}{\partial y} \quad (30.21)$$

and \mathbf{M}_∞ is a reference Mach number corresponding to the freestream state in which $\rho = 1$ and $u^2 + v^2 = 1$. The steady form of the Euler equations then reduces to the single equation

$$\frac{\partial \rho u}{\partial x} + \frac{\partial \rho v}{\partial y} = 0 \quad (30.22)$$

Equation (30.19) can be used to eliminate the density from Eq. (30.22), which then can be expanded to the form

$$(a^2 - u^2) \frac{\partial^2 \Phi}{\partial x^2} - 2uv \frac{\partial^2 \Phi}{\partial x \partial y} + (a^2 - v^2) \frac{\partial^2 \Phi}{\partial y^2} = 0 \quad (30.23)$$

where a is the local speed of sound, which is a function only of the fluid speed $V = \sqrt{u^2 + v^2}$. Thus, Equation 30.23 is a single equation that can be solved for the velocity potential Φ .

Equation 30.23 is a second-order quasilinear partial differential equation whose type depends on the sign of the discriminant $1 - \mathbf{M}^2$, where \mathbf{M} is the *local* Mach number. The equation is elliptic or hyperbolic according as the Mach number is less than or greater than unity. Thus, the nonlinear potential equation contains a mathematical description of the physics necessary to predict the important features of transonic flows. It is capable of changing type, and the conservation form of Equation 30.22 allows surfaces of discontinuity, or shock waves, to be computed. Solutions at this level of approximation, corresponding to stage IIa, are considerably less expensive to compute than solutions of the full Euler equations, since only one dependent variable need be computed and stored. The jump relation corresponding to weak solutions of the potential equation is different than the Rankine–Hugoniot relations, but is a good approximation to the latter when the shocks are not too strong.

Finally, if the flow can be approximated by small perturbations to some uniform reference state, Equation 30.23 can further be simplified to

$$(1 - \mathbf{M}_\infty^2) \frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} = 0 \quad (30.24)$$

where ϕ is the *perturbation* velocity potential defined according to

$$\Phi = x + \phi \quad (30.25)$$

if the uniform velocity in the reference state is assumed to be parallel to the x -axis and be normalized to have unit magnitude. Further, if the flow can be approximated as incompressible, i.e., in the limit as $\mathbf{M}_\infty \rightarrow 0$, Equation 30.23 reduces to

$$\frac{\partial^2 \Phi}{\partial x^2} + \frac{\partial^2 \Phi}{\partial y^2} = 0 \quad (30.26)$$

Since Equation 30.24 and Equation 30.26 are linear, superposition of elementary solutions can be used to construct solutions of arbitrary complexity. Numerical methods to determine the singularity strengths for aerodynamic problems are called **panel methods**, and constitute stage I in the hierarchy of approximations.

It is important to realize that, even though the time periods for development of some of the different models overlap, the applications of the various models may be for problems of significantly differing complexity. For example, DNS calculations were performed as early as the 1970s, but only for the simplest flows — homogeneous turbulence — at very low Reynolds numbers. Flows at higher Reynolds numbers and nonhomogeneous flows are being performed only now, whereas calculations for three-dimensional flows with modeled turbulence were performed as early as the mid 1980s.

30.2.2 Treatment of Geometry

For all numerical solutions to partial differential equations, including those of fluid mechanics, it is necessary to discretize the boundaries of the flow domain. For the panel method of stage I, this is all that is required, since the problem is linear and superposition can be used to construct solutions satisfying the boundary conditions. For nonlinear problems, it is necessary to discretize the entire flow domain. This can be done using either structured or unstructured grid systems. *Structured grids* are those in which the grid points can be ordered in a regular Cartesian structure; i.e., the points can be given indices (i, j) such that the nearest neighbors of the (i, j) point are identified by the indices $(i \pm 1, j \pm 1)$. The grid cells for these meshes are thus quadrilateral in two dimensions and hexahedral in three dimensions. *Unstructured grids* have no regular ordering of points or cells, and a connectivity table must be maintained to identify which points and edges belong to which cells. Unstructured grids most often consist of triangles (in two dimensions), tetrahedra (in three dimensions), or combinations of these and quadrilateral and hexahedral cells, respectively. In addition, grids having purely quadrilateral cells may also be unstructured, even though they have a locally Cartesian structure — e.g., when multilevel grids are used for adaptive refinement.

Implementations on structured grids are generally more efficient than those on unstructured grids, since indirect addressing is required for the latter, and efficient implicit methods often can be constructed that take advantage of the regular ordering of points (or cells) in structured grids. A great deal of effort has been expended to generate both structured and unstructured grid systems, much of which is closely related to the field of computational geometry.

30.2.2.1 Structured Grids

A variety of techniques are used to generate structured grids for use in fluid-mechanical calculations. These include relatively fast algebraic methods, including those based on transfinite interpolation and conformal mapping, as well as more costly methods based on the solution of either elliptic or hyperbolic systems of partial differential equations for the grid coordinates. These techniques are discussed in a review article by Eiseman [1985].

For complex geometries, it often is not possible to generate a single grid that conforms to all the boundaries. Even if it is possible to generate such a grid, it may have undesirable properties, such as excessive skewness or a poor distribution of cells, which could lead to poor stability or accuracy in the numerical algorithm. Thus, structured grids for complex geometries are generally constructed as combinations of simpler grid blocks for various parts of the domain. These grids may be allowed to overlap, in which case they are referred to as *Chimera* grids, or be required to share common surfaces of intersection, in which case they are identified as *multiblock* grids. In the latter case, grid lines may have varying degrees of continuity across the interblock boundaries, and these variations have implications for the construction and behavior of the numerical algorithm in the vicinity of those boundaries. Grid generation techniques based on the solution of systems of partial differential equations are described by Thompson et al. [1985].

Numerical methods to solve the equations of fluid mechanics on structured grid systems are implemented most efficiently by taking advantage of the ease with which the equations can be transformed to a generalized coordinate system. The expression of the system of conservation laws in the new, body-fitted coordinate system reduces the problem to one effectively of Cartesian geometry. The transformation will be described here for the Euler equations.

Consider the transformation of Equation 30.17 to a new coordinate system (ξ, η) . The local properties of the transformation at any point are contained in the Jacobian matrix of the transformation, which can be defined as

$$J = \begin{Bmatrix} x_\xi & x_\eta \\ y_\xi & y_\eta \end{Bmatrix} \quad (30.27)$$

for which the inverse is given by

$$J^{-1} = \begin{Bmatrix} \xi_x & \xi_y \\ \eta_x & \eta_y \end{Bmatrix} = \frac{1}{h} \begin{Bmatrix} y_\eta & -x_\eta \\ -y_\xi & x_\xi \end{Bmatrix} \quad (30.28)$$

where $h = x_\xi y_\eta - y_\xi x_\eta$ is the determinant of the Jacobian matrix. Subscripts in Equation 30.27 and Equation 30.28 denote partial differentiation.

It is natural to express the fluxes in conservation laws in terms of their contravariant components. Thus, if we define

$$\{\mathbf{F}, \mathbf{G}\}^T = J^{-1} \{\mathbf{f}, \mathbf{g}\}^T \quad (30.29)$$

then the transformed Euler equations can be written in the compact form

$$\frac{\partial h\mathbf{w}}{\partial t} + \frac{\partial h\mathbf{F}}{\partial \xi} + \frac{\partial h\mathbf{G}}{\partial \eta} = 0 \quad (30.30)$$

if the transformation is independent of time (i.e., if the grid is not moving). If the grid is moving or deforming with time, the equations can be written in a similar form, but additional terms must be included that allow for the fluxes induced by the motion of the mesh.

The Navier–Stokes equations can be transformed in a similar manner, although the transformation of the viscous contributions is somewhat more complicated and will not be included here. Since the nonlinear potential equation is simply the continuity equation (the first of the equations that comprise the Euler equations), the transformed potential equation can be written as

$$\frac{\partial}{\partial \xi}(\rho h U) + \frac{\partial}{\partial \eta}(\rho h V) = 0 \quad (30.31)$$

where

$$\begin{Bmatrix} U \\ V \end{Bmatrix} = J^{-1} \begin{Bmatrix} u \\ v \end{Bmatrix} \quad (30.32)$$

are the contravariant components of the velocity vector.

30.2.2.2 Unstructured Grids

Unstructured grids generally have greater geometric flexibility than structured grids, because of the relative ease of generating triangular or tetrahedral tessellations of two- and three-dimensional domains. Advancing-front methods and Delaunay triangulations are the most frequently used techniques for generating triangular/tetrahedral grids. Unstructured grids also are easier to adapt locally so as to better resolve localized features of the solution.

30.3 Best Practices

30.3.1 Panel Methods

The earliest numerical methods used widely for making fluid-dynamical computations were developed to solve linear potential problems, described as stage I calculations in the previous section. Mathematically, panel methods are based upon the fact that Equation 30.26 can be recast as an integral equation giving the solution at any point (x, y) in terms of the freestream speed U (here assumed unity) and angle of attack α and the line integrals of singularities distributed along the curve \mathcal{C} representing the body surface:

$$\Phi(x, y) = x \cos \alpha + y \sin \alpha + \int_{\mathcal{C}} \sigma \ln \left(\frac{r}{2\pi} \right) ds + \int_{\mathcal{C}} \delta (\partial/\partial n) \ln \left(\frac{r}{2\pi} \right) ds \quad (30.33)$$

In this equation, σ and δ represent the source and doublet strengths distributed along the body contour, respectively, r is the distance from the point (x, y) to the boundary point, and n is the direction of the outward normal to the body surface. When the point (x, y) is chosen to lie on the body contour \mathcal{C} , Equation 30.33 can be interpreted as giving the solution Φ at any point on the body in terms of the singularities distributed along the surface. This effectively reduces the dimension of the problem by one (i.e., the two-dimensional problem considered here becomes essentially one-dimensional, and the analogous procedure applied to a three-dimensional problem results in a two-dimensional equation requiring the evaluation only of integrals over the body surface).

Equation 30.33 is approximated numerically by discretizing the boundary \mathcal{C} into a collection of panels (line segments in this two-dimensional example) on which the singularity distribution is assumed to be of some known functional form, but of an as yet unknown magnitude. For example, for a simple nonlifting body, the doublet strength δ might be assumed to be zero, while the source strength σ is assumed to be constant on each segment. The second integral in Equation 30.33 is then zero, while the first integral can be written as a sum over all the elements of integrals that can be evaluated analytically as

$$\Phi(x, y) = x \cos \alpha + y \sin \alpha + \sum_{i=1}^N \sigma_i \int_{\mathcal{C}_i} \ln \left(\frac{r}{2\pi} \right) ds \quad (30.34)$$

where C_i is the portion of the body surface corresponding to the i th segment and N is the number of segments, or panels, used.

The source strengths σ_i must be determined by enforcing the boundary condition

$$\frac{\partial \Phi}{\partial n} = 0 \quad (30.35)$$

which specifies that the component of velocity normal to the surface be zero (i.e., that there be no flux of fluid across the surface). This is implemented by requiring that Equation 30.35 be satisfied at a selected number of control points. For the example of constant-strength source panels, if one control point is chosen on each panel, the requirement that Equation 30.35 be satisfied at each of the control points will result in N equations of the form

$$\sum_{i=1}^N A_{i,j} \sigma_i = \mathbf{U} \cdot \hat{\mathbf{n}}, \quad j = 1, 2, \dots, N \quad (30.36)$$

where $A_{i,j}$ are the elements of the influence-coefficient matrix that give the normal velocity at control point j due to sources of unit strength on panel i , and \mathbf{U} is a unit vector in the direction of the freestream. Equation 30.35 and Equation 30.36 constitute a system of N linear equations that can be solved for the unknown source strengths σ_i . Once the source strengths have been determined, the velocity potential, or the velocity itself, can be computed directly at any point in the flowfield using Equation 30.34. A review of the development and application of panel methods is provided by Hess [1990].

A major advantage of panel methods, relative to the more advanced methods required to solve the nonlinear problems of stages II–V, is that it is necessary to describe (and to discretize into panels) only the surface of the body. While linearity is a great advantage in this regard, it is not clear that the method is computationally more efficient than the more advanced nonlinear field methods. This results from the fact that the influence-coefficient matrix in the system of equations that must be solved to give the source strengths for each panel is not sparse; i.e., the velocities at each control point are affected by the sources on all the panels. In contrast, the solution at each mesh point in a finite-difference formulation (or each mesh cell in a finite-volume formulation) is related to the values of the solution at only a few neighbors, resulting in a very sparse matrix of influence coefficients that can be solved very efficiently using iterative methods. Thus, the primary advantage of the panel method is the geometrical one associated with the reduction in dimension of the problem. For nonlinear problems the use of finite-difference, finite-element, or finite-volume methods requires discretization of the entire flowfield, and the associated mesh generation task has been a major pacing item limiting the application of such methods.

30.3.2 Nonlinear Methods

For nonlinear equations, superposition of elementary solutions is no longer a valid technique for constructing solutions, and it becomes necessary to discretize the solution throughout the entire domain, not just the boundary surface. In addition, since the equations are nonlinear, some sort of iteration must be used to compute successively better approximations to the solution. This iterative process may approximate the physics of an unsteady flow process or may be chosen to provide more rapid convergence to the solution for steady-state problems. Solutions for both the nonlinear potential and Euler equations are generally determined using a finite-difference, finite-volume, or finite-element method. In any of these techniques a grid, or network of points and cells, is distributed throughout the flowfield. In a finite-difference method the derivatives appearing in the original differential equation are approximated by discrete differences in the values of the solution at neighboring points (and times, if the solution is unsteady), and substitution of these into the differential equation yields a system of algebraic equations relating the values of the solution at neighboring grid points. In a finite-volume method, the unknowns are taken to be representative of the values of the solution in the control volumes formed by the intersecting grid surfaces, and the equations are constructed by balancing fluxes across the bounding surfaces of each control volume with the rate of change of the solution within the control volume. In a finite-element method, the solution is represented

using simple interpolating functions within each mesh cell, or element, and equations for the nodal values are obtained by integrating a variational or residual formulation of the equations over the elements. The algebraic equations relating the values of the solution in neighboring cells can be very similar (or even identical) in appearance for all three methods, and the choice of method often is primarily a matter of taste. Stable and efficient finite-difference and finite-volume methods were developed earlier than finite-element methods for compressible flow problems, but finite-element methods capable of treating very complex compressible flows now are available. A review of recent progress in the development of finite-element methods for compressible flows and remaining issues is given by Glowinski and Pironneau [1992].

Since the nonlinear potential, Euler, and Navier–Stokes equations all are nonlinear, the algebraic equations resulting from these discretization procedures also are nonlinear, and a scheme of successive approximation usually is required to solve them. As mentioned earlier, however, these equations tend to be highly local in nature, and efficient iterative methods have been developed to solve them in many cases.

30.3.2.1 Nonlinear Potential-Equation Methods

The primary advantage of solving the potential equation rather than the Euler (or Navier–Stokes) equations derives from the fact that the flowfield can be described completely in terms of a single scalar function, the velocity potential Φ . The formulation of numerical schemes to solve Equation 30.22 is complicated by the fact that, as noted earlier, the equation changes type according to whether the local Mach number is subsonic or supersonic. Differencing schemes for the potential equation must, therefore, be type-dependent — i.e., they must change their form depending on whether the local Mach number is less than or greater than unity. These methods usually are based upon central, or symmetric, differencing formulas that are appropriate for the elliptic case (corresponding to subsonic flows); they are then modified by adding an upwind bias to maintain stability in hyperbolic regions (where the flow is supersonic). This directional bias can be introduced into the difference equations either by adding an artificial viscosity proportional to the third derivative of the velocity potential Φ in the streamwise direction, or by replacing the density at each point in supersonic zones with its value at a point slightly upstream of the actual point. Mathematically, these two approaches can be seen to be equivalent, since the upwinding of the density evaluation also effectively introduces a correction proportional to the third derivative of the potential in the flow direction.

It is important to introduce such artificial viscosity (or compressibility) terms in such a way that their effect vanishes in the limit as the mesh is refined. In this way, the numerical approximation will approach the differential equation in the limit of zero mesh spacing, and the method is said to be consistent with the original differential equation. In addition, for flows with shock waves, it is important that the numerical approximation be **conservative**; this guarantees that the properties of discontinuous solutions will be consistent with the jump relations of the original conservation laws. The shock jump relations corresponding to Equation 30.22, however, are different from the Rankine–Hugoniot conditions describing shocks within the framework of the Euler equations. Since entropy is everywhere conserved in the potential theory, and since there is a finite entropy jump across a Rankine–Hugoniot shock, it is clear that the jump relations must be different. For weak shocks, however, the differences are small and the economies afforded by the potential formulation make computations based on this approximation attractive for many transonic problems.

Perturbation techniques can be used to demonstrate that the effect of entropy jump across the shocks is more important than the rotationality introduced by these weak shocks. Thus, it makes sense to develop techniques that allow for the entropy jump, but are still within the potential formulation. Such techniques have been developed (see, e.g., Hafez [1985]), but have been relatively little used, as developments in techniques to solve the Euler equations have overtaken these approaches.

The nonlinear difference equations resulting from discrete approximations to the potential equation generally are solved using iterative, or relaxation, techniques. The equations are linearized by computing approximations to all but the highest (second) derivatives from the preceding solution in an iterative sequence, and a correction is computed at each mesh point in such a way that the equations are identically satisfied. It is useful in developing these iterative techniques to think of the iterative process as a discrete approximation to a continuous time-dependent process [Garabedian 1956]. Thus, the iterative process

approximates an equation of the form

$$\beta_0 \frac{\partial \Phi}{\partial t} + \beta_1 \frac{\partial^2 \Phi}{\partial \xi \partial t} + \beta_2 \frac{\partial^2 \Phi}{\partial \eta \partial t} = \frac{a^2}{\rho} \left\{ \frac{\partial}{\partial \xi} (\rho h U) + \frac{\partial}{\partial \eta} (\rho h V) \right\} \quad (30.37)$$

The parameters β_0 , β_1 , and β_2 , which are related to the mix of old and updated values of the solution used in the difference equations, can then be chosen to ensure that the time-dependent process converges to a steady state in both subsonic and supersonic regions. The formulation of transonic potential flow problems and their solution is described by Caughey [1982].

Even when the values of the parameters are chosen to provide rapid convergence, many hundreds of iterations may be necessary to achieve convergence to acceptable levels, especially when the mesh is very fine. This slow convergence is a characteristic of virtually all iterative schemes, and is a result of the fact that the representation of the difference equations must be highly local if the scheme is to be computationally efficient. As a result of this locality, the reduction of the low-wave-number component of the error to acceptable levels often requires many iterations. A powerful technique for circumventing this difficulty with the iterative solution of numerical approximations to partial differential equations, called the multigrid technique, has been applied with great success to problems in fluid mechanics.

The multigrid method relies for its success on the fact that after a few cycles of any good iterative technique, the error remaining in the solution is relatively smooth, and can be represented accurately on a coarser grid. Application of the same iterative technique on the coarser grid soon makes the error on this grid smooth as well, and the grid-coarsening process can be repeated until the grid contains only a few cells in each coordinate direction. The corrections that have been computed on all coarser levels are then interpolated back to the finest grid, and the process is repeated. The accuracy of the converged solution on the fine grid is determined by the accuracy of the approximation on that grid, since the coarser levels are used only to effect a more rapid convergence of the iterative process.

A particularly efficient multigrid technique for steady transonic potential-flow problems has been developed by Jameson [1979]. It uses a generalized alternating-direction implicit smoothing algorithm in conjunction with a full-approximation-scheme multigrid algorithm. In theory, for a wide class of problems, the work (per mesh point) required to solve the equations using a multigrid approach is independent of the number of mesh cells. In many practical calculations, 10 or fewer multigrid cycles may be required even on very fine grids.

30.3.2.2 Euler-Equation Methods

As noted earlier, the Euler equations constitute a hyperbolic system of partial differential equations, and numerical methods for solving them rely heavily upon the rather well-developed mathematical theory of such systems. As for the nonlinear potential equation, discontinuous solutions corresponding to flows with shock waves play an important role. Shock-capturing methods are much more widely used than shock-fitting methods, and for these methods it is important to use schemes that are conservative.

As mentioned earlier, it is necessary to add artificial, or numerical, dissipation to stabilize the Euler equations. This can be done by adding dissipative terms explicitly to an otherwise nondissipative central difference scheme or by introducing upwind approximations in the flux evaluations. Both approaches are highly developed. The most widely used central difference methods are those modeled after the approach of Jameson et al. [1981]. This approach introduces an adaptive blend of second and fourth differences of the solution in each coordinate direction; a local switching function, usually based on a second difference of the pressure, is used to reduce the order of accuracy of the approximation to first order locally in the vicinity of shock waves and to turn off the fourth differences there. The second-order terms are small in smooth regions where the fourth-difference terms are sufficient to stabilize the solution and ensure convergence to the steady state. More recently, Jameson [1992] has developed improved symmetric limited positive (SLIP) and upstream limited positive (USLIP) versions of these blended schemes (see also Tatsumi et al. [1995]).

Much effort has been directed toward developing numerical approximations for the Euler equations that capture discontinuous solutions as sharply as possible without overshoots in the vicinity of the discontinuity. For purposes of exposition of these methods, we consider the one-dimensional form of the

Euler equations, which can be written

$$\frac{\partial \mathbf{w}}{\partial t} + \frac{\partial \mathbf{f}}{\partial x} = 0 \quad (30.38)$$

where $\mathbf{w} = \{\rho, \rho u, e\}^T$ and $\mathbf{f} = \{\rho u, \rho u^2 + p, (e + p)u\}^T$. Not only is the exposition clearer for the one-dimensional form of the equations, but the implementation of these schemes for multidimensional problems also generally is done by dimensional splitting in which one-dimensional operators are used to treat variations in each of the mesh directions.

For smooth solutions, Equation 30.38 are equivalent to the quasilinear form

$$\frac{\partial \mathbf{w}}{\partial t} + \mathbf{A} \frac{\partial \mathbf{w}}{\partial x} = 0 \quad (30.39)$$

where $\mathbf{A} = \{\partial \mathbf{f} / \partial \mathbf{w}\}$ is the Jacobian of the flux vector with respect to the solution vector. The eigenvalues of \mathbf{A} are given by $\lambda = u, u + a, u - a$, where $a = \sqrt{\gamma p / \rho}$ is the speed of sound. Thus, for subsonic flows, one of the eigenvalues will have a different sign than the other two. For example, if $0 < u < a$, then $u - a < 0 < u < u + a$. The fact that various eigenvalues have different signs in subsonic flows means that simple one-sided difference methods cannot be stable. One way around this difficulty is to split the flux vector into two parts, the Jacobian of each of which has eigenvalues of only one sign. Such an approach has been developed by Steger and Warming [1981]. They used a relatively simple splitting that has discontinuous derivatives whenever an eigenvalue changes sign; an improved splitting has been developed by van Leer [1982] that has smooth derivatives at the transition points.

Each of the characteristic speeds can be identified with the propagation of a wave. If a mesh surface is considered to represent a discontinuity between two constant states, these waves constitute the solution to a Riemann (or shock-tube) problem. A scheme developed by Godunov [1959] assumes the solution to be piecewise constant over each mesh cell, and uses the fact that the solution to the Riemann problem can be given in terms of the solution of algebraic (but nonlinear) equations to advance the solution in time. Because of the assumption of piecewise constancy of the solution, Godunov's scheme is only first-order accurate. Van Leer [1979] has shown how it is possible to extend these ideas to a second-order monotonicity-preserving scheme using the so-called monotone upwind scheme for systems of conservation laws (MUSCL) formulation. The efficiency of schemes requiring the solution of Riemann problems at each cell interface for each time step can be improved by the use of approximate solutions to the Riemann problem [Roe 1986].

More recent ideas to control oscillation of the solution in the vicinity of shock waves include the concept of total-variation-diminishing (TVD) schemes, first introduced by Harten (see, e.g., Harten [1983, 1984]), and essentially nonoscillatory (ENO) schemes, introduced by Osher and his coworkers (see, e.g., Harten et al. [1987] and Shu and Osher [1988]).

Hyperbolic systems describe the evolution in time of physical systems undergoing unsteady processes governed by the propagation of waves. This feature frequently is used in fluid mechanics, even when the flow to be studied is steady. In this case, the unsteady equations are solved for long enough times that the steady state is reached asymptotically — often to within roundoff error. To maintain the hyperbolic character of the equations, and to keep the numerical method consistent with the physics it is trying to predict, it is necessary to determine the solution at a number of intermediate time levels between the initial state and the final steady state. Such a sequential process is said to be a time marching of the solution.

The simplest practical methods for solving hyperbolic systems are **explicit** in time. The size of the time step that can be used to solve hyperbolic systems using an explicit method is limited by a constraint known as the Courant–Friedrichs–Lewy or **CFL condition**. Broadly interpreted, the CFL condition states that the time step must be smaller than the time required for a signal to propagate across a single mesh cell. Thus, if the mesh is very fine, the allowable time step also must be very small, with the result that many time steps must be taken to reach an asymptotic steady state.

Multistage, or Runge–Kutta, methods have become extremely popular for use as explicit time-stepping schemes. After discretization of the spatial operators, using finite-difference, finite-volume, or finite-element approximations, the Euler equations can be written in the form

$$\frac{d\mathbf{w}_i}{dt} + Q(\mathbf{w}_i) + D(\mathbf{w}_i) = 0 \quad (30.40)$$

where \mathbf{w}_i represents the solution at the i th mesh point, or in the i th mesh cell, and Q and D are discrete operators representing the contributions of the Euler fluxes and numerical dissipation, respectively. An m -stage time integration scheme for these equations can be written in the form

$$\mathbf{w}_i^{(k)} = \mathbf{w}_i^{(0)} - \alpha_k \Delta t \left[Q(\mathbf{w}_i^{(k-1)}) + D(\mathbf{w}_i^{(k-1)}) \right], \quad k = 1, 2, \dots, m \quad (30.41)$$

with $\mathbf{w}_i^{(0)} = \mathbf{w}_i^n$, $\mathbf{w}_i^{(m)} = \mathbf{w}_i^{n+1}$, and $\alpha_m = 1$. The dissipative and dispersive properties of the scheme can be tailored by the sequence of α_i chosen; note that, for nonlinear problems, this method may be only first-order accurate in time, but this is not necessarily a disadvantage if one is interested only in the steady-state solution. The principal advantage of this formulation, relative to versions that may have better time accuracy, is that only two levels of storage are required regardless of the number of stages used. This approach was first introduced for problems in fluid mechanics by Graves and Johnson [1978], and has been further developed by Jameson et al. [1981]. In particular, Jameson and his group have shown how to tailor the stage coefficients so that the method is an effective smoothing algorithm for use with multigrid (see, e.g., Jameson and Baker [1983]).

Implicit techniques also are highly developed, especially when structured grids are used. Approximate factorization of the implicit operator usually is required to reduce the computational burden of solving a system of linear equations for each time step. Methods based on alternating-direction implicit (ADI) techniques date back to the pioneering work of Briley and McDonald [1974] and Beam and Warming [1976]. An efficient diagonalized ADI method has been developed within the context of the multigrid method by Caughey [1987], and a lower-upper symmetric Gauss–Seidel method has been developed by Yoon and Kwak [1994]. The multigrid implementations of these methods are based on the work of Jameson [1983].

30.3.3 Navier–Stokes Equation Methods

As described earlier, the relative importance of viscous effects is characterized by the value of the Reynolds number. If the Reynolds number is not too large, the flow remains smooth, and adjacent layers (or laminae) of fluid slide smoothly past one another. When this is the case, the solution of the Navier–Stokes equations is not too much more difficult than solution of the Euler equations. Greater resolution is required to resolve the large gradients in the boundary layers near solid boundaries, especially as the Reynolds number becomes large, so more mesh cells are required to achieve acceptable accuracy. In most of the flowfield, however, the flow behaves as if it were nearly inviscid, so methods developed for the Euler equations are appropriate and effective. The equations must, of course, be modified to include the additional terms resulting from the viscous stresses, and care must be taken to ensure that any artificial dissipative effects are small relative to the physical viscous dissipation in regions where the latter is important. The solution of the Navier–Stokes equations for laminar flows, then, is somewhat more costly in terms of computer resources, but not significantly more difficult from an algorithmic point of view, than solution of the Euler equations. Unfortunately, most flows of engineering interest occur at large enough Reynolds numbers that the flow in the boundary layers near solid boundaries becomes turbulent.

30.3.3.1 Turbulence Models

Solution of the Reynolds-averaged Navier–Stokes equations requires modeling of the Reynolds stress terms. The simplest models, based on the original mixing-length hypothesis of Prandtl, relate the Reynolds stresses to the local properties of the mean flow. The Baldwin–Lomax model [Baldwin and Lomax 1978] is the

most widely used model of this type and gives good correlation with experimental measurements for wall-bounded shear layers so long as there are no significant regions of separated flow.

The most complete commonly used turbulence models include two additional partial differential equations that determine characteristic length and time scales for the turbulence. The most widely used of these techniques is called the k - ϵ model, since it is based on equations for the turbulence kinetic energy (usually given the symbol k) and the turbulence dissipation rate (usually given the symbol ϵ). This method has grown out of work by Launder and Spaulding [1972]. Another variant, based on a formulation by Kolmogorov, calculates a turbulence frequency ω instead of the dissipation rate (and hence is called a k - ω model). More complete models that compute all elements of the Reynolds stress tensor are in an active state of development. The common base for most of these models is the work of Launder et al. [1975], with more recent contributions by Lumley [1978], Speziale [1987], and Reynolds [1987]. These models, and their implementation within the context of CFD, are described in the book by Wilcox [1993].

More limited models, based on a single equation for a turbulence scale, also have been developed. These include the models of Baldwin and Barth [1991] and of Spalart and Allmaras [1992]. These models are applicable principally to boundary-layer flows of aerodynamic interest.

30.3.3.2 Large-Eddy Simulations

The difficulty of developing generally applicable phenomenological turbulence models on the one hand, and the enormous computational resources required to resolve all scales in turbulent flows at large Reynolds number on the other, have led to the development of large-eddy simulation (LES) techniques. In this approach, the largest length and time scales of the turbulent motions are resolved, but the smaller (subgrid) scales are modeled. This is an attractive approach because it is the largest scales that contain the preponderance of turbulent kinetic energy and that are responsible for most of the mixing. At the same time, the smaller scales are believed to be more nearly isotropic and independent of the larger scales, and thus are less likely to behave in problem-specific ways — i.e., it should be easier to develop universal models for these smaller scales.

A filtering technique is applied to the Navier–Stokes equations which results in equations having a form similar to the original equations, but with additional terms representing a subgrid-scale tensor that describes the effect of the modeled terms on the larger scales. The solution of these equations is not well posed if there is no initial knowledge of the subgrid scales; the correct statistics are predicted for the flow, but it is impossible to reproduce a specific realization of the flow without this detailed initial condition. Fortunately, for most engineering problems, it is only the statistics that are of interest.

LES techniques date back to the pioneering work of Smagorinsky [1963], who developed an eddy-viscosity subgrid model for use in meteorological problems. The model turned out to be too dissipative for large-scale meteorological problems in which large-scale, predominantly two-dimensional motions are affected by three-dimensional turbulence. Smagorinsky's model finds wide application in engineering problems, however. Details of the LES approach are discussed by Rogallo and Moin [1984], and more recent developments and applications are described by Lesieur and Méttais [1996].

30.3.3.3 Direct Numerical Simulations

Direct numerical simulations generally use spectral or pseudospectral approximations for the spatial discretization of the Navier–Stokes equations (see, e.g., Gottlieb and Orszag [1977] or Hussaini and Zang [1987]). The difference between spectral and pseudospectral methods is in the way that products are computed; the advantage of spectral methods, which are more expensive computationally, is that aliasing errors are removed exactly [Orszag 1972].

A description of the issues involved and some results are given by Rogallo and Moin [1984]. Direct numerical simulations are particularly valuable for the insight that they provide into the fundamental nature of turbulent flows. The computational resources required for DNS calculations grow so rapidly with increasing Reynolds number that they are unlikely to be directly useful for engineering predictions, but they will remain an invaluable tool providing insight needed to construct better turbulence models for use in LES and with the Reynolds-averaged equations.

30.4 Research Issues and Summary

Computational fluid dynamics continues to be a field of intense research activity. The development of accurate algorithms based on unstructured grids for problems involving complex geometries, and the increasing application of CFD techniques to unsteady problems, including aeroelasticity and acoustics, are examples of areas of great current interest. Algorithmically, there continues to be fruitful work on the incorporation of adaptive grids that automatically increase resolution in regions where it is required to maintain accuracy, and on the development of inherently multidimensional high-resolution schemes. Finally, the continued expansion of computational capability allows the application of DNS and LES methods to problems of higher Reynolds number and increasingly realistic flow geometries.

Defining Terms

- Artificial viscosity:** Terms added to a numerical approximation that provide artificial — i.e., nonphysical — dissipative mechanisms to stabilize a solution or to allow shock waves to be captured automatically by the numerical scheme.
- CFL condition:** The Courant–Friedrichs–Lewy (CFL) condition is a stability criterion that limits the time step of an explicit time-marching scheme for hyperbolic systems of differential equations. In the simplest one-dimensional case, if Δx is the physical mesh spacing and $\rho(\mathbf{A})$ is the spectral radius of the Jacobian matrix \mathbf{A} corresponding to the fastest wave speed for the problem, then the time step for explicit schemes must satisfy the constraint $\Delta t \leq K \Delta x / \rho(\mathbf{A})$, where K is a constant. For the simplest explicit schemes, $K = 1$, which implies that the time step must be less than that required for the fastest wave to cross the cell.
- Conservative:** A numerical approximation is said to be conservative if it is based on the conservation (or divergence) form of the differential equations, and the net flux across a cell interface is the same when computed from either direction; in this way the properties of discontinuous solutions are guaranteed to be consistent with the jump relations for the original integral form of the conservation laws.
- Direct numerical simulation (DNS):** A solution of the complete Navier–Stokes equations in which all length and time scales, down to those describing the smallest eddies containing significant turbulent kinetic energy, are fully resolved.
- Euler equations:** The equations describing the inviscid flow of a compressible fluid. These equations constitute a hyperbolic system of differential equations; the Euler equations are nondissipative, and weak solutions containing discontinuities (which can be viewed as approximations to shock waves) must be allowed for many practical problems.
- Explicit method:** A method in which the solution at each point for the new time level is given explicitly in terms of values of the solution at the previous time level; to be contrasted with an *implicit method*, in which the solution at each point at the new time level also depends on the solution at one or more neighboring points at the new time level, so that an algebraic system of equations must be solved at each time step.
- Finite-difference method:** A numerical method in which the solution is computed at a finite number of points in the domain; the solution is determined from equations that relate the solution at each point to its values at selected neighboring points.
- Finite-element method:** A numerical method for solving partial differential equations in which the solution is approximated by simple functions within each of a number of small elements into which the domain has been divided.
- Finite-volume method:** A numerical method for solving partial differential equations, especially those arising from systems of conservation laws, in which the rate of change of quantities within each mesh volume is related to fluxes across the boundaries of the volume.
- Implicit method:** See **explicit method**.
- Large-eddy simulation:** A numerical solution of the Navier–Stokes equations in which the largest, energy-carrying eddies are completely resolved, but the effects of the smaller eddies, which are more nearly isotropic, are accounted for by a subgrid model.

- Mach number:** The ratio $M = V/a$ of the fluid velocity V to the speed of sound a . This nondimensional parameter characterizes the importance of compressibility in the dynamics of the fluid motion.
- Mesh generation:** The generation of mesh systems suitable for the accurate representation of solutions to partial differential equations.
- Panel method:** A numerical method to solve Laplace's equation for the velocity potential of a fluid flow. The boundary of the flow domain is discretized into a set of nonoverlapping facets, or panels, on each of which the strength of some elementary solution is assumed constant. Equations for the normal velocity at control points on each panel can be solved for the unknown singularity strengths to give the solution. In some disciplines this approach is called the *boundary integral element method* (BIEM).
- Reynolds-averaged Navier–Stokes equations:** Equations for the mean quantities in a turbulent flow obtained by decomposing the fields into mean and fluctuating components and averaging the Navier–Stokes equations. Solution of these equations for the mean properties of the flow requires knowledge of various correlations (the Reynolds stresses), of the fluctuating components.
- Shock capturing:** A numerical method in which shock waves are treated by smearing them out with artificial dissipative terms in a manner such that no special treatment is required in the vicinity of the shocks; to be contrasted with *shock fitting* methods in which shock waves are treated as discontinuities with the jump conditions explicitly enforced across them.
- Shock fitting:** See **shock capturing**.
- Shock wave:** Region in a compressible flow across which the flow properties change almost discontinuously; unless the density of the fluid is extremely small, the shock region is so thin relative to other significant dimensions in most practical problems that it is a good approximation to represent the shock as a surface of discontinuity.
- Turbulent flow:** Flow in which unsteady fluctuations play a major role in determining the effective mean stresses in the field; regions in which turbulent fluctuations are important inevitably appear in fluid flow at large Reynolds numbers.
- Upwind method:** A numerical method for CFD in which upwinding of the difference stencil is used to introduce dissipation into the approximation, thus stabilizing the scheme. This is a popular mechanism for the Euler equations, which have no natural dissipation, but is also used for Navier–Stokes algorithms, especially those designed to be used at high Reynolds number.
- Visualization:** The use of computer graphics to display features of solutions to CFD problems.

Further Information

Several organizations sponsor regular conferences devoted completely, or in large part, to computational fluid dynamics. The American Institute of Aeronautics and Astronautics (AIAA) sponsors the AIAA Computational Fluid Dynamics Conferences in odd-numbered years, usually in July; the proceedings of this conference are published by AIAA. In addition, there typically are many sessions on CFD and its applications at the AIAA Aerospace Sciences Meeting, held every January, and the AIAA Fluid and Plasma Dynamics Conference, which is held every summer, in conjunction with the AIAA CFD Conference in those years when the latter is held. The Fluids Engineering Conference of the American Society of Mechanical Engineers, held every summer, also contains sessions devoted to CFD. In even-numbered years, the International Conference on Numerical Methods in Fluid Dynamics is held, alternating between Europe and America; the proceedings of this conference are published in the *Lecture Notes in Physics* series by Springer-Verlag. The International Symposium on Computational Fluid Dynamics, sponsored by the CFD Society of Japan, is held in odd-numbered years, alternating between the U.S. and Asia; in September 1997 this meeting will be held in Beijing, China.

The *Journal of Computational Physics* contains many articles on CFD, especially covering algorithmic issues. The *AIAA Journal* also has many articles on CFD, including aerospace applications. The *International Journal for Numerical Methods in Fluids* contains articles emphasizing the finite-element method applied to problems in fluid mechanics. The journals *Computers and Fluids* and *Theoretical and Computational Fluid Dynamics* are devoted exclusively to CFD, the latter journal emphasizing the use of CFD to elucidate basic fluid-mechanical phenomena. The first issue of the *CFD Review*, which attempts to review important developments in CFD, was published in 1995. The *Annual Review of Fluid Mechanics* also contains a number of review articles on topics in CFD.

The following textbooks provide excellent coverage of many aspects of CFD:

- Anderson, D. A., Tannehill, J. C., and Pletcher, R. H. 1984. *Computational Fluid Mechanics and Heat Transfer*. Hemisphere, Washington.
- Hirsch, C. 1988, 1990. *Numerical Computation of Internal and External Flows, Vol. I: Fundamentals of Numerical Discretization, Vol. II: Computational Methods for Inviscid and Viscous Flows*. Wiley, Chichester.
- Wilcox, D. C. 1993. *Turbulence Modeling for CFD*. DCW Industries, La Cañada, CA.

An up-to-date summary on algorithms and applications for high-Reynolds-number aerodynamics is found in Caughey, D. A. and Hafez, M. M., eds. *Frontiers of Computational Fluid Dynamics — 1994*. J. Wiley Chichester, U.K.

31.1 Introduction

Oceanography is a relatively young field, barely a century old; major discoveries — such as the reason for the western intensification of currents such as the Gulf Stream and Kuroshio, and the existence of a deep sound channel in which acoustic energy can travel for thousands of kilometers with little attenuation — were not made till the 1940s. Even today, our knowledge of the circulation in the global oceans is rather sketchy. Computational ocean modeling is even younger; the very first comprehensive numerical global ocean model was formulated by Kirk Bryan [1969] in the late 1960s. However, the advent of supercomputers has led to a phenomenal growth in the field, especially in the last decade. In a brief chapter such as this, it is impossible to provide a detailed account of the many different versions of the ocean models that exist at present. Instead we will attempt to provide a bird's-eye view of the field and a detailed account of a selected few. The objective is to provide a road map that enables an interested reader to consult appropriate sources for details of a particular approach.

Oceans act as thermal flywheels and moderate our long-term weather. They are also huge reservoirs of CO₂ and have long memory and therefore play a crucial role in determining the climatic conditions on our planet on a variety of time scales. A better understanding of the oceans is also important for other reasons, including defense and commerce needs of nations. They are a source of protein, and might be able to supply part of our energy and mineral needs in the coming century. However, the oceans are data-poor

in general. It is only in the last decade or so that satellite-borne sensors such as infrared radiometers, microwave imagers, and altimeters have begun to fill in the data gaps, especially in the poorly explored southern-hemisphere oceans. Since collection of in situ data in the oceans is quite expensive, and since satellite-borne sensors provide information mostly on the near-surface layers of the ocean, it is often thought that ocean models are central to understanding the way the oceans function. The hope is that comprehensive ocean models in combination with sparse in situ and relatively abundant remotely sensed data will provide the best means of studying and monitoring the oceans. Herein lies the importance of ocean modeling. For prediction purposes, of course, numerical ocean models are quite indispensable.

31.2 Underlying Principles

The choice of a particular ocean model or modeling approach depends very much on the intended application and on the computational and pre- and postprocessing capabilities available. A judicious compromise is essential for success. With this in mind, numerical ocean models can be classified in many different ways.

31.2.1 Global or Regional

The former necessarily requires supercomputing capabilities, whereas it may be possible to run the latter on powerful modern workstations. Even then, the resolution demanded (grid sizes in the horizontal and vertical) is critical. A doubling of the resolution in a three-dimensional model often requires an order of magnitude increase in computing (and analysis) resources. It is therefore quite easy to overwhelm even the most modern supercomputer (or workstation), whether it be a coarse-grained multiple CPU vector processor such as a Cray C-90 or a modern massively parallel machine such as a CM5 or Cray T3-D, irrespective of whether the model is global or regional. Regional models have to contend with the problem of how to inform the model about the state of the rest of the ocean, in other words, of prescribing suitable conditions along the open boundaries. Often the best solution is to nest the fine-resolution regional model in a coarse-resolution model of the basin.

31.2.2 Deep Basin or Shallow Coastal

The prevailing physical processes and the underlying driving mechanisms are essentially different for the two cases. Circulation in shallow coastal regions is highly variable, driven primarily by synoptic wind and other rapidly changing surface forcing (and, near river outflows, by buoyancy differences between the fresh river water and saline ambient shelf water). Wind mixing at the surface and benthic processes are important, and a numerical model that has reliable mixing physics and that resolves the benthic boundary layer is therefore better suited for coastal applications. A model such as the one developed at Princeton University, which employs a bottom-following, sigma-coordinate vertical grid and incorporates an advanced turbulence closure [Blumberg and Mellor 1987; Kantha and Piacsek 1993], may be essential for such applications.

Deep basins, on the other hand, are comparatively sluggish, and the horizontal density gradients, especially below the wind-mixed upper layers, are a dominant factor in the circulation. The upper mixed layer can often be modeled less rigorously, especially for applications that do not require consideration of air-sea interaction processes. The popular *z*-level Geophysical Fluid Dynamics Laboratory Modular Ocean Model (MOM), with or without an upper mixed layer, is a good candidate for modeling the ocean basins (and deep marginal and semienclosed seas) on a variety of time scales ranging from synoptic to climate. The very first global ocean model [Bryan 1969], on which many modern global models are based [Semtner and Chervin 1992], was a *z*-level model without an upper mixed layer.

In a *z*-level model, a number of horizontal levels are defined in the water column, and the equations are written for the oceanic variables at each level and each point on the model grid in the horizontal and solved. This is an Eulerian approach. Another equally viable approach is a semi-Lagrangian approach [Hurlburt and Thompson 1980] that divides the ocean vertically into a number of layers and models the variation in

properties such as the thickness and density of each layer at each grid point on the horizontal grid. More recently developed isopycnal models [Oberhuber 1993, Bleck and Smith 1990] belong to this category. Since mixing in the deep oceans is primarily along **isopycnals** (density surfaces), isopycnal models perform a better job of depicting interior mixing and are ideal for long-term simulations of circulation in the global oceans.

31.2.3 Rigid Lid or Free Surface

Oceanic response to surface forcing can often be divided into two parts: fast barotropic response mediated by external Kelvin and gravity waves on the sea surface, and relatively slow baroclinic adjustment via internal gravity and other waves. On long time scales, it is the internal adjustment that is important to model and it is possible to suppress the external gravity waves by imposing a *rigid lid* on the free surface. This permits larger time-stepping of the model, and models used for climatic-type simulations are usually the rigid-lid kind. The very first global ocean model [Bryan 1969] was a rigid-lid model. At each time step an elliptic Poisson equation for the stream function has to be solved. This is difficult to carry out efficiently on vector and parallel processors and for complicated basin shapes (including islands). Also, under synoptic forcing, the convergence of the iterative solver slows down. For these reasons, free-surface models are becoming more popular for nonclimatic simulations. A mode-splitting technique must then be employed to circumvent the severe limitation on time-stepping that would otherwise be imposed. For shallow-water applications, such as storm-surge and tide modeling, free-surface dynamics must be retained. To diminish the drawbacks of a rigid-lid model, Dietrich et al. [1987] and Dukowicz and Smith [1994] have developed versions in which one works with the pressure on the rigid lid, rather than the barotropic stream function, leaving the domain multiply connected and with better matrix inversion characteristics.

31.2.4 Comprehensive or Purely Dynamical

Since the density gradients are overwhelmingly important and the density below the upper layers in the global oceans changes very slowly, it is often possible to ignore completely the changes in density with time. The model then becomes purely dynamical and can be used to explore the consequences of changing wind forcing at the surface. Purely dynamical layered models, originally developed at Florida State University [Metzger et al. 1992; Wallcraft 1991], belong to this category and are essentially isopycnal models without the thermodynamic component [Hurlburt and Thompson 1980]. Their principal advantage is that it is often possible to select a limited number of layers in the vertical (as few as two) and still include salient dynamical processes. This enables very high horizontal resolutions necessary for resolving mesoscale eddies in the oceans to be afforded. The highest-resolution global model at present is the Naval Research Laboratory $\frac{1}{8}^\circ$ eddy-resolving global model [Metzger et al. 1992] that needs a 16-processor Cray C-90 for multiyear simulations.

Even with modern computing power, it is necessary to sacrifice either vertical or horizontal resolution for many (especially global) simulations. The layered (and isopycnal) models sacrifice vertical resolution, whereas the z -level models, employing large numbers of levels in the vertical, are necessarily comparatively coarse-grained in the horizontal. The highest-resolution dynamical–thermodynamic z -level model at present is the $\frac{1}{6}^\circ$ Semtner model at Los Alamos (Dukowicz and Smith 1994; see Semtner and Chervin 1992 for a description of the basic model) and it stretches the capability of a 256-processor CM5 to the limit.

31.2.5 With Applications to Short-Term Simulations or Long-Term Climate Studies

On climatic time scales, it is extremely important to model correctly the thermohaline circulation driven by the formation of dense deep-water masses during strong wintertime cooling in subpolar seas, especially in the Atlantic. These water masses flow along the ocean bottom, and several centuries are needed for a water particle that sank (say) in the north Atlantic to surface again in the Indian or the Pacific Ocean.

Because of this long memory of the deep oceans, it is necessary to make multicentury simulations, and, irrespective of whether isopycnal or z -level models are employed, the horizontal and vertical resolutions that can be afforded are necessarily coarse. Accurate ocean simulations on climatic time scales belong to the category of grand challenge problems requiring a teraflop (10^{12} floating-point operations per second) computing capability that has been the holy grail of the computer industry.

31.2.6 Quasigeostrophic (QG) or Primitive-Equation-Based

In the 1970s and early 1980s, the limited computing power available led some to explore simplifications to the governing equations to be solved. QG models assume that there is a near-balance between the Coriolis acceleration and pressure gradient in the dynamical equations in the rotating coordinate frame of reference in which most ocean models are formulated. The resulting simplification enables higher vertical and horizontal resolutions to be achieved. QG models have strong limitations with respect to the accuracy with which physical processes are depicted and are becoming obsolete in the modern high-computing-power environment. We will not discuss QG models in this article, but instead refer the reader to Holland [1986]. Neither shall we discuss intermediate models, which are in between QG and primitive equation (PE) models in complexity.

31.2.7 Barotropic or Baroclinic

In the former, the density gradients are neglected and therefore the currents become independent of the depth in the water column. Many phenomena, such as tidal sea-surface elevation fluctuations and storm surges, can be simulated quite adequately by a **barotropic** model, which is a two-dimensional (in the horizontal) model based on the vertically integrated equations of motion. The advantage is that a barotropic model requires an order of magnitude less computing resources than a comparable baroclinic model. However, when it is important to model the vertical structure of currents, or the density field, a fully three-dimensional **baroclinic** model is necessary.

31.2.8 Purely Physical or Physical–Chemical–Biological

Often there is a need to model the fate of chemical and biological constituents in the ocean, and to do so it is essential to include not only the dynamical equations governing the circulation and other physical variables, but also the conservation equations for chemical and biological variables. Modeling the fate of inorganic CO_2 in the oceans (a problem germane to global warming) and modeling the primary production in the upper layers of the ocean are two such examples. The former requires solving for at least two more variables, the total CO_2 and alkalinity, whereas the simplest biological model must solve for at least three additional quantities, the nutrient, phytoplankton, and zooplankton concentrations (the so-called NPZ model). The governing equations are transport equations with appropriate source and sink terms, whose parametrization is not always quite straightforward. This not only implies additional complexity but also requires considerably more computing (and data) resources.

31.2.9 Process-Studies-Oriented or Application-Oriented

Models that are used to study some salient processes (for example western boundary currents and gyre circulation) can often be considerably simplified and hence made less computationally (and observational data-) intensive, since it is often possible to isolate and retain only the relevant physical process and ignore the rest in the model. Also, such models may not require extensive observational data for model initialization or forcing. They are most often run free in a predictive (or prognostic) mode. On the other hand, application-oriented models such as those used for ocean prediction purposes require extensive observational data for realistic initialization, forcing, and data assimilation. Assimilation into the model by one means or other of observational data is indispensable for **nowcast**, forecast, and **hindcast** applications,

and data-assimilative models often employ approaches very much similar to those employed by numerical weather prediction (NWP) models in the atmosphere.

31.2.10 With and Without Coupling to Sea Ice

Global ocean models do not at present include sea ice. Ice-ocean-coupled basin models of the Arctic exist, however; for coupling to a z -level ocean model, see Hibler and Bryan [1987], and to an isopycnal model, see Oberhuber [1993]. Sea ice insulates the ocean from the cold atmosphere and mediates the exchange of heat and momentum between the two, and therefore such models involve solving dynamical and thermodynamic equations for the sea ice cover and its coupling to the underlying ocean.

31.2.11 Coupled to the Atmosphere or Uncoupled

Finally, for accurate simulation of long-time-scale processes, it is essential to couple ocean models with atmospheric models. Such coupled models are being increasingly used for such things as forecasting **El Niño** events. Most often, either the atmosphere or the ocean is highly simplified in such models, although modern supercomputers are enabling comprehensive atmospheric general circulation models to be coupled to global ocean models, at least for simulations of interannual variability. Truly comprehensive coupled models with applications to long-term climate studies require teraflop computing capability that might be routinely available in the coming century.

All numerical ocean models solve one form or other of the same governing equations for oceanic motions, written in a rotating coordinate frame of reference. These equations are essentially Navier–Stokes equations (or more appropriately **Reynolds-averaged** equations for mean term quantities, since the flow is invariably turbulent), but with the buoyancy and Coriolis force terms (fictitious accelerations due to the noninertial nature of the rotating coordinate frame) prominent in the dynamical balance. In addition, an equation of state relating the density of seawater to its temperature and salinity, and conservation equations for temperature and salinity, are also solved. In those models which model turbulence explicitly, equations for turbulence quantities such as the turbulence velocity scale (or equivalently turbulence kinetic energy) and turbulence macroscale are also solved. If chemical or biological components are included, conservation equations for relevant species with appropriate source and sink terms are solved as well.

Global and basin-scale models are formulated in spherical coordinates, but regional models are usually cast in rectangular coordinates instead. For simplicity we present the governing equations in rectangular Cartesian coordinates (spherical coordinate version can be found for example in Semtner [1986]). The x_1 -axis is usually taken to be in the zonal direction (positive to the east), the x_2 -axis is in the meridional direction (positive to the north), and the z -axis is in the vertical direction, positive upwards, with the origin located at the sea surface. Using tensorial notation and treating the horizontal coordinates separately from the vertical (indices take values 1 and 2 only), the governing equations consist of the continuity equation

$$\frac{\partial U_k}{\partial x_k} + \frac{\partial W}{\partial z} = 0 \quad (31.1)$$

where U_k denotes the horizontal components of velocity and W the vertical, and the momentum equations

$$\frac{\partial U_j}{\partial t} + \frac{\partial}{\partial x_k}(U_k U_j) + \frac{\partial}{\partial z}(W U_j) + f \epsilon_{j3k} U_k = -\frac{\partial P}{\partial x_j} + \frac{\partial \Phi}{\partial x_j} + \frac{\partial}{\partial z} \left(K_M \frac{\partial U_j}{\partial z} \right) + F_j \quad (31.2)$$

$$\frac{\partial P}{\partial z} = -\frac{\rho}{\rho_0} g \quad (31.3)$$

where f is the Coriolis parameter ($2 \Omega \cos \phi$), Ω the earth's angular velocity, ϕ the latitude, P the kinematic pressure, K_M the vertical mixing coefficient, ρ the in situ density, ρ_0 the reference density, g the gravitational acceleration, and Φ the gravitational potential.

The transport equations for **potential temperature** Θ and salinity S are

$$\frac{\partial \Theta}{\partial t} + \frac{\partial}{\partial x_k}(U_k \Theta) + \frac{\partial}{\partial z}(W \Theta) = \frac{\partial}{\partial z} \left(K_H \frac{\partial \Theta}{\partial z} \right) + S_\Theta + F_\Theta \quad (31.4)$$

$$\frac{\partial S}{\partial t} + \frac{\partial}{\partial x_k}(U_k S) + \frac{\partial}{\partial z}(W S) = \frac{\partial}{\partial z} \left(K_H \frac{\partial S}{\partial z} \right) + F_S \quad (31.5)$$

where K_H is the vertical mixing coefficient for scalar quantities, and S_Θ denotes a volumetric heat source such as due to penetrative solar heating. The equation of state is given by

$$\rho = \rho(\Theta, S) \quad (31.6)$$

Various simplifications have been made in deriving the above equations. The ocean is considered incompressible, a very good approximation for most applications. It is also considered to be in hydrostatic balance in the vertical, and hence the only terms remaining in the vertical component of the momentum equations are the buoyancy and pressure gradient terms. The hydrostatic approximation involves neglecting the vertical acceleration and regarding the fluid as essentially motionless in the vertical. In addition, the Boussinesq approximation has been used. This involves considering the ocean to be of constant density except when buoyancy forces are computed, thus assuming $\rho = \rho_0$ in all except the terms involving gravitation. Also, terms containing the horizontal component of rotation are neglected. The resulting equations are sufficiently accurate for most ocean circulation modeling. The equation of state employed is the so-called UNESCO equation [Pond and Pickard 1979] and is in the form of polynomial expansions in temperature and salinity. The pressure P is given by

$$P = g\eta + \frac{g}{\rho_0} \int_z^0 \rho(x_j, z', t) dz' \quad (31.7)$$

where η is the sea surface height. The terms F_j , F_Θ , F_S are horizontal mixing terms corresponding to unresolved subgrid-scale processes and are most often parametrized simply as Laplacian diffusion terms:

$$F_{j,\Theta,S} = A_{M,H} \frac{\partial^2}{\partial x_k \partial x_k} (U_j, \Theta, S) \quad (31.8)$$

where $A_{M,H}$ are horizontal mixing coefficients. A more rigorous form for these terms can be found in Blumberg and Mellor [1987]. The values for these coefficients are most often chosen as constants in a rather ad hoc manner based on purely numerical considerations. While the vertical mixing coefficients K_M and K_H can be rigorously modeled by turbulence closure theories [for example, Kantha and Clayson 1994, Mellor and Yamada 1982], there does not exist a similar approach for these terms. One approach, widely used in atmospheric modeling, is that due to Smagorinsky [1963], which is similar to the classical mixing-length theory of turbulence. Here the mixing coefficient is assumed to be proportional to the mean strain rate, so that

$$A_M = C(\Delta x_1)(\Delta x_2) \left[\left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i} \right) \left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i} \right) \right]^{1/2}, \quad A_H \sim A_M \quad (31.9)$$

where C is the Smagorinsky coefficient, with a value of around 0.04, and Δx_1 and Δx_2 are the grid sizes. This approach assumes that the subgrid scales fall within the Kolmogoroff inertial subrange, an assumption not always satisfied. A practical consequence of using this model is that strong horizontal shear is accompanied by strong horizontal mixing, which tends to smear out thermal fronts. A more general approach is to assume that the mixing coefficients are a sum of a constant background value and the Smagorinsky value given by Equation 31.9 and to choose the values assigned to each appropriately [for example, Kantha 1995]. Another approach is to assign a constant cell Reynolds number $R_N = |U_j| |\Delta x_j| / A_M$ and determine the

value of the mixing coefficient thus [Choi and Kantha 1995]. Some modelers have used biharmonic form

$$\frac{\partial^2}{\partial x_k \partial x_k} \frac{\partial^2}{\partial x_k \partial x_k}$$

to model these terms [O'Brien 1985]. In this form, the terms serve principally to control the so-called $2 \Delta x$ noise in the numerical solutions. Suffice it to say that modeling horizontal diffusion terms is still rather ad hoc.

The oceans are driven by momentum, heat, and salt fluxes at the air–sea interface. The boundary conditions at the sea surface ($z = \eta$) are therefore

$$\begin{aligned} K_M \left(\frac{\partial U_j}{\partial z} \right) &= \tau_{0j} \\ K_H \left(\frac{\partial}{\partial z} (\Theta, S) \right) &= (q_H, q_S) \\ W &= \frac{\partial \eta}{\partial t} + U_j \frac{\partial \eta}{\partial x_j} \end{aligned} \quad (31.10)$$

where τ_{0j} is the kinematic shear stress acting at the free surface due to the action of winds and waves (taken mostly as equal to the kinematic wind stress) and $q_{H,S}$ are the kinematic heat and salt fluxes. The value of q_H is determined by the net heat balance at the air–sea interface due to short-wave and long-wave solar heating, back radiation by the ocean surface, and the turbulent sensible and latent heat exchanges, and that of q_S is determined by the difference between evaporation and precipitation. Accurate parametrization of these air–sea fluxes has been the subject of intense research for several decades (for example, the 1992 multinational Tropical Ocean Global Atmosphere/Coupled Ocean Atmosphere Response Experiment).

The conditions at the ocean bottom ($z = -H$) are of no mass transfer through the bottom

$$W = -U_j \frac{\partial H}{\partial x_j}$$

and

$$\begin{aligned} K_M \left(\frac{\partial U_j}{\partial z} \right) &= \tau_{bj} \\ K_H \left(\frac{\partial}{\partial z} (\Theta, S) \right) &= (0, 0) \end{aligned} \quad (31.11)$$

The last of the above conditions implies no heat or salt transfer through the ocean bottom. The bottom stresses are usually parametrized using a quadratic drag law with $c_d \sim 0.0025$:

$$\tau_{bj} = c_d |U_{bj}| U_{bj} \quad (31.12)$$

or by assuming that the lowest model grid point falls within the logarithmic-law region and using the well-known logarithmic relationship between the mean velocity and the friction velocity to derive the drag coefficient [Blumberg and Mellor 1987, Kantha and Piacsek 1993, for example].

When additional quantities such as turbulence velocity and length scales are modeled explicitly, corresponding conservation equations need to be solved along with appropriate boundary conditions at the ocean surface and bottom [Blumberg and Mellor 1987, Kantha and Clayson 1994, Kantha and Piacsek 1993]. The same holds for modeling of chemical and biological quantities.

If the lateral boundary is closed, then it is straightforward to apply the lateral boundary condition; the component of velocity perpendicular to the boundary is zero, and there is no lateral mass, heat, or salt flux through the boundary. If it is open, on the other hand, as is usual in regional models of coastal and marginal seas, then it is necessary to prescribe open boundary conditions. This is a difficult problem, since

complete information on various flow properties must be specified, and this depends to a large extent on how well the flow at the boundary is known. The best strategy is to nest the model in a coarser-resolution model of the basin. In many cases, this is not feasible, and hence it is not possible to inform the model about what the rest of the ocean is doing. The best under these conditions is some form of Sommerfeld radiation boundary condition on dynamical quantities, which ensures that disturbances approaching the boundary from the inside are radiated out and not bottled up [Blumberg and Kantha 1985, Kantha et al. 1990, Roed and Cooper 1986]. This is usually of the form

$$\frac{\partial \zeta}{\partial t} + C \frac{\partial \zeta}{\partial x_n} = 0 \quad (31.13)$$

where ζ is a variable such as the sea surface height, n denotes direction normal to the boundary, and C is the phase speed of the approaching disturbance. Proper prescription of C is important to the success of the radiative boundary condition and has been the subject of much research [Blumberg and Kantha 1985, Orlonski 1976].

If there is inflow at the lateral boundary, temperature and salinity of the incoming flow must be prescribed. If there is outflow, on the other hand, these quantities are simply advected out:

$$\frac{\partial(\Theta, S)}{\partial t} + U_n \frac{\partial(\Theta, S)}{\partial x_n} = 0 \quad (31.14)$$

31.3 Best Practices

In many applications, ocean simulation is an initial-value problem and therefore the initial state of the modeled ocean must be prescribed as accurately as possible. This is difficult to do in practice, since observational data are insufficient to specify the state of the ocean at any given point in time. The best alternative is to prescribe some sort of a climatological average as the initial state and spin up the ocean from that state under prescribed surface forcing. Here appeal is made to databases such as [Levitus 1982] (updated in 1995) and the U.S. Navy GDEM that contain distributions of climatological average temperature and salinity in the global oceans derived from historical archives of in situ observations.

Prescription of surface forcing is itself a major problem. Both momentum and buoyancy fluxes need to be specified at the sea surface, and both are determined by processes in the adjacent atmospheric boundary layer. For determining the long-term average state of the oceans, it is once again possible to appeal to climatological databases such as that due to Hellerman and Rosenstein [1983] and the Comprehensive Ocean-Atmosphere Data Set (COADS) database (the database has been updated to 1990s recently), which provide gridded monthly average values of wind stress over the global oceans derived from historical marine surface observations. However, for many applications, including ocean prediction, it is necessary to provide surface forcing on a daily or even a multihourly basis. This is impossible to do from observations alone (although satellite-sensed air-sea fluxes may help in the future), and one has little choice but to appeal to six-hourly analyses and predictions of NWP centers, even though the accuracy of the surface forcing so derived depends very much on the skill of the particular NWP model and methodology.

Finally, the governing equations are discretized and the resulting finite-difference equations (or a set of algebraic equations) are solved to determine the evolution with time of the various oceanic variables such as temperature, salinity, and velocity at each model grid point. There are two principal means of discretization in the horizontal direction: finite differences [for example, Blumberg and Mellor 1987, Choi and Kantha 1995, Semtner and Chervin 1992] and finite elements [Le Provost et al. 1994], the latter being quite popular with civil engineers. The principal advantage of the latter is the flexibility the finite-element grid provides in assigning localized high resolution where needed. The reader is referred to Kantha [1995] for an example of a finite-difference approach to modeling the barotropic equations for global tides and to Le Provost et al. [1994] for a finite-element approach to the same problem. Advanced discretization techniques such as adaptive grids and nonorthogonal coordinate systems that are quite routinely used in

conventional computational fluid dynamics are still in the developmental stage in ocean modeling; their efficacy is still largely unproven.

The finite-difference grid can be staggered or nonstaggered, with the former being more accurate. There are several possibilities [Mesinger and Arakawa 1976], including the so-called Arakawa C-grid, where the velocity component U_1 is displaced half a grid to the west and U_2 half a grid to the south of the grid center where all scalar quantities such as η , Θ , and S reside. The C-grid has better wave propagation characteristics if the grid size is smaller than the Rossby radius of deformation. The Arakawa B-grid, where both velocities are displaced half a grid point to the west, is better if it is larger [Semtner 1986]. With increased computing power and hence finer resolution, C-grid is becoming more popular.

Explicit or implicit methods can be used for time-stepping the equations; the latter are more efficient but require more complex simultaneous solution at all model grid points. The former are more easily adapted to massively parallel processors and are being increasingly used despite the limitation imposed by numerical stability considerations. The maximum time step that can be taken in an explicit scheme (for a staggered grid) is given by the Courant–Friedrichs–Lewy (CFL) condition, which is of the form

$$\Delta t \leq 0.5(\Delta x_e/C_e) \quad (31.15)$$

where

$$\Delta x_e = (1/(\Delta x_1)^2 + 1/(\Delta x_2)^2)^{-1/2}$$

is the effective grid size, which is smaller than the grid size in the individual directions, and C_e is the effective gravity-wave speed, which is the sum of the gravity-wave speed and the advection velocity. In the barotropic problem, for example, $C_e = \max[|U_j| + \sqrt{gH}]$.

Explicit inclusion of the free-surface dynamics in a model requires that a mode-splitting technique [Blumberg and Mellor 1987, Kantha and Piacsek 1993, Madala and Piacsek 1977] be employed to overcome the severe limitations on the solution due to stability considerations imposed by fast-moving external gravity waves on the free surface. This technique consists essentially of splitting the solution into barotropic and baroclinic modes, with the barotropic part solved at the time step dictated by external gravity waves and the baroclinic part at a much larger time step, 20 to 50 times larger. This approach takes into account the fact that internal baroclinic adjustments are much slower.

It is the discretization of the vertical coordinate that is the most distinguishing feature of various ocean models. Several choices are possible, including that of no discretization (for a barotropic model). We will describe these next.

31.3.1 Barotropic Models

If the density gradients are neglected in the governing equations, or alternatively the ocean is considered to be of uniform density, the current distribution in the vertical becomes independent of depth (away from regions of frictional influence such as the surface and the bottom). Under these conditions, it is possible to ignore the transport equations for Θ and S and integrate the governing equations for continuity and momentum over the water column to arrive at a vertically integrated set of equations that govern the sea-surface elevation η and the vertically averaged velocity components \bar{U}_j :

$$\begin{aligned} \frac{\partial \eta}{\partial t} + \frac{\partial}{\partial x_k}(\bar{U}_k D) &= 0 \\ \frac{\partial}{\partial t}(\bar{U}_j D) + \frac{\partial}{\partial x_k}(\bar{U}_j \bar{U}_k D) + f \varepsilon_{j3k}(\bar{U}_k D) &= -g D \frac{\partial \eta}{\partial x_j} - D \frac{\partial P_a}{\partial x_j} \\ &+ g D \frac{\partial \xi}{\partial x_j} + (\tau_{0j} - \tau_{bj}) + D \bar{F}_j \end{aligned} \quad (31.16)$$

where $D = H + \eta$ is the total depth of the water column.

The bottom friction is now determined using the column average velocity \bar{U}_j . Note the presence of tidal potential terms involving ξ on the right-hand side of the momentum equations that contain astronomical forcing terms due to the gravitational forces of the moon and the sun. Note also the terms due to atmospheric pressure and wind stress forcing. The astronomical forcing can be prescribed a priori from a knowledge of the ephemerides of the sun and the moon [see, for example, Kantha 1995, Schwiderski 1980]. The atmospheric forcing terms are also known and can be prescribed as a function of time during the model run. This set of equations can be used to solve for the sea surface height (SSH) and depth-averaged currents due to phenomena such as tides and storm surges.

Figure 31.1 shows an example of the application of barotropic equations to the problem of deducing the tidal SSH in the global oceans. The reader is referred to Kantha [1995] for details, but, briefly, the equations are cast in spherical coordinates, and the tidal potential terms are expressed as a sum of a series containing various tidal components such as the semidiurnal M_2 , with a period of 12.42 h, and the diurnal K_1 , with a period of 23.93 h (the atmospheric forcing terms are zeroed out for this application). The resulting equations are solved on a $\frac{1}{5}^\circ$ latitude–longitude C-grid covering the global oceans (excluding the Arctic) for each tidal component. The bottom depths over the model grid are derived from a digital database (ETOP05 from NOAA) containing world topography at $\frac{1}{12}^\circ$ resolution. However, for the results to be accurate enough for certain applications such as altimetry, inevitable errors that result from inaccurate knowledge of bottom depths and friction coefficients have to be overcome by data assimilation. Tidal SSHs can be derived in the deeper parts of the oceans quite accurately from measurements of SSH fluctuations by a satellite-borne microwave altimeter. The tidal SSH data derived from the currently operational NASA/CNES TOPEX/Poseidon precision **altimeter** [Desai and Wahr 1995] have been assimilated into the model as well as those from coastal tide gauges around the world's coastlines. A simple data assimilation scheme has been used where, at each time step, the model-predicted SSH is replaced by a weighted sum of the model SSH and the observed SSH, with weights determined a priori. The result is tidal SSH that is accurate to within a few centimeters over the global oceans, including shallow coastal and semienclosed seas. This information is useful for many applications, such as an accurate determination of the subtidal SSH variability from altimetric data, gravimetry, and determination of tidal dissipation. Figure 31.1 shows the M_2 **coamplitude and cophase** (with respect to Greenwich) distributions of the tidal SSH and the tidal-current ellipses over the global oceans. Figure 31.2 shows the accuracy attained by this data-assimilative tidal model in the form of scatterplots of comparison of modeled and observed tides from an independent set of accurate tide and bottom-pressure gauges over the global oceans, whose locations are also shown.

Barotropic models such as these can also be used to study the response of the SSH to atmospheric pressure forcing [Kantha et al. 1994, Ponte 1994]. It is often assumed that the ocean responds instantaneously to pressure forcing as an inverse barometer with roughly one centimeter of increase (decrease) for every millibar of drop (rise) in atmospheric pressure. This is not always true, and the departures from the inverse-barometer response are quite important to satellite ocean altimetry [Kantha et al. 1994].

Finally, a very important application of barotropic models is for prediction of storm surge effects along a coastline due to approaching hurricanes. The strong hurricane-force winds (augmented by the pressure drop in the eye of the hurricane) pile up water against the coast that often leads to an increase in sea level of several meters and consequent inundation of structures along the coastline. Hurricane Camille in 1969 caused a storm surge of nearly 8 m along the Mississippi coast, leading to widespread destruction and devastation. Provided the local bathymetry is known accurately and the characteristics of the hurricane (such as the wind stress distribution and forward velocity) can be deduced reasonably well from NWP forecasts, it is possible to predict the resulting storm surge quite accurately using a barotropic model driven by the wind stress and atmospheric pressure terms on the right-hand side.

31.3.2 z-Level Models

The Bryan–Cox–Semtner z -level model [Bryan 1969, Cox 1985, Semtner and Chervin 1992] is the oldest and the most popular global ocean model. Several versions exist, including the Modular Ocean Model (MOM) from the Geophysical Fluid Dynamics Laboratory in Princeton, New Jersey, the latest version

CU Global Tide Model
 version 1.3

of which (MOM2) includes free-surface dynamics. A version optimized for massively parallel processors, called POPS (Parallel Ocean Prediction System), is available from Los Alamos Scientific Laboratory [Smith et al. 1992]. Recent improvements include inclusion of a free surface in a variety of versions around the world [Killworth et al. 1991, Dukowicz and Smith 1994], and adoption of a C-grid. A recent review of the current state of ocean modeling using z-level models can be found in Semtner [1995].

Imposition of a rigid lid (via the boundary condition $W = 0$ at $z = 0$) means that the pressure at $z = 0$ enters as an unknown. It is eliminated from Equation 31.2 by cross-differentiation, and an equation for the stream function ψ for vertically integrated transport in the water column is derived (for details, see

Semtner [1986]). This is an elliptic equation and is solved subject to conditions imposed on lateral ocean boundaries, which are in general multiply connected. Herein lies the principal problem with rigid-lid models. While they are efficient, the solution technique is more complicated and not easily adapted to vector and parallel processors. The problem is alleviated somewhat by not cross-differentiating to derive the stream function, but working with the pressure on the rigid lid (Section 31.2, “Rigid Lid or Free Surface”).

Numerous applications of the z -level Bryan–Cox–Semtner model and its various versions can be found in the literature (for example in the *Journal of Physical Oceanography* and the *Journal of Geophysical Research, Oceans*). It has been used extensively to study the seasonal, interannual, and climatic variations in the global oceans. It is also a central part of the ocean analysis system for the tropical oceans [Leetma and Ji 1989], where a best estimate of the state of these oceans is determined by assimilation of observational data into a tropical-ocean version of the model. The most recent application can be found in [Semtner and Chervin 1992]. The highest-resolution global z -level model at present is the $\frac{1}{6}^\circ$ POPS model at Los Alamos that is run on a 256-node CM5 (A. Semtner, personal communication).

31.3.3 Sigma-Coordinate Models

Governing Equations 31.1 to 31.5 can be cast in a bottom-topography-following coordinate system by defining a new variable $\sigma = (z - \eta)/(H + \eta)$ and transforming the equations to the new coordinate system [Blumberg and Mellor 1987]; (see also Kantha and Piacsek [1993] for the general orthogonal curvilinear coordinate form):

$$\frac{\partial \eta}{\partial t} + \frac{\partial(U_k D)}{\partial x_k} + \frac{\partial \omega}{\partial \sigma} = 0 \quad (31.17)$$

$$\frac{\partial(U_j D)}{\partial t} + \frac{\partial}{\partial x_k}(U_k U_j D) + \frac{\partial}{\partial \sigma}(\omega U_j) + f \varepsilon_{j3k} U_k D = -D \frac{\partial P}{\partial x_j} + D \frac{\partial \Phi}{\partial x_j} + \frac{\partial}{\partial \sigma} \left(\frac{K_M}{D} \frac{\partial U_j}{\partial \sigma} \right) + DF_j \quad (31.18)$$

$$\frac{\partial P}{\partial \sigma} = -\frac{\rho}{\rho_0} g D \quad (31.19)$$

$$\frac{\partial(\Theta D)}{\partial t} + \frac{\partial}{\partial x_k}(U_k \Theta D) + \frac{\partial}{\partial \sigma}(\omega \Theta) = \frac{\partial}{\partial \sigma} \left(\frac{K_H}{D} \frac{\partial \Theta}{\partial \sigma} \right) + DS_\Theta + DF_\Theta \quad (31.20)$$

$$\frac{\partial(SD)}{\partial t} + \frac{\partial}{\partial x_k}(U_k SD) + \frac{\partial}{\partial \sigma}(\omega S) = \frac{\partial}{\partial \sigma} \left(\frac{K_H}{D} \frac{\partial S}{\partial \sigma} \right) + DF_S \quad (31.21)$$

where $D = H + \eta$, the total depth of the water column, and ω is the pseudo vertical velocity in the new coordinate system, zero at the ocean surface ($\sigma = 0$) and the bottom ($\sigma = -1$).

These equations, along with corresponding conservation relations for turbulence quantities, form the basis of the popular **sigma-coordinate** Princeton model developed by George Mellor’s group at Princeton University [Blumberg and Mellor 1987; see also Mellor 1991, Kantha and Piacsek 1993]. In this coordinate system, the number of levels is the same everywhere in the ocean, irrespective of the depth of the water column. It is therefore possible to resolve the bottom boundary layer where needed. This set of equations is best suited to modeling the shallow coastal oceans, although there is no inherent barrier to its application to deep basins. The principal problem is in applying it over sharply changing topography such as the continental slope separating the shelf from the deep basin. Here, unless the topographic gradients are suitably reduced by a nonlinear smoother, the errors in the calculation of pressure gradients induced by horizontal gradients of density can lead to spurious along-slope currents [Haney 1991]. While the problem due to strong topographic changes manifests itself in one form or another in all ocean models, the problem is particularly serious in sigma-coordinate models.

Many applications of this model can be found in the literature (for example in the *Journal of Physical Oceanography* and the *Journal of Geophysical Research, Oceans*). An application of a modified version developed at the University of Colorado, incorporating an improved mixed-layer formulation [Kantha and

Clayson 1994] and involving assimilation of altimetric data, is given in [Section 31.4](#). This version has also been converted to CM5 and applied to the Straits of Sicily, and its Cray T3-D version is being applied to the North Pacific Ocean.

31.3.4 Layered Models

In layered models, the ocean is divided into several (N) layers in the vertical, and Equation 31.1 to Equation 31.3 are integrated over each layer ($n = 1, \dots, N$) to obtain expressions for the thickness of and velocity in each layer. For example, Wallcraft [1991] obtains

$$\begin{aligned}
 \frac{\partial h^n}{\partial t} + \frac{\partial}{\partial x_k} (h^n U_k^n) &= w^n - w^{n-1} \\
 \frac{\partial (h^n U_j^n)}{\partial t} + \left[\frac{\partial}{\partial x_k} (h^n U_k^n) + U_k^n \frac{\partial}{\partial x_k} \right] U_j^n + f \varepsilon_{j3k} h^n U_k^n \\
 &= -h^n \sum_{k=1}^N G_k^n \frac{\partial}{\partial x_k} (h^n - h_0^n) + (\tau_j^{n-1} - \tau_j^n) + A_M \frac{\partial^2}{\partial x_k \partial x_k} (h^n U_j^n) \\
 &\quad + \max(0, -w^{n-1}) U_j^{n-1} + \max(0, w^k) U_j^{n+1} - [\max(0, -w^n) \\
 &\quad + \max(0, w^{n-1})] U_j^n + \max(0, -c_{de} w^{n-1}) (U_j^{n-1} - U_j^n) \\
 &\quad + \max(0, -c_{de} w^n) (U_j^{n+1} - U_j^n)
 \end{aligned} \tag{31.22}$$

where h^n is the thickness and U_j^n the velocity of the n th layer, w^k is the vertical velocity at the k th interface, and h_0 is the layer thickness at rest. The N th layer contains the model basin topography, and its thickness is the total depth of the water column minus the sum of the thicknesses of the remaining layers. Finally,

$$\begin{aligned}
 G_k^n &= \begin{cases} g, & k \geq n \\ g \left[1 - \frac{\rho^n - \rho^k}{\rho_0} \right], & k < n \end{cases} \\
 \tau_j^n &= \begin{cases} \tau_w, & n = 0 \\ c_{dn} |U_j^n - U_j^{n+1}| (U_j^n - U_j^{n+1}), & n = 1, \dots, N-1 \\ c_{db} |U_j^N| U_j^N, & n = N \end{cases}
 \end{aligned} \tag{31.23}$$

The factor c_d is the drag coefficient, c_{de} is the drag due to entrainment of fluid from one layer to the adjacent one, τ_w is the wind stress, and ρ^n is the density of the n th layer. Note that the layer densities do not change with time, only their thickness does at each model grid point. The conditional statements have to do with entrainment and detrainment at each interface between two adjacent layers, the details of which can be found in Wallcraft [1991].

The thinning of a layer to vanishing thickness is a major problem in layered models that leads to numerical difficulties. The traditional solution has been to make each layer thick enough, but this distorts the representation of the oceanic vertical structure. An alternative solution is to entrain fluid into the thinning layer from below to thicken it. Such entrainment has to be balanced by global detrainment in the layer so as to keep the density of each layer constant in space and time. For details of this and the model numerics, see Wallcraft [1991].

It is essential to select the number and rest thicknesses of layers carefully in layered models. Since topographic variations are contained in the bottommost layer only, these models are generally incapable of simulating circulation in coastal and shallow seas. They are, however, excellent at capturing the important lowest-order dynamics of the basin circulation and are therefore widely used for process-oriented studies. They are also being increasingly used for a variety of applications. One example is the six-layer, $\frac{1}{8}^\circ$ global

model at the Naval Research Laboratory at Stennis Space Center, Mississippi, the SSH from which is shown in two parts, the Atlantic and Indian Oceans in Figure 31.3a and the Pacific Ocean in Figure 31.3b. Realistic depiction of mesoscale activity, especially in regions of strong ocean currents — such as the Gulf Stream in the Atlantic, Kuroshio in the Pacific, the Brazil/Malvinas Current off Brazil, the Agulhas Current off Africa, and the Circumpolar Current around the continent of Antarctica — are noteworthy. The SSH variability from a layered model like this, driven by synoptic winds from a NWP center such as Fleet Numerical Meteorology and Oceanography Center, compares well with the variability indicated by altimeters such as the U.S. Navy's GEOSAT.

A simple subset of the layered model is the so-called reduced-gravity model (also called $1\frac{1}{2}$ -layer model), where the water column is assumed to consist of two layers: an active top layer of thickness H and a quiescent bottom layer of infinite thickness, with a density interface between the two of intensity $\Delta\rho$. It is remarkable that this very simple model often captures the essential dynamics of the circulation; for example, a reduced-gravity model of the Gulf of Mexico demonstrated conclusively that it is the instability of the Loop Current that is responsible for the shedding of the Loop Current eddies [Hurlburt and Thompson 1980]. The governing equations are identical to the barotropic Equation 31.15, except that the gravity parameter g is replaced by $g' = g (\Delta\rho/\rho_0)$, the reduced gravity (whose value is two orders of magnitude smaller than g ; hence the name reduced-gravity model), with H now denoting the rest thickness of the upper layer and η denoting the deflection of the interface.

31.3.5 Isopycnal Models

Isopycnal models are similar to the layered models discussed above but are fully dynamical and thermodynamic. Despite the numerical problems associated with surfacing and vanishing of layers, they are well suited to simulate basin dynamics. Considerable progress has been made over the last decade in isopycnal modeling, and with the inclusion of adequate upper-mixed-layer physics they are also becoming quite practical. Examples of applications can be found in Oberhuber [1993] and Bleck and Smith [1990]. Since they principally deal with isopycnals (surfaces of equal density) and do not consider temperature and salinity separately, but instead treat density as the prognostic variable, they are not well suited to handling situations where temperature and salinity must be computed separately. A linear equation of state and identical diffusion characteristics for temperature and salinity are implicit in these models. This is valid over a majority of the global oceans, if one excludes regions such as those near river outflows and sea-ice formation.

31.3.6 Data Assimilation

Inevitable errors in initial conditions and imperfect parametrization of physical processes make a model ocean diverge rapidly from the real ocean. This is simply due to the extreme sensitivity of this system to even minute changes in initial conditions, typical of chaotic nonlinear systems. It is therefore essential to employ observational data in ocean models to retain the modeled ocean state close to the real state. The situation is no different from that in modeling the state of the atmosphere for NWP purposes, except that the time scales for loss of predictability is weeks for the oceans compared to days for the atmosphere. The process of employing observed data from the real ocean (atmosphere) to keep the modeled ocean (atmosphere) realistic is called data assimilation [for example, Anderson and Moore 1986] and consists of combining the modeled fields with observed data at various points in the domain to produce the best possible estimate of the real state of the ocean over the entire model domain. Exactly how this is best done has been the subject of considerable research in the atmospheric community [Bengtsson et al. 1981] over the past few decades, and more recently in the oceanic community as well [Haidvogel and Robinson 1989].

NWP centers use predominantly the so-called analysis–forecast cycle of assimilation. Here, the current state of the modeled atmosphere as predicted by the previous forecast is combined with observations of the atmosphere by radiosondes and surface stations all over the world, by an analysis–initialization process, to produce initial fields of various model variables suitable for describing the initial state for the next model

Note the eddy-resolving capability of this model displayed in the realistic mesoscale activity in regions of strong currents such as the Agulhas around Africa.

forecast. The forecast skill depends very much on the accuracy of the initial state so derived, since errors in the latter tend to get magnified with time during the forecast.

Another possible assimilation method is the so-called continuous assimilation [Bengtsson 1981], where a numerical model is kept running and current by assimilation of observed data as and when they become available. A forecast can then be initiated by a similar model running forward *free* (without any data assimilation). The principal advantage of this method over the analysis–forecast cycle is that the model derives benefit from all past data as opposed to a single set of observations at a particular time. Also, the shock of data insertion due to inevitable mismatch between the model and observed states is less severe. Since such a mismatch can lead to severe noise superimposed on the true state of the forecast atmosphere (ocean), often making the forecast worthless, considerable effort has been expended in devising means to minimize such a mismatch, resulting in a procedure called *initialization* in NWP terminology. Continuous assimilation tends to reduce this shock and is therefore often preferable. The reader is referred to Bengtsson et al. [1981] and Haidvogel and Robinson [1989] for a discussion of assimilation philosophies.

The method of combining data into a model can vary from the simplest one (called data insertion), in which the model-predicted values are just replaced by observed values, to Kalman filters [Gelb 1988] (which blend the model and observed values optimally, taking into account the model error and observational

(b)

FIGURE 31.3 *continued*

error statistics), adjoint techniques [Thacker and Long 1987], and variational methods [Derber and Rosati 1989]. It is also possible to use nudging techniques in which appropriate Newtonian damping terms that damp the variable to the observed value with a predetermined time scale are introduced into the governing equations. The most commonly employed method is optimal interpolation [see Choi and Kantha 1995, for example], since methods such as Kalman filters and adjoint techniques are computationally expensive and at present still impractical for applications in NWP and ocean prediction.

It is beyond the scope of this article to go into details of data assimilation methods. Instead, the reader is referred to the above references (and more recent work in the literature, especially on NWP), with a reminder that most assimilation methods replace the model-predicted values by a weighted combination of model-predicted value and observed values during the assimilation step, with the weight either determined a priori by statistical methods such as optimal interpolation or updated at each assimilation step by a method such as Kalman filtering. For examples of oceanic data assimilation, the reader is referred to Derber and Rosati [1989], Glenn and Robinson [1995], and Choi and Kantha [1995].

31.3.7 Computational Issues

Ocean models make a large demand on computer resources, CPU time, core memory, and disk storage, because ocean eddies are much smaller than weather systems, and the resolution needed is therefore much

finer. Fine resolution also forces one to take smaller time steps in explicit models on account of CFL constraints. Even in “implicit” ocean models, the advection terms are treated explicitly, thus imposing a time-step limitation.

For explicit free-surface models, the time step is limited by the step of the fast-moving surface gravity waves, and one has to take a large number of small time steps to integrate over a simulation or forecast period (mode splitting helps alleviate this problem). For implicit ocean models, which filter out these gravity modes, the CPU-time requirement is governed by the rate of convergence of the iterative method used to solve the resulting Poisson equation.

Explicit model codes are usually readily vectorizable and parallelizable and generally need few additional arrays to store the auxiliary variables that may be needed to speed up the computations. In contrast, the vectorization/parallelization of the Helmholtz solvers associated with implicit codes is usually a nontrivial problem and, for some schemes that have been used up to now on serial machines, not at all feasible. The extra work resulting from the iterative or matrix inversion solution can often increase the total CPU time so that it is comparable to, or even exceeds, that for explicit codes, especially on vector/parallel computers. In addition, there are almost always extra arrays needed during this stage of the computations. The two- or four-color versions of the successive overrelaxation (SOR) and the conjugate-gradient method are two techniques that are well suited to vectorization and parallelization in implicit codes.

In the early days of supercomputers, the core memory available was usually so small that all the arrays needed for computations in ocean models, especially global ones, would not fit within the core, and elaborate methods were employed to make efficient use of high-speed disks to transfer arrays into and out of core as needed. GFDL models (MOM2 for example) still retain such an architecture. With high-speed memory becoming much cheaper, modern supercomputers have core memories measured in gigawords (Gw), and many ocean models can now reside in memory, although the need for out-of-core models has not totally vanished, especially for very high resolutions and global coverage. In-core models such as the Los Alamos POPS are, however, better suited to efficient massive parallelization than the out-of-core ones such as MOM, because of the considerable disk I/O involved.

Disk/tape storage requirements for storing ocean model results are also often in tens to hundreds of gigabytes and depend on the length of the simulation and on how often and how many variables are required to be stored for later analyses. Disk storage and postprocessing requirements often constrain the temporal resolution and the details of the analyses carried out on the results of an ocean model.

Data-assimilative ocean models require even more resources than the free-running ones, with the additional memory and CPU-time requirements depending very much on the method of assimilation. It is not unusual for assimilation to more than double the CPU time requirements, even for simple OI-type schemes. Methods such as Kalman filters and adjoint methods are even more demanding. Generally, data assimilation on massively parallel computers requires considerable investment of time and effort for efficient implementation. We will give some typical CPU-time and memory requirements for large ocean models and for diverse computers, to cover a spectrum of configurations and to familiarize the reader with resource requirements of computational ocean modeling. The $\frac{1}{8}^\circ$ six-layer NRL global model ($2051 \times 1145 \times 6$ grid) requires 1.8 Gw of memory and 2 CPU hours per month of simulation on a 256-node CM5-E. The $\frac{1}{16}^\circ$ Pacific model ($1977 \times 1313 \times 6$ grid) requires 385 Megawords (Mw) and 17 single-processor CPU hours per month on a Cray C-90. The $\frac{1}{5}^\circ$ global explicit barotropic tidal model discussed in [Section 31.3](#) under “Barotropic Models” (1801×729 grid) employs a time step of 13 s, assimilates 4000 data points every time step, and requires 65 Mw of memory and 22 single-processor CPU hours for a 10-day simulation on a 16-processor Cray C-90, assimilating 4000 data points every time step. A 15-level northern hemisphere Arctic ice–ocean model ($360 \times 360 \times 15$ grid) requires 40 Mw of memory and 25 CPU hours per month on a Cray C-90. A 30-level sigma-coordinate model of the eastern Pacific ($163 \times 229 \times 30$ grid) requires 42 Mw of memory and 4 CPU hours per month on Cray C-90. The small Gulf of Mexico sigma-coordinate nowcast–forecast model ($85 \times 86 \times 22$ grid) discussed in the next section requires 30 Mw of memory and 6 CPU hours for a month-long simulation in the nowcast mode, and 4 CPU hours in the forecast mode, the additional time requirements for the simple OI-based data assimilation being in this case about 50%. An idea of the storage requirements can be obtained from the fact that

even this small model required 2 Gbytes to store the model output at 5-day intervals for a 10-year-long simulation without any data assimilation, and postprocessing of this output required numerous hours on a powerful Sun Sparc workstation.

31.4 Nowcast/Forecast in the Gulf of Mexico (a Case Study)

An important application of ocean models is in prediction of the current (nowcast) and future (forecast) state of the ocean. Given the fact that more than 50% of the burgeoning human population lives within 100 miles of a coastline and hence uses/abuses the coastal oceans, such predictions, especially in the coastal and marginal seas, might be particularly useful for societal needs such as sea-level predictions, mapping of currents, and pollution tracking. We will provide one such example from a marginal semienclosed sea in the north Atlantic, the Gulf of Mexico. The offshore oil fields of this “mini-ocean basin” account for roughly half the U.S. domestic oil production, and the Louisiana–Texas (LATEX) continental shelf is dotted with thousands of oil platforms. Exploration and production are expanding steadily into deeper waters, waters as deep as 1000 m.

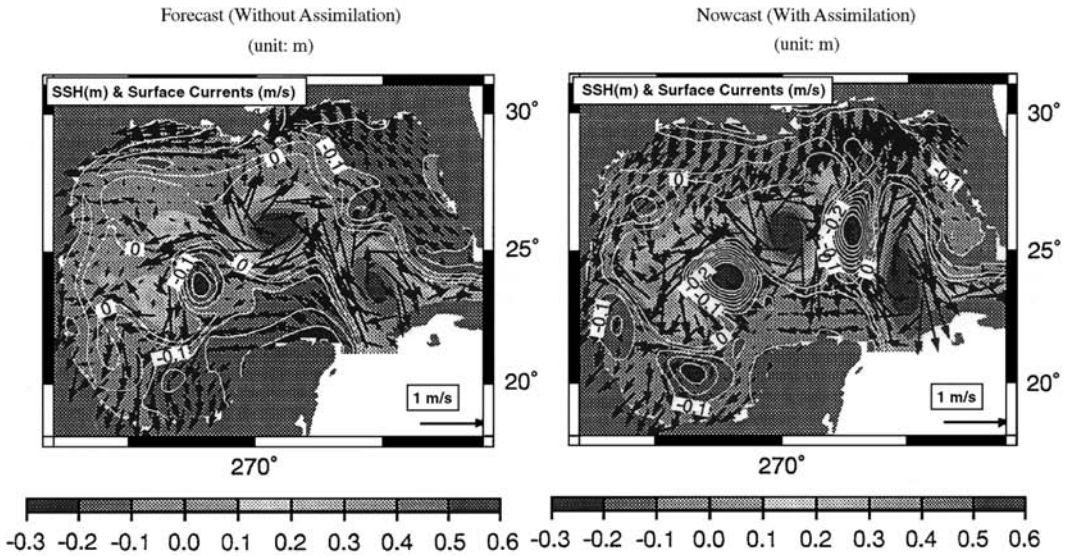

The major oceanic phenomenon in the Gulf is the so-called Loop Current variability. Every second, about 28 million cubic meters of subtropical waters enter the Gulf through the Yucatan Straits between Mexico and Cuba and leave it through the Florida Straits between Florida and Cuba to eventually become the Gulf Stream. The extent of penetration of this so-called Loop Current into the Gulf is highly variable. Occasionally the Loop Current becomes unstable and sheds off a huge anticyclonic (clockwise) eddy, anywhere from 100 to 350 km in diameter, that pinches off the Loop Current and moves into the western Gulf. This Loop Current eddy (LCE) is the principal mechanism for renewal of waters in the western Gulf [Hurlburt and Thompson 1980]. The path of LCEs is also highly variable, and occasionally a LCE traverses the Gulf in close proximity to the LATEX continental shelf. Because of the strong currents (often as much as 4 knots, 2 m s^{-1} in magnitude) associated with LCEs, this is the second major source of concern (the first being hurricanes in late summer and fall) to production and exploration activities in the Gulf. A capability to accurately forecast the movement of a LCE is valuable to the oil industry.

A forecast of the path an LCE takes is possible with the use of a numerical model of the Gulf. However, accurate information on the initial location of the LCE once it is shed and the corresponding Gulf-wide oceanic state is crucial to the forecast skill. An accurate nowcast is therefore essential, and this requires a data-assimilative numerical model. Since in situ data, even in the Gulf, are sparse and often nonexistent, remotely sensed data need to be relied upon for this purpose. Since the sea surface temperature from IR sensors is not always useful in locating a LCE (especially in summer) and since altimetry can almost always detect such an eddy if it happens to straddle its track, altimetric SSH anomalies can be assimilated into the ocean model to provide a reliable nowcast of not only the eddy location but also the initial state of the Gulf. Forecasts can then be made from this nowcast and the path of the LCE predicted.

The methodology employed by Choi and Kantha [1995] for producing a nowcast (in a hindcast mode, that is, prediction of past events for which data are available for verification) is called the *continuous* or *four-dimensional* assimilation method and has its origins in NWP. The model is run from a time in the past to the present, assimilating altimetric data track by track [see Choi and Kantha 1995 for details]. Altimetric SSH anomalies derived from NASA/CNES TOPEX and ESA ERS1 altimeters are converted to anomalies in the temperature in the water column and assimilated into the model using simple optimal interpolation. In the particular example shown here, the model was run starting at the beginning of January 1993 (day 1 corresponds to Jan. 1) to produce a nowcast for day 240, at which a LCE pinches off and separates from the Loop Current. The model is then run forward free (without assimilation) to produce a forecast over the next 40 days, assuming nonchanging winds over the period. The forecast skill is assessed by comparison with the nowcast, which was also carried out over the rest of 1993.

Figure 31.4 shows a comparison of the forecast and nowcast SSH fields over the Gulf at days 260 (top) and 280 (bottom). The forecasts are shown on the left and the corresponding nowcasts on the right.

Gulf of Mexico
 Model Run Day 260

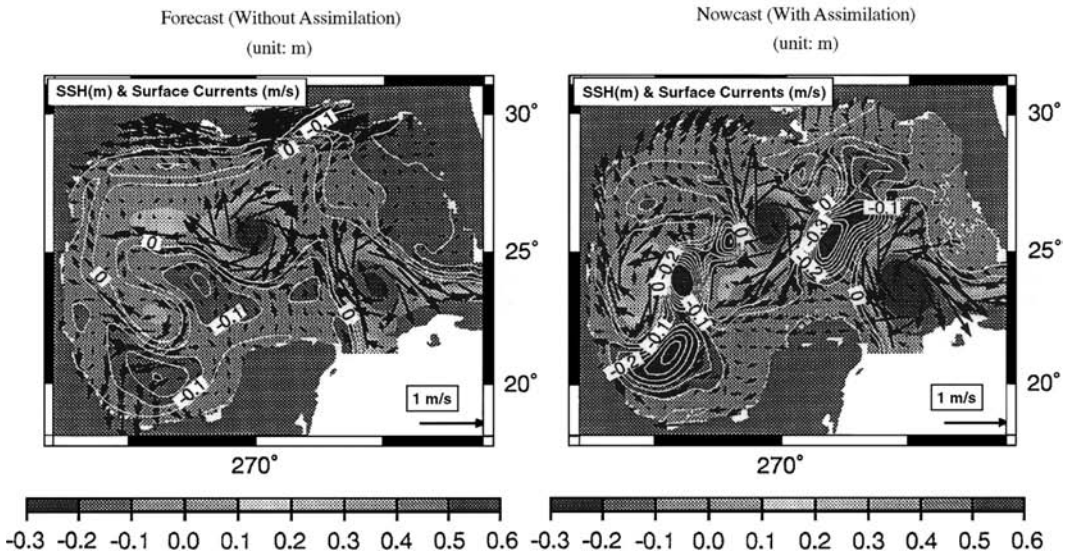

FIGURE 31.4 The sea surface elevation and currents from the forecast (left) and the nowcast (right) at days 260 (top) and 280 (bottom) from a three-dimensional circulation model of the Gulf of Mexico assimilating altimetric data from TOPEX and ERS1. The forecast was started at day 240. Compare the forecast with the corresponding nowcast to assess the model skill.

There is a close correspondence between forecast LCE position and the nowcast position, suggesting that the LCE path is being predicted reasonably well. The error, however, between forecast and nowcast LCE positions is larger at day 280 than at day 260. This particular experiment suggests that the forecast has some skill to about 30 days or so, beyond which the predicted path (forecast) deviates increasingly from the actual path (nowcast for the corresponding day). Since altimetric data are available within several days of their collection by the sensor, this experiment suggests that with some skill forecasts can be made two to three weeks in advance. If this is proven correct, this nowcast–forecast capability might be useful to drilling/exploration activities in the Gulf. It is in applications such as this that an ocean model, acting in concert with routine ocean monitoring via satellite-borne sensors, can prove useful.

31.5 Research Issues and Summary

We have provided a thumbnail sketch of ocean modeling as it is practiced today. As we said earlier, the field has undergone a phenomenal growth in recent years, and it is impossible to do justice to the subject in a short review like this. The reader is encouraged to pursue a particular model or approach of interest via the references cited.

The major issue in ocean modeling is the dearth of data for model initialization, forcing, assimilation, and of course verification or skill assessment. In situ data are rather sparse and, given the cost of ship time, likely to remain so. Therefore, increasing reliance will be placed on remote sensing to fill in gaps. However, this approach itself has limitations, and it is not clear what might fill the gap. Smart autonomous vehicles, a product of the Cold War, roaming the world oceans, and buoys sprinkled into the global oceans, telemetering data via communication satellites, may one day provide more in situ data than we currently acquire. Combined with multiteraflop computing capabilities of the coming century, an ocean observing and monitoring system consisting of satellites, moored arrays, buoys, and autonomous vehicles might one day finally enable us to set up realistic ocean prediction systems to satisfy the needs of the coming generations. Ocean modeling will play a central role in all this.

Acknowledgments

Lakshmi Kantha acknowledges with pleasure the support provided by The Minerals Management Service of the Department of the Interior through an interagency agreement with the U.S. Navy through contract N00014-92C-6011, administered by Walter Johnson of MMS and Donald Johnson of the Naval Research Laboratory. Lakshmi Kantha was also supported by the NOMP program of the Office of Naval Research under contract N00014-95-1-0343, administered by Tom Curtin, and by the Coastal Sciences Section of the Office of Naval Research under contract N00014-92-J-1766, administered by Thomas Kinder.

Defining Terms

Altimeter: A microwave device measuring the time delay between an emitted microwave signal and its return by reflection from the sea surface. When the position of the instrument in space is independently determined, it enables sea surface topography to be measured to an accuracy of a few centimeters along the satellite track.

Baroclinic: Conditions in which the vertical shear is generated because of the horizontal gradients of density.

Barotropic: Conditions in which there are no variations in currents in the vertical direction.

Coamplitude and cophase: Lines of maximum tidal amplitude and lines of the time of occurrence of maximum tide, referred to either local or universal time.

Coriolis force: A fictitious force needed to allow for the noninertial nature of a rotating coordinate system.

Data assimilation: The process of blending observational data into numerical models.

- El Niño:** A frequent phenomenon in the tropical Pacific, occurring at 3–7-year intervals, when the eastern Pacific gets anomalously warm and sets off changes in the tropical atmosphere that affect weather all over the globe.
- Gravimetry:** The science of precise measurement of the earth's gravity.
- Hindcast:** A forecast exercise conducted for a period in the past to take account of the availability of accurate observational data for forcing, assimilation, and verification.
- Inverse barometer effect:** The effect where the changes in the atmospheric pressure are compensated exactly by the ocean by inverse changes in its height so that no oceanic motions are induced.
- Isopycnal:** A surface on which the density is constant.
- Kelvin waves:** Waves that run along the ocean margins (with the coast to the right in the northern hemisphere) at the speed of the shallow-water gravity wave. These waves are important for oceanic adjustment to changing surface forcing.
- Nowcast:** An estimate of the present state, often by an optimal blend of model and data.
- Potential temperature:** The temperature attained by a parcel of water brought adiabatically to a reference depth.
- Reynolds averaging:** The process of obtaining equations for mean quantities in a turbulent flow by considering each quantity to consist of a mean and a fluctuating component and taking averages over time or realizations.
- Sigma coordinates:** A coordinate system where the vertical coordinate is normalized by local depth; it is bottom-fitting or topographically conformal.
- Synoptic forcing:** Multihourly forcing from atmospheric models run at NWP centers, obtained in the past from a synopsis of weather charts.
- Western intensification (boundary current):** Strong currents found at the western boundaries of the ocean basins or eastern sides of continents because the effect of Earth's rotation variation with latitude (the so-called β -effect).

Further Information

This review chapter has been necessarily sketchy. The reader is therefore encouraged to consult the various references cited for more details. The monograph on numerical ocean modeling edited by James O'Brien [1985] is still the best starting point, especially since the models described there have remained essentially unchanged, undergoing only small evolutionary changes such as adaptation to massively parallel computers and inclusion of better mixing algorithms. A good starting point in coastal ocean modeling is the American Geophysical Union (AGU) volume edited by N. Heaps [1987]. Kowalik and Murty [1993] is an excellent “cookbook” for details of numerics such as finite-differencing and the split-mode technique. Reference can be made to Haidvogel and Robinson [1989] for a good description of data assimilation methods. Textbooks by Pond and Pickard [1979] and Gill [1982] are good starting points for exploring the dynamics of the oceans. The Henry Stommel 60th Birthday volume on physical oceanography [Warren and Wunsch 1981] is a good followup.

There is no specific journal for ocean modeling; instead, modeling advances are published in journals such as the *Journal of Physical Oceanography* of the American Meteorological Society (AMS) and *Journal of Geophysical Research (Oceans)* of the American Geophysical Union (AGU). The *Journal of Hydraulic Engineering* of the American Society of Civil Engineers publishes modeling papers mostly related to coastal and estuarine studies. The *Journal of Continental Shelf Research* specializes in coastal research, including coastal modeling. Purely computational advances often appear in journals such as the *Journal of Computational Physics*. Semiyearly meetings of the AGU, meetings of the AMS and biennial Ocean Sciences, and quadrennial meetings of the International Union of Geodesy and Geophysics (IUGG) are examples of venues where latest advances in ocean modeling are presented and critiqued.

The GFDL z -level deep-water-basin model (<ftp.gfdl.gov>; directory pub/ GFDL_MOM3), Princeton sigma-coordinate shallow-water coastal model (<ftp.gfdl.gov>; directory pub/slm), and University of Miami isopycnal model (<http://oceanmodeling.rsmas.miami.edu/micom>) are all available. Readers are encouraged to offload the model codes and experiment with them. A good starting point for hands-on ocean modeling is the Ocean Models chapter of the Computational Science Education Project [Kantha and Piacsek 1993], available on the World Wide Web at <http://csepl.phy.oral.gov/csep.html>. It contains model code, graphics, animation, and exercises on simple ocean models that serve as a good introduction to the field.

32.1 Introduction

The use of computational methods in the study of chemistry touches upon every area of chemical inquiry. Indeed, the art and the science of computation are a natural fit with the study of chemistry. From the earliest times, beginning even with alchemy, chemists have used models to render comprehensible the abstract theories and concepts of their field. It is only logical, therefore, that chemists would use the power of modern computational methods to extend and explore their understanding of chemical compounds and processes.

Computational applications in chemistry are so vast and varied that it would be impossible to cover the entire field within the confines of this chapter. Instead, we will provide an overview of the types of computational applications in the field of chemistry, followed by a more detailed presentation in a few areas to show how chemists integrate computation into their discipline.

Anyone who has taken an introductory course in chemistry will remember using calculations to solve chemical problems — at least equilibrium, kinetics, and stoichiometry problems. Chemists have become adept at using computational tools to solve such mathematical problems and in using those tools to model,

and thereby test, their understanding of chemical phenomena and processes. Tools such as spreadsheets, math programs, graphing calculators, and iconic modeling programs have replaced the slide rule of 40 years ago. These tools bring greater predictive power, better understanding, and the potential to solve ever more complex problems.

Chemists describe compounds at the most fundamental level as a reflection of the nature of the atoms, the bonds between those atoms, and the electrons that comprise them. In fact, since Schrödinger's development of functions in the 1920s to describe electrons as waves, chemists have attempted to describe chemical compounds and processes, with increasing sophistication, in purely mathematical terms. The limitations in this approach are both theoretical (the conceptual framework for our understanding of chemistry is not perfect) and practical (the mathematical and computational tools are not perfect, either). Since this approach was initiated, however, great strides have been and continue to be made in both the theoretical and practical arenas.

This overview of computational chemistry begins with a presentation of how students are introduced to computation, followed by a description of how mathematical modeling is used to comprehend chemical processes that do not require detailed understanding of the chemicals involved. The chapter concludes with a description of how chemists use computational methods to understand the structure of compounds and the nuances of chemical reactions.

32.1.1 Underlying Principles

For many areas of computational chemistry, mathematicians, physicists, and chemists (such as Schrödinger, Hartree, and Pauling) laid the theoretical foundation in the 1920s and 1930s. The power of today's desktop computers allow experimental chemists to bring these principles into practice. As these theories are tested and as the comparison of experimental and computational results reveals the theories' limitations, advances in theory continue to be made.

32.2 Computational Chemistry in Education

In the chemistry classroom, computation ranges from various forms of modeling (molecular and mathematical modeling, solving complex simulation problems, and molecular animation) to text and class supplements (homework and testing, computational tools, demonstrations and animations, and interactive figures). Computation appears in the chemistry laboratory as prelaboratory assignments (discussion of theoretical concepts and the proper use of equipment), simulated experiments and instruments, and the use of computational tools for data analysis.

Through the *Journal of Chemical Education (JCE)*, the Division of Chemical Education of the American Chemical Society publishes articles on the theory and application of computational chemistry, summarizes symposia from national meetings, and reviews software programs. In addition, the division makes available inexpensive, high-quality software to instructors and students from pre-high school through graduate school through *JCE Software*, Project SERAPHIM, and the various Web-based services available to *JCE* subscribers. Software capabilities have paralleled advances in operating systems, from various flavors of Apple II and MS/PC-DOS to Macintosh and Windows.

32.2.1 Journal of Chemical Education

For more than 75 years, *JCE* has served as the primary source of information for chemical educators. Today, *JCE* offers monthly published issues, software through *JCE Software*, online access, and various printed materials. In addition to the general articles in *JCE*, several feature columns are useful to computational chemistry:

- Reviews of books, media, and software
- Computer Bulletin Board
- JCE* Online

JCE Software

Molecular Modeling

Only@JCE Online, featuring JCE WebWare, Mathcad in the Chemistry Curriculum, and WWW site reviews

Teaching with Technology

The journal is fully searchable, with approximately 15 index keywords related to computational chemistry. To illustrate the current quality of coverage, a search using the keywords *computation chemistry* for the year 2002 resulted in nearly 200 hits.

Many general articles and Only@JCE Online features carry a symbol resembling the capital letter *W*. This symbol indicates that supplementary material (such as software, live spreadsheets and worksheets, additional data and exercises, laboratory instructions, animations, and video) is available to subscribers online. For example, one can link to the programs needed to analyze a kinetics simulation model for a drug poisoning victim, the software for finding the irreducible representations in a reducible representation for hybridization of orbitals and molecular vibrational motion, or Mathcad worksheets for Hückel theory calculations.

A relatively new addition to JCE is the regular feature JCE WebWare, which presents various Web-based applications suitable for computational chemistry in the laboratory, the classroom, or at home. Typically, the WebWare consists of small software programs, add-ins for spreadsheets and other standard programs, animations, movies, Java applets, or static and dynamic HTML pages. Recently, JCE WebWare included offerings for acid–base equilibria, nomenclature, games, chemical formatting add-ins for MS Word and Excel, spreadsheet analysis for first-order kinetics, a determinant solver for Hückel theory calculations, mechanism-based kinetics simulations, data analysis tools, and point group calculations. Each month, links are provided for fully interactive Chime-based models of some of the molecules discussed in the general articles in JCE.

Mathcad, a symbolic math software program, has become important in chemistry and, in particular, in physical chemistry. The JCE regular feature, Mathcad in the Chemistry Curriculum, presents abstracts of submitted documents that are useful for various chemistry courses. Recent worksheets include Hückel theory calculations, Bohr correspondence principle, NMR, modeling pH in natural waters, and variational treatment of a harmonic oscillator.

32.2.2 Project SERAPHIM

Project SERAPHIM began over 20 years ago as a clearinghouse for software and materials for computational chemistry. Membership fees support the clearinghouse, teacher workshops, and summer fellowships for software development. Software was distributed at a modest cost to members. A catalog listing several hundred different computer programs is available at the SERAPHIM Web site (<http://ice.chem.wisc.edu/seraphim>). These programs include

Databases — NMR library and experiments published in JCE

Data analysis tools — Significant figures, least squares analysis, dimensional analysis, spreadsheet calculations, and integration techniques

Chemical clip art

Teaching support — Quiz preparation and computer testing

Simulation problems — Wastewater treatment and water pollution

Tutorials and games

Laboratory — Experiment simulations, analytical techniques, and instrument interfacing

Core curriculum topics include states of matter (gases and crystals), nomenclature and formulas, stoichiometry (chemical equations, titrations, limiting reactants, and equilibria), thermochemistry, atomic structure (**electron configurations**, orbitals, and **SCF** calculations), chemical bonding (**molecular orbitals**, **HF** calculations, **Hückel calculations**, and **group theory**), spectroscopy (atomic, NMR, and ESR), dynamics (distribution of gas molecular speeds and chemical reaction kinetics), and descriptive chemistry

(acid–base, redox and electrochemistry, complexes, qualitative analysis, reaction prediction, organic molecules, biochemistry, polymers, and industrial chemistry). Currently, all Project SERAPHIM materials are available as free downloads from the Web site.

32.2.3 JCE Software

JCE Software resulted from collaboration between *JCE* and Project SERAPHIM with initial support from the Dreyfus Foundation. The motto of the journal is “*JCE Software* is not *about* software, it *is* software.” Originally, the journal contained three series: for Apple II, Macintosh, and MS/PC-DOS users; later, a fourth series was added for Windows users. The software and corresponding printed materials were sent to subscribers twice a year. Currently, in addition to various video materials, *JCE Software* offers over 15 special issue software collections, covering laboratory and supplementary classroom materials for Macintosh and Windows users:

General and advanced chemistry collections — Student-designed collections featuring animations, simulations, and computational tools for acid–base chemistry, equilibria, spectroscopy, crystal structure, and **quantum mechanics**

Chemistry Comes Alive! collections — Movies, pictures, and animations of reaction types, stoichiometry, states of matter, thermodynamics and electrochemistry, organic chemistry and biochemistry, and laboratory techniques

Collections on specific topics — Periodic table, laboratory techniques, NMR, solid-state surfaces, material science, crystallography, and problem-based learning

Many of the software programs are Web-ready, and appropriate licensing is available for local intranets. Much of the older software for MS/PC-DOS is available to subscribers as free downloads at the *JCE* Web site.

32.3 Computational Aspects of Chemical Kinetics

Chemical reaction sequences (CRSes) are ubiquitous in chemistry and biochemistry. CRSes are used to describe models of phenomena as diverse as the sequence of elementary steps occurring in a single chemical or biochemical reaction, a metabolic sequence of reactions, and the complex chemical processes occurring in environmental systems, such as the atmosphere. It is almost always of interest to understand the evolution of these systems in time. Writing the differential rate equations for each elementary reaction in the sequence conveniently expresses the theoretical temporal evolution. If the rate constant for each elementary step is known, then, in principle, one has a complete description of the temporal evolution of that CRS. However, since experimentally one can usually measure the concentration of one or more of the species involved in a CRS at different times, comparing the theoretical model and the experimental data involves one of the following:

Differentiating the experimental data — Analysis of enzyme kinetics using the **Michaelis–Menton** equation

Integrating the coupled set of differential rate equations associated with the CRS — Determining the order of a chemical reaction by plotting $\ln([\text{Reactant}])$ vs. time, $1/[\text{Reactant}]$ vs. time, etc.

A great deal of effort has gone into developing computational procedures that can convert the theoretical description of CRS into concentration vs. time information, which may then be compared directly to experimental results. There are two major approaches used to accomplish that goal: the numerical solution of differential equations and the **Monte Carlo** approach. Each has its own set of advantages and disadvantages, and software packages are available for each.

32.3.1 Numerical Solution of Differential Equations

CRS can be described by coupled sets of differential equations. Integrating these equations analytically is often not possible, so numerical techniques must be used. The various numerical techniques have been

described and sample programs have been presented in the literature (e.g., [Press et al., 1992]). Many CRSes of interest are **stiff**, that is, they contain rate constants that span many orders of magnitude. In order to analyze these systems effectively, implicit numerical methods, such as the one developed by Gear [Gear, 1971], must be used. The following programs, some of which may be downloaded free or for a modest fee, accomplish integration of coupled sets of stiff differential rate equations:

Gespasi [Mendes, 1993, 1997]

KINSIM [Frieden, 1993]

BerkeleyMadonna

Kintecus

Many of these software packages offer the capability to optimize the CRS under consideration. That is, the set of kinetic constants that bring the model in closest agreement with the kinetic data can be found [Mendes and Kell, 1998]. It is also possible to simulate stiff problems using Mathcad in conjunction with VisSim. Other software packages, which do not handle stiff differential equations (e.g., STELLA), have been used for less demanding applications. One of the most dramatic uses of stiff differential equation solvers to study CRS is the study of the ozone chemistry in the atmosphere. There, laboratory studies of individual atmospheric elementary reactions, coupled with atmospheric models, led to the decision to stop using CFCs. The 1995 Nobel lectures of Rowland, Molina, and Crutzen summarize this research [Crutzen, 1996; Molina, 1996; Rowland, 1996].

32.3.2 Monte Carlo Methods

Using an entirely different approach, researchers have developed methods to model the stochastic events of CRS rather than find numerical solutions to the coupled differential equations describing the CRS. An early report by Kibby [Kibby, 1969], followed by a complete theoretical exposition by Gillespie [Gillespie, 1976, 1977], describes **Monte Carlo** methods for simulating the time evolution of molecular events occurring in CRS. The probability of a particular reaction event occurring is the product of the intrinsic probability of such a reaction event (given by the rate constant) and the number of possible reaction events (given by the numbers of reacting molecules). The time interval is chosen in which the next reaction event is likely to occur, and then the particular reaction event that occurs is chosen from all possible reaction events. After adjusting the number of molecules for that event, the process is repeated.

This is how the actual stochastic events in a CRS are simulated. While the simulation can involve a very large number of events, stiff CRSes are simulated in exactly the same way as nonstiff CRSes. Furthermore, the method applies to very small-volume systems, such as a living cell or cellular organelle. This makes the method attractive to biochemists, in whose work it may not be appropriate to treat concentrations of molecules as a continuously varying quantity that changes deterministically over time [McAdams and Arkin, 1997]. A software package developed at IBM is available for free download that implements stochastic simulations of CRS.

32.4 Molecular Dynamics Simulations

In general chemistry, students are introduced to Dalton's intuitive picture of chemical reactions, in which atoms collide and rearrange to form new combinations. The computational method of molecular dynamics (MD) simulations maintains this classical view by treating atoms as billiard balls, with forces between them akin to springs [Garrison et al., 2000]. MD has a breadth of applications in chemistry, ranging from the determination of the lowest energy configuration of a protein to the study of mechanisms of chemical reactions. A distinct advantage of MD over methods based on electronic structure theory is that MD can be applied to large systems composed of thousands of atoms. Quantities can be calculated from the simulations, which can be compared with experimental values. Animations of atomic motions as a function of time are created, which can contribute mechanistic insights on a microscopic level unobtainable by experiment.

This section focuses on the application of MD simulations to study the high-energy bombardment of organic targets with atomic and polyatomic projectiles [Garrison et al., 2000; Zaric et al., 1998; Townes et al., 1999; Nguyen et al., 2000], which is important in secondary ion mass spectrometry (**SIMS**). In SIMS, a primary ion beam bombards the surface with a low enough dose that each impact samples a fresh, undamaged portion of the surface. Secondary ions ejected from the surface are detected by a mass spectrometer.

SIMS is a widely used analytical technique, which is being developed for applications to molecular-specific imaging on a submicron scale [Berry et al., 2001]. Experiments have demonstrated that the secondary ion yield depends nonlinearly on the number of atoms in the projectile, and the nonlinear enhancement increases with the number of atoms [Van Stipdonk, 2001]. Therefore, polyatomic projectiles have the potential to improve significantly the sensitivity of SIMS. Sensitivity is the limiting factor in imaging applications, in which the maximum amount of analytical information must be obtained from a limited number of target molecules on the surface.

The objective of the simulations is to understand the mechanisms by which polyatomic projectiles enhance the secondary ion yield and to determine the optimum conditions for the use of polyatomic projectiles. The model systems used in these studies are composed of a thin organic film that is physisorbed to an atomic substrate. The simulations have compared the effect of Cu_n clusters with the same kinetic energy per atom [Zaric et al., 1998]. Simulations with SF_5 and Xe, which have the same mass, have been compared at the same bombarding energy. An illustration of the bombardment process is shown in Figure 32.1. Here, an SF_5 projectile impacts a monolayer of biphenyl molecules on a silicon substrate [Townes et al., 1999]. The energetic particle strikes the surface and dissipates its kinetic energy through the solid. Collision cascades develop, and molecules are lifted from the surface into the vacuum by the underlying substrate atoms.

32.4.1 The Methodology of Molecular Dynamics Simulations

A microcrystallite composed of N atoms is constructed that models the experimental system of interest. The nuclear motions of the atoms are assumed to obey the laws of classical mechanics:

$$\mathbf{F}_i = m_i \mathbf{a}_i = m_i \frac{d^2 \mathbf{r}_i}{dt^2} \text{ which can be expressed as } \frac{d\mathbf{v}_i}{dt} = \frac{\mathbf{F}_i}{m} \text{ and } \frac{d\mathbf{r}_i}{dt} = \mathbf{v}_i \quad (32.1)$$

The force is obtained as the gradient of the **potential energy function** that describes the interactions between the atoms in the system:

$$\mathbf{F}_i = -\nabla V(\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_N) \quad (32.2)$$

After the initial positions and velocities are chosen, Hamilton's equations of motion are numerically integrated to determine the position and velocity of each atom as a function of time. From the final positions and velocities of the atoms, the identity and kinetic energy of all ejected species can be calculated. Additionally, the atomic motions leading to the ejection of the molecule can be analyzed [Garrison et al., 2000; Garrison, 2001].

A limitation of MD is that atoms are assumed to obey the laws of classical mechanics. Therefore, quantum effects such as electronic excitation and ionization are not included. The questions that one is hoping to answer should be chosen so that quantum mechanical effects are not essential. Furthermore, it should be kept in mind how the assumption of classical behavior may affect the results [Garrison et al., 2000; Garrison, 2001].

The chemical interactions between atoms are modeled by potential energy functions that describe how the energy depends on their relative positions. Ideally, the potential energy function would be the solution to the electronic Schrödinger equation within the **Born–Oppenheimer approximation**. However, such a solution is not possible in simulations with thousands of atoms. Instead, a suitable mathematical function that models the physical behavior is used. Parameters in the equation are fit to available experimental data [Garrison et al., 2000; Garrison, 2001].

FIGURE 32.1 Collision cascade and ejection occurring for SF₅ bombardment of a monolayer of biphenyl molecules on Si{100}-(2x1). The Si atoms are represented by silver spheres, the carbon and hydrogen atoms are represented by dark gray spheres, and the S and F atoms are represented by black spheres. (a) An early snapshot in time that shows the SF₅ projectile as it moves toward the surface. (b) At 150 fs, the SF₅ projectile has penetrated into the open lattice and has broken up within the substrate. In this frame, the radii of the silicon spheres are drawn smaller so that the projectile can be seen within the substrate. (c) At 1500 fs, collision cascades initiated by the breakup of the projectile within the surface lead to the ejection of biphenyl molecules and molecular fragments.

Initially, the only available potential energy functions were **pair potentials** that depend on the distance between two atoms, such as the **Morse potential** and the **Lennard–Jones potential**. The total potential energy is calculated as a sum of the pairwise potential between each pair of atoms in the system. The **pairwise additive assumption** cannot take into account the effect of neighboring atoms. Therefore, this approach is not successful for modeling extended solids. Pairwise potentials are especially limited for chemistry applications, because they cannot accurately describe polyatomic molecules. For example, the pairwise additive approach would predict that H₃ is more stable than H₂ [Garrison, 2001]. The potential energy between each pair of atoms in a molecule depends on the coordination number of the central atom, the bond angle, and the torsion angle. In order to model chemical reactions, changes in hybridization must also be taken into account.

In the last decade, a great stride in these simulations was taken with the development of **many-body potentials** that include the effect of neighboring atoms on the interaction between a pair of atoms [Garrison et al., 2000; Garrison, 2001]. This development produced accurate potential energy functions for modeling face-centered cubic metals and silicon. Of particular interest to chemists is Brenner’s reactive empirical bond-order (REBO) potential [Brenner, 1990], which varies the bond strength depending on

the coordination number, bond angles, and **conjugation** effects. This potential is able to model bond breaking and formation because atoms may change neighbors and their hybridization state. These sophisticated many-body potentials are blended with empirical pairwise potentials to model keV bombardment of organic films on metal surfaces [Garrison et al., 2000; Zaric et al., 1998; Townes et al., 1999; Nguyen et al., 2000; Garrison, 2001].

A limitation of the Brenner REBO potential is that it cannot describe long-range interactions between molecules. Recently, Stuart et al. have developed a reactive potential for hydrocarbons that includes both **covalent** bonds and intermolecular interactions [Stuart et al., 2000]. The adaptive intermolecular REBO (AIREBO) potential introduces nonbonded interactions through an adaptive treatment, which allows the reactivity of the REBO potential to be maintained. A possible problem with the introduction of intermolecular interactions is that the repulsive barrier between nonbonded atoms may prevent chemical reactions from taking place. The AIREBO potential corrects for this problem by modifying the strength of the intermolecular forces between pairs of atoms, depending on their local environment. For example, the interaction between two fully **saturated** methane molecules will be unmodified, producing a large barrier to reaction. The carbon atoms in two neighboring methyl **radicals**, on the other hand, will have a repulsive interaction that is diminished, or even completely absent, allowing them to react.

32.4.2 Applications of MD Simulations

MD simulations of the high-energy bombardment of organic films on atomic substrates with atomic and polyatomic projectiles have led to interesting insights about the mechanisms by which polyatomic projectiles enhance the ejection yield [Garrison et al., 2000; Zaric et al., 1998; Townes et al., 1999; Nguyen et al., 2000]. The simulations also have contributed information about the optimum conditions for the effectiveness of polyatomic projectiles. As a result of the simulations, three factors have been identified as important to the enhancement in yield with polyatomic projectiles:

- Collaborating collision cascades
- Open lattice structure of the substrate
- Mass matching

First, molecules that have multiple contact points to the surface are ejected intact when several substrate atoms hit different parts of the molecule from below. Polyatomic projectiles enhance the emission yield by increasing the probability of adjacent collision cascades in the substrate, which can collaborate to lift the molecule gently from the surface, as shown in [Figure 32.2](#).

Second, the nature of the substrate is a critical factor in the effectiveness of polyatomic projectiles [Townes et al., 1999; Nguyen et al., 2000]. The enhancement in yield is greater on a substrate with a more open lattice structure, such as silicon, than on a more closely packed substrate, such as copper. When SF₅ bombards an organic layer on copper, a densely packed solid, the polyatomic projectile breaks apart as it hits the surface and is reflected toward the vacuum. With the silicon substrate, on the other hand, the entire SF₅ projectile is able to penetrate the surface and break apart within the substrate, as shown in [Figure 32.1](#). The breakup of the cluster within the lattice initiates upward-moving collision cascades that work together to lift intact molecules from the surface.

Third, polyatomic projectiles are most effective when there is mass matching between the atoms in the projectile and the atoms in the target solid [Townes et al., 1999; Nguyen et al., 2000]. When the mass of the atom (or atoms) of the projectile is much larger than the mass of the substrate atoms, the projectile passes through the solid without transferring much energy to the atoms in the top surface layers. When the projectile atom (or atoms) has much less mass than the substrate atoms, the projectile reflects from the surface, retaining much of its initial kinetic energy.

32.4.3 Concluding Comments on MD Simulations

The mechanistic insights obtained from MD simulations are significant for the further development of SIMS as an analytical tool. The simulations predict that the greatest enhancements with polyatomic

FIGURE 32.2 Schematic diagram illustrating the mechanism for the ejection of a biphenyl molecule with a diatomic projectile at 0.200 keV or 0.100 keV per atom. The incoming cluster atoms are black, and the biphenyl molecule is shaded gray. As atoms become part of the collision sequence leading to ejection of the molecule, they are shaded a darker gray. The two atoms in the dimer act collaboratively to initiate two adjacent collision cascades that lead to hitting carbon atoms in each ring of the molecule. (a) 45 fs, top view. (b) 63 fs, top view. (c) 84 fs, top view. (d) 104 fs, top view.

projectiles such as SF_5^+ and C_{60}^+ will be on organic solids, which have an open-lattice structure and are composed of light atoms. The development of focused polyatomic ion beams would have a significant impact on molecular specific imaging experiments, for which sensitivity is presently the limiting factor [Berry et al., 2001]. With the recent development of the AIREBO potential, the next challenge is to perform MD simulations of the high-energy bombardment of molecular solids, in which both short-range intramolecular forces and long-range intermolecular forces are present.

32.5 Modeling Organic Compounds

Organic chemistry encompasses all aspects of carbon-containing compounds, including the study of their chemical and physical properties, reactions, synthesis, and various uses. Organic chemistry is the foundation of biochemistry, polymer chemistry, materials science, medicinal chemistry, colorants, fragrances, the pulp and paper industry, and many other areas. The history of organic chemistry has been relatively brief: its formal beginnings were in 1826, with Friedrich Wöhler's preparation of urea that debunked the hypothesis of a **vital force**. Since that time, the use of models has been fundamental to the field. Organic chemistry is driven largely by the modeling tools that organic chemists use. Computational chemistry is currently one of the most powerful, and most rapidly developing, of those tools.

Two key models for chemical bonding guide the work of organic chemists: **valence bond theory** and molecular orbital theory. Organic computational chemistry is founded in both theories. Organic chemists use computational chemistry as a tool to solve three general types of problems:

- Predicting or rationalizing chemical or physical properties
- Predicting or rationalizing the stabilities of compounds
- Predicting or rationalizing the reactions of compounds

The computational software used by particular organic chemists depends on personal preferences and abilities, and it varies in robustness and hardware availability. There are many sources — some free — for computational chemistry software. Because not all software packages use exactly the same programs or parameters, the publisher of the software and the specific program(s) used for each research project must

be stated in any publications on that project. Generally, the hardware is less of a significant limiting factor (although the hardware can determine the speed of the calculation) and often is not mentioned in the publication.

The front end of most computational chemistry software is now so automated and polished that its effective use in computational chemistry is as simple as the following procedure:

Draw a 2-D structure of a molecule

Select a computational method from a drop-down menu of listed options (which can include **empirical**, **semiempirical**, and **DFT/ab initio** methods)

Wait for the computer to generate an output file, consisting of a three-dimensional structural representation, maps of potential energy surfaces, and a listing of computed values

Look over the output to see what it reveals

The computational time depends on both the computer and the complexity of the computation. For example, on a robust desktop PC, a moderately sized organic compound with 20 to 40 atoms might take less than a minute to compute using an empirical method, several minutes to an hour with a semiempirical method, and a week or more for a DFT/*ab initio* process. Unless the chemist is a specialist in computation, most of the personnel time is spent on the correct selection of the computational method to be performed (definition of the model), and then on the analysis of the output. End users are indebted to those computational chemists who have pioneered these techniques and made the tools of computational chemistry available to all chemists. For example, Professor Norman L. Allinger at the University of Georgia led a group that developed MM3, one of the more popular methods currently in use [Allinger et al., 1989].

32.5.1 Empirical Solutions

For many organic chemists, empirical methods, known collectively as **molecular mechanics** (MM) routines or *force-field methods*, are the easiest, fastest, and most generally used computational tools. This is not surprising, because these programs were originally designed for application to organic compounds. Conceptually, these methods fit easily into the historical development of valence bonding theory, and they are rooted mathematically in expressions of Hooke's law. By summing the energies of all bonded atoms, an estimate of the relative energy of the entire structure is derived. The force-field methods are, in a sense, mathematical extensions of valence bond theory's physical constructs of bonds and molecules, which contributed to early discoveries such as the alpha helix and **conformations** of cyclic and acyclic structures.

In practice, the proper selection of both the force-field routine and the parameter sets used for the class of compound being evaluated is crucial to getting a reliable result. Most bench chemists use an unmodified parameter set provided with the software. An empirical program will typically evolve over several years. The identities of these programs may be designated by year (e.g., MM3[92] or MM3[96]), by special characters (e.g., MM2*), or by a generic description of change (e.g., MM2 augmented). A problem with any computational result, but especially with an empirical calculation, is that the result occurs even if it has no practical validity. Thus, the user must know the limitations of the method and verify the reliability of any calculation.

Despite this limitation, the development of force-field programs over the years has created an ability to model reliably many classes of organic compounds, making these programs the first choice of many chemists. The basic set of equations used to model an organic compound computationally partitions and sums the contribution of the several factors to total energy. Those factors are related to the mass of the atoms in the molecule, the known preferences for bond angles and bond lengths between those atoms, **van der Waals forces** between atoms, interaction of bonds with dihedral relationships, and electrostatic interactions between atoms. In one commercially available software package, CAChe, the MM3 augmented routine includes bond stretch, bond angle, dihedral angle, improper **torsion**, torsion stretch, bend bend, van der Waals forces, electrostatics, and hydrogen bond terms. In comparison, the augmented MM2 routine in the same package does not include the bend bend interaction.

Parameters developed to describe a term in one force field are not necessarily useful in other force fields to describe the same term. It takes significant effort to develop and validate new parameters when a new routine is developed to solve a new problem or when an existing force field is modified to deal more effectively with a new functional group [Woods et al., 1992; Todebush et al., 2002]. In most MM programs, the molecule is modeled without molecular solvent or other interacting molecules, effectively modeling the preferences of a compound as a gas. Because organic chemistry is often performed in the solid state or solution phase, the influences of these states must be considered separately. As previously mentioned, the major limitation of MM methods is that they do not describe electronic properties of molecules.

Case Study

To illustrate the use of computational tools, we review the application of molecular mechanics in the development of the synthesis of a vasopressin receptor antagonist, SR 121463 A, as presented in [Venkatesan et al., 2001].

A key step in this synthesis involves the stereoselective reduction of a ketone, which results in the formation of two different alcohol products, designated **syn** and **anti** isomers. (The *syn/anti* nomenclature describes the relative position of the alcohol to the amide carbonyl in the product.) While reduction with a commonly employed reagent (LiAlH_4) gives acceptable initial results (4:1 *syn:anti*), Venkatesan et al. sought improved selectivity. They wanted to avoid loss of product by minimizing the amount of the anti product formed. They also wanted to reduce the effort needed to separate the *syn* from the anti alcohol.

The researchers used MM routines in MacroModel, a software package that allows for incorporation of solvent effects by means of a continuum model. They demonstrated computationally that, in the preferred conformation for the *syn* alcohol in solution, the alcohol was in an **equatorial** position. (This position is preferred over an alternative structure with the alcohol in the **axial** position by 2.0 kcal/mol using MM3*, by 1.1 kcal/mol using MMFF and, as determined for comparative purposes here, by 1.5 kcal/mol using MM3 in CAChe without solvent parameterization). This was in agreement with known general stabilities for equatorial and axial alcohols. However, upon examination of a solid state X-ray structure of the *syn* alcohol, it was clear that the alcohol in the *syn* compound was axial. The researchers rationalized that the rather small energy preference for the equatorial alcohol in the *syn* compound was easily outweighed in the solid state by the increased stabilization from intermolecular hydrogen bonding in the solid state when the alcohol was axial.

To explain the increased preference for production of the *syn* alcohol when using lithium cation-derived reagents (as opposed to sodium cation reagents, which gave *syn:anti* product ratios of only 3:1), the starting material was modeled when complexed with a cationic replacement (ammonium ion) for the lithium cation (because the parameters for Li atom were not in the programs used). If the cation is coordinated to both the ketone and the amide carbonyls, the modeled minimum energy structure adopts a **twist boat conformation**, which is only 2.7 kcal/mol higher in energy than the normally expected **chair** structure. If the compound were to react exclusively from the di-coordinated twist boat structure, then the expected product would be the *syn* alcohol. They also determined that the barrier for conversion from the chair to the twist boat (which requires adoption of a higher energy structure, known as a **half chair** conformer) was only 4.0 kcal/mol. This represents a significant increase in the stability of the twist boat structure compared to the normally more stable chair structure. In the absence of other influences, the chair form is generally 5.5 kcal/mol more stable and the barrier for interconversion (via the half chair) is about 10 kcal/mol. While this does not entirely account for the increased preference for forming the *syn* alcohol as one varies the reducing reagent from NaBH_4 to LiAlH_4 to L-selectride (which gave a 66:1 *syn:anti* preference), it aids in understanding the process, which is important if this process of stereoselective reduction is to be extended to use in other systems.

32.5.2 Semiempirical Methods

Organic chemists often use more complex methods than empirical force-field methods in order to accurately predict chemical process, especially if the nature of the electronic interactions is a controlling factor. In computational organic chemistry, molecular orbital theory provides an effective methodology. On a simple level, many problems can be evaluated by taking into consideration only the electrons most intimately involved in a chemical process. Semiempirical methods do this, by applying approximations based on empirically derived data to the **Hamiltonian** equations used to model the compound.

For example, an estimate of electronic transitions in ultraviolet-visible spectrophotometric measurements is modeled and understood by looking at the **frontier molecular orbitals** (FMO) of the **pi** system undergoing a transition, rather than including all electrons in the molecule (nonbonded and **sigma** bonded). A semiempirical method, such as **ZINDO**, is often used for this purpose. Other semiempirical methods make different approximations to simplify the computational task, and their approximations are included as look-up parameters from experimentally determined data. Three that are commonly found in software packages are the modified neglect of diatomic overlap (MNDO), the Austin models (AM1, AM3), and the third parametrization of the MNDO model (PM3). The best strategy for selecting a semiempirical method is often simply to use the one that comes closest to fitting the experimental truth.

Although FMO had been used qualitatively for many years by organic chemists to rationalize chemical reactions [Fleming, 1976], the semiempirical methods, which may or may not provide accurate quantitative results, often fail even at a qualitative level.

32.5.3 *Ab Initio* Methods

The most robust computational methods employ full quantum mechanical methods. Even here, approximations are made, but they are minor compared to semiempirical methods. Such methods are often referred to as *ab initio* calculations, because they derive the energy of the molecule entirely from its native collected electrons.

There are different ways to perform *ab initio* calculations, allowing the electrons to express differing degrees of sophistication and freedom. It is possible to include all electrons, or to consider only the valence electrons, treating the nonvalence electrons as the so-called *frozen core*. Borden and Davidson elucidate the need to include all electrons with full electron correlation in complex computational chemistry problems [Borden and Davidson, 1996]. Although they take more time and employ more sophisticated calculations based on application of the Schrödinger equation, these *ab initio* methods (and DFT-type *ab initio* calculations) are required to evaluate **transition states of pericyclic processes**, chemistry of the **excited state**, and studies on radical structures or processes that have potential radical intermediates. Problems that must be addressed by DFT/*ab initio* methods are generally evaluated in stages: using empirical methods to get an initial structure, using semiempirical methods to get a refined structure, then crunching out the DFT/*ab initio* calculations.

Case Study

Here, we summarize the use of DFT methods to ascribe the stable conformers of a set of similar molecules, each of which undergoes an intramolecular **Diels–Alder** reaction, and then to ascertain the transition states of the Diels–Alder reactions [Bur et al., 2002].

Bur et al. set out to determine why four seemingly similar molecules required such vastly different experimental conditions to undergo an intramolecular Diels–Alder reaction. In the first part of the analysis, they identified a problem in the use of empirical methods (MM2* or MMFF using MacroModel7.0) for determining of the lowest energy conformation of the starting materials. They employed Monte Carlo searching in conjunction with applied force fields to identify the lowest energy structures. However, the lowest energy output placed two hydrogen atoms too close to each other in the molecule (in one case at a distance of only 2.40 Å, which implies contact between the two).

To resolve this issue, the researchers employed DFT calculations with **B3LYP/3-21G* basis sets** using Gaussian 98, followed by further refinement using 6-31G* to obtain stable conformers that had reasonable interatomic distances. They then used a 6-31G* basis set to model the Diels–Alder transition states and found that the results were qualitatively useful (the compounds requiring external heat in excess of 100°C to bring about a reaction also had computed activation energies of about 4.7 kcal/mol over the reactions known to occur at room temperature). However, the authors recognized that the results were not quantitative. By comparing the calculated activation energies for the two slower reactions (requiring heating to 145°C or 110°C, respectively), they saw that the energy difference of the transition states, only 0.3 kcal/mol, could not explain the temperature differences needed to bring about reaction.

Recognizing that the difference in transition state energy alone would not account for the observed discrepancy in the reactivities of the systems, they reexamined the conformational profiles of the starting materials for other factors. They identified two computationally modeled factors for the conformations of the reactants that corresponded to the reaction rates. The first was the influence of the carbonyl linkage (present only in the faster-reacting compound) between the 2- π electron system and the 4- π electron system, which resulted, as one might expect, in a more favorable alignment in the structure. The second accelerating feature was a preferential rotation about the C–N bond in the linkage that again favored a conformation of prealignment between the 2- π and 4- π systems in the faster-reacting materials.

Computational analysis is now central to the practice of organic chemistry (as spectroscopic analysis had become in the middle of the 20th century). The importance of computational chemistry for organic chemists is likely to increase as they find more useful tools for predicting and rationalizing chemical processes — and as computational chemists continue to advance and refine their science.

32.6 Computational Organometallic and Inorganic Chemistry

The application of modern computational techniques to inorganic and organometallic chemistry has truly undergone a renaissance during the past decade. Stoichiometric and catalytic metal reactions have attracted great interest for their many applications in industrial and synthetic processes. Metal reactions are critical in many thermodynamically feasible processes, because they accelerate the reaction by opening a lower **activation energy** pathway. These metal-centered reactions consist of one or more elementary reactions, such as substitution, oxidative addition, reductive elimination, migratory insertion, hydrogen exchange, β -hydrogen transfer, σ -bond **metathesis**, and **nucleophilic** addition.

However, unlike organic compounds, inorganic compounds are unsuited to the application of empirical molecular mechanics calculations. As mentioned in the case study in [Section 32.4.1](#), parameters for many of the most common elements (e.g., Li) are not included in these programs, and the terms used were not developed to handle issues relevant to inorganic compounds (e.g., expanded octets, multiple stable valences, etc.).

Recent progress in computational chemistry has shown that many important chemical and physical properties of the species involved in these reactions can be predicted. Calculated values, such as predicted geometries, **vibrational frequencies**, bond dissociation energies, and other chemically important properties, have become reliable enough to complement and sometimes even challenge experimental data, especially in those cases in which experimental results are difficult to obtain. The most challenging aspect of this area has undoubtedly been to model the **metallic** elements reliably and efficiently. Metals, particularly the **d-** and **f-block elements**, typically present three main challenges for modeling:

The large number of orbitals, many of which are core orbitals

The **electron correlation** problem, which is accentuated by the presence of low-energy excited states

Relativistic effects for the heaviest metals

32.6.1 Semiempirical Methods

A range of quantum chemical methodologies can be used to study inorganic and organometallic compounds. The semiempirical quantum mechanics methods have great latitude in the number and type of approximations made to the full Schrödinger equation that involve the replacement of quantities that are difficult to determine with experimental or theoretical estimates or the removal of interactions, like electron interactions, which are thought to be of lesser importance. The trade-off for such approximate methods is accuracy vs. computational efficiency. For many inorganic or organometallic materials, the sacrifice of accuracy for speed is problematic because of the challenges listed previously.

The use or extension of approximate semiempirical methods necessitates a parameterization phase. Here, it is necessary to determine those parameters that maintain computational efficiency, while maximizing the model's descriptive and predictive power. Ideally, the parameterization process should incorporate the full range of motifs that characterize a chemical family. Therefore, one major issue for parameterizing metal-containing compounds is the development of a robust parameterization to handle a diverse set of influences. Such chemical diversity may be defined as the ability of metals to stabilize distinct bonding environments involving different bond types, bound-atom types, **spin** and **formal oxidation** states, **coordination numbers**, and geometries. For these reasons, it is difficult to use semiempirical methods when the calculations involve metal atoms.

32.6.2 *Ab Initio* Methods

At the other end of quantum chemical methodology spectrum lie *ab initio* methods. These techniques employ computations derived from theoretical principles without inclusion of experimental data. While *ab initio* methods such as **Hartree–Fock** (HF) and **Møller–Plesset** (MP2) have been utilized extensively for organic compounds, their application to metal-containing systems is limited. Results from such calculations involving metals have been more-or-less useless: bond lengths were wrong by tenths of angstroms, the relative energies of **isomers** were often wrong, and the relative energies of possible spin multiplicities were wrong, to name a few instances. For organometallic compounds, the primary problem with application of *ab initio* methods was founded in the change in the error with bond length that exceeds the change in the actual energy. This swamped other errors that result from use of simplified models for complicated **ligands**, neglect of the solvent, and neglect of relativistic corrections.

However, two techniques have been developed to deal with these challenges: quasi-relativistic **effective core potentials** (ECP) (also commonly referred to as *pseudopotentials*) and **density functional theory** (DFT). There is general agreement that DFT methods are superior to classical *ab initio* methods at the HF and MP2 levels for the calculation of metal compounds. This is because the accuracy of the DFT results is similar to, or in some cases even better than, MP2 data, and the computational time costs are significantly less. DFT combined with ECPs are now considered the standard operating procedure for handling inorganic and organometallic compounds. Indeed, computational inorganic and organometallic chemistry is almost synonymous with DFT for medium-sized molecules. This is due in part to computational improvements but also, perhaps more importantly, to the inclusion of these techniques in powerful, yet relatively user-friendly computational chemistry packages, such as Gaussian, Spartan, Jaguar, GAMESS, MOLPRO, CAChe, Hyperchem and ADF.

Powerful DFT methods incorporating ECPs allow many topics of interest to inorganic and organometallic chemists to be studied. A significant body of literature has been produced concerning theoretical studies of **transition metal**-catalyzed chemical reactions including industrially relevant processes, such as Ziegler–Natta polymerization, copolymerization, hydroformylation, and the water–gas shift reaction [Torrent et al., 2000]. Other catalytic systems studied include hydrogenation, epoxidation, dihydroxylation, and thio-oration [Torrent et al., 2000]. It remains to be seen whether there is a catalytic system unamenable to computational study, such as **heterogeneous** catalysts, for which it is difficult to characterize intermediates experimentally.

Another topic of interest to inorganic and organometallic chemists is the nature of bonding. Included in bonding studies is the multiple bonding to ligands and other metals, both transition and main group

[Frenking and Fröhlich, 2000; Cundari, 2000]. The aim of most theoretical investigations of the chemical bond is to find a correlation between the chemical behavior of a molecule or its physical observables and calculated data, such as charge distribution or orbital structure. When including metals in theoretical models, a considerable problem is understanding the energetic contributions to the chemical bonds in terms of what the electrons are doing. Much progress has been made in understanding the nature of bonding to metals, and the future of this area is robust with possibilities.

The advent of faster computers and better algorithms has made possible new areas of theoretical work with metals. Until recently, there has been a paucity of work with **actinide** complexes, undoubtedly due to the experimental and computational difficulties in handling these elements. In addition to the problems mentioned earlier, the application of theoretical electronic structure methods to actinide complexes has long been deterred by several well known challenges. The ability to accommodate f orbitals with computational efficiency; the incorporation of a larger number of valence electrons; dynamic electron correlation effects; the large number of low-lying, near-degenerate states; the severe relativistic effects caused by the large atomic numbers of the actinides; and the overall large size of actinide complexes place extremely high demands on the choice of suitable basis sets, efficient numerical algorithms, and computational resources.

With DFT methods, actinide complexes are no longer ignored [Li and Bursten, 2001]. DFT methodology allows experimentally important properties (such as the geometry, vibrational frequencies, and infrared absorption intensities) to be calculated, even for large actinide systems. Many aspects of actinide chemistry are experimentally challenging, so reliable theoretical calculations provide a valuable adjunct to experimental studies and can provide theoretical interpretations of experimental results.

Accurate quantum chemical treatment of transition metal complexes in biochemical systems is a relatively new area [Siegbahn and Blomberg, 2000]. With each passing discovery of an important metalloenzyme or metal-mediated biological process, the ability to predict *in vivo* function of metals in biological systems is becoming increasingly important. There are two striking differences in the application of computational chemistry to biological systems, in contrast with other chemical systems such as **homogeneous** catalysis. The first difference is that the overall chemistry that affects biochemical complexes is considerably more complicated than in a typical catalytic cycle of a laboratory process. The second difference is that the amount of experimental information on biochemical systems is immense. Often, decades of experimental investigations are done by researchers focusing on only one system. To make significant contributions, the large amount of biochemical information must be put in the context of a quantum chemical modeling, which is not a trivial matter.

As with inorganic and organometallic systems, metal-containing biological systems must be studied with methods that incorporate correlation (e.g., DFT), because significant errors occur in **thermodynamic** properties, which are at least an order of magnitude larger. It is safe to predict that almost all future studies of biological transition metal systems will be accomplished using more accurate methods, such as gradient-corrected DFT. Systems that have been treated quantum-mechanically include accurate geometric determinations of the metal binding site in blue copper proteins, mechanisms of methane monooxygenase, and water oxidation in photosystem II. The number of applications is still not large, but this area will grow rapidly in the future. It is increasingly common in the computational study of large biological systems to use hyphenated methodologies, such as QM-MM. Quantum mechanical (QM) methods are employed to study the inner working of the active site or the metal center of the metalloprotein (where electron correlations are of paramount importance); empirical methods (MM) are used to define the carbon skeleton scaffolding that comprises the bulk of the system. The interface of the quantum mechanical region and the empirical region of the system is difficult, and discussion of how to address that problem is treated elsewhere [Carloni et al., 2002; Monard and Merz, 1999].

Finally, while recent work has focused on the use of DFT, it must be noted that such methods do not solve all problems. The magnetism and spin states of multimetal clusters and solids are not well determined by DFT; these are most easily described by an empirical Heisenberg Hamiltonian. Detailed potential curves and states of very small molecules to spectroscopic accuracy require configuration interaction (CI) methods. Solvent effects on spectra remain a difficult problem as well. While DFT certainly has revolutionized inorganic and organometallic computational chemistry, it is not a panacea for all problems

facing the discipline. However, the growth and development of computational inorganic chemistry has been unprecedented over the past decade and will likely continue to expand in coming years.

32.7 Use of *Ab Initio* Methods in Spectroscopic Analysis

It is now possible to carry out molecular orbital *ab initio* calculations on a reasonably complex molecular structure. These calculations can yield details on a number of important molecular properties, such as the following:

- Geometry in ground and excited states
- Atomic charge and dipole moment
- Molecular energy
- Conformational stability and structure of macromolecules and biomolecules
- Vibrational frequencies
- Infrared intensities
- Raman** activities
- Electrostatic potential energy
- Force constants
- Dynamics of molecular collision
- Rate constants of elementary reaction
- Simulation of molecular motions
- Thermodynamic properties

The challenge here is determining how to obtain this information and what tools are needed to do so. As previously noted, much *ab initio* computational chemistry is based on the Schrödinger equation, $H\Psi = E\Psi$, developed in 1926 by the Austrian mathematician and physicist Erwin Schrödinger. This is a single equation, whose solution is the wave function for the system under consideration and describes the spatial motion of all particles of the molecular system. In order for the equation to work, the wave function must satisfy certain properties. Unfortunately, the exact solution of this equation can be used to calculate the energy of only a single atom: the one-electron hydrogen atom. Exact solutions are not possible for even the two-electron helium atom, or for any other elements or compounds. Still, the Schrödinger equation is utilized for larger systems consisting of many interacting electrons and nuclei. To do this, a number of mathematical methods that use approximation techniques such as the **variational** theorem, self-consistent field theory (Hartree–Fock approximation), and **linear combination of atomic orbitals** (LCAO) are applied to solve this equation and to describe the atomic and molecular structures.

32.7.1 Hartree–Fock Approximation

The central difficulty in solving the Schrödinger equation is dealing with electron–electron interactions. The energy of a particular electron depends on the electric field generated by the nuclei of the elements and all the other electrons in the system. According to the **variational principle**, we can approach an accurate solution of many electron wave functions once a set of adjustable coefficients is used with each orbital to minimize the total energy of the system. All the contributing one-electron functions are then varied until the energy obtained is at its lowest value. Such orbitals are referred to as *self-consistent field* or **Hartree–Fock** molecular orbitals.

The advantage of this method is that it allows us to interpret the molecular properties as derived from those of the constituent atoms. Further, this method assumes that the electrons are moving in an environment that is an average potential of the other electrons. Thus, the instantaneous position of an electron is not influenced by the presence of neighboring electrons. It should be noted that the HF approach fails to take into consideration the Pauli exclusion principle that two electrons cannot have the same quantum numbers, so HF does not account for electron–electron repulsion. Several methods are used to represent this electron correlation, as mentioned in the following section.

32.7.2 Electron Correlations

The correlation of electrons is crucial in studying the optimization of structural parameters, energies of conformational stabilities, and vibrational frequencies, each of which is essential to spectroscopic analysis. In HF calculations, as mentioned earlier, every electron is affected by the average of the other electrons in the atoms but is insensitive to any individual electron–electron interaction. Several electron correlation methods are used, such as Møller–Plesset to the n th order of correlations (MP n), configuration interaction (CI), multiconfigurational self-consistent field (MCSCF), generalized valence bond theory (GVB), and coupled cluster theory (CC). Including correlation functions in the calculations results in more accurate computational energies and structural parameters.

32.7.3 Gaussian Basis Functions

In 1930, Slater defined a particular set of functions associated with the molecular configuration. This set, which depends only on the nuclear charge, results in what are known as Slater-type atomic orbitals (STO), which have exponential radial components represented as $e^{-\xi r}$. Slater functions are of limited use because such integrals must be solved by numerical methods and are not well suited to numerical calculations in molecular systems. In 1950, a suggestion was made by S.F. Boys that the atomic orbitals should be expressed in terms of Gaussian-type orbitals (GTOs), in which the exponential radial parts are represented as $e^{-\alpha r^2}$, instead of $e^{-\xi r}$ as in Slater-type atomic orbitals. The exponential terms ξ and α are constants that determine the size of the orbital.

The advantage to using GTOs is that they do not require numerical integration, and the product of two Gaussian functions is another Gaussian function. The disadvantage to using Gaussians is that the atomic orbital is not well represented by a simple Gaussian function but by a sum of several Gaussian functions. That is, a Gaussian function decays too slowly and thus lacks a cusp at the origin, as is required by STO representations. (See [Figure 32.3](#)). Although fast, modern computers make the use of multiple Gaussian functions feasible, there is still some debate over the intrinsic value of using multiple Gaussians. One school of thought holds that increasing the number of basis functions will improve the model for the calculation of structural parameters. Others believe, however, that this will not improve the model but give rise to erroneous results.

In any event, the basis functions for multiple Gaussians are further modified by adding polarization and diffusion functions for hydrogen and heavy atoms. The choice of basis set affects the computation time to perform the calculation to the order N^4 , where N is the number of basis functions. The smallest basis set used in the calculations is called the *minimal basis set*, for example, STO-3G. Despite this cost in computational time, polarization functions are still used because they often produce more accurately computed geometries and frequencies.

32.7.4 Notation

In the literature, there are two popular types of basis sets: designated STO- n G and the Pople or split valence set. The latter is designated a-bcG, where n , a , b , and c correspond to number of Gaussian functions used to form each Slater-type orbital. In STO-3G set, the 3 corresponds to the use of three Gaussian functions to mimic Slater orbitals; STO-4G indicates that four Gaussian functions are used, and so on. In split valence sets, such as 3-21G (which is the minimal basis set in this family), three primitive Gaussian functions are used to describe the core shell (nonvalence orbital). The valence shell is described by the linear combination of two primitive Gaussian functions and one primitive Gaussian function, so that a total of six GTOs are utilized to mimic the Slater-type orbital. In 6-31G, the core orbital is represented by six primitive Gaussian functions, and the valence shell is described by two functions that are linearly combined: one with three primitive Gaussian functions and the other with one.

As stated, these two basis sets (3-21G and 6-31G) do not allow for the polarization of the orbitals. This means that the electrons are not allowed to occupy orbitals other than those they would occupy based

FIGURE 32.3 Representation of Slater-type orbital (heavy solid line) using various Gaussian-type orbitals.

on standard electron configuration principles. Polarization allows orbitals to change shape (e.g., from a spherically symmetrical s shape to a dumbbell p shape), and this is an important feature of orbitals that can be achieved by applying a polarization function to the basis set. This is designated by adding one or two asterisks to the basis set: for example, 6-31G* or 6-31G**. The polarization functions give the **wave function** flexibility to change its shape by adding another set of primitives. Polarization functions are crucial in the computation of structural parameters and vibrational frequencies. In the first case (6-31G* or 3-21G*), the single asterisk means that the basis set has a polarization function on the heavy atoms or nonhydrogen atoms in the molecule. Addition of a second asterisk (6-31G** or 3-21G**) indicates the use of a polarization function for the hydrogen atoms, so that polarization of all orbitals is manifest. A diffusion function can also be added to the basis set, indicated by a plus sign (as in 6-31⁺G and 6-31⁺⁺G). This is important for calculations involving **anions**. A single plus sign indicates that the diffusion function has been added to the heavy atoms (nonhydrogen atoms); adding two plus signs indicates that the diffusion function is added to all atoms.

32.7.5 Vibrational State and Spectra

In order to carry out the quantum mechanical treatment of molecular vibration, it is necessary to introduce a new set of coordinates, Q_k , $k = 1, 2, 3 \dots 3N$, called *normal coordinates*. Each normal mode of vibration can be characterized by a single normal coordinate Q , which varies periodically. A given normal coordinate is a measure of the amplitude of a specific normal mode of vibration. The energy levels of a harmonic oscillator are given by the expression $W = (\nu + \frac{1}{2})h\nu$, where ν is the quantum number, ν is the classical frequency of the system, and h is Planck's constant. Consequently, the vibrational energy of the molecule

with several classical frequencies ν_k is described as shown in Equation 32.3.

$$W = \left(\nu_1 + \frac{1}{2}\right)h\nu_1 + \left(\nu_2 + \frac{1}{2}\right)h\nu_2 + \cdots + \left(\nu_{3N-6} + \frac{1}{2}\right)h\nu_{3N-6} \quad (32.3)$$

In other words, every frequency coordinate Q_k has associated with it a quantum number ν_k and a normal frequency ν_k , which is the classical normal frequency of vibration.

In order to obtain a more complete description of the molecular motions involved in the normal modes of a molecule, a normal coordinate analysis is performed. The force field in Cartesian coordinates can be obtained by the Gaussian program from the calculations of Hartree–Fock or Møller–Plesset perturbation level of theory utilizing any basis set. The force constants that result from the *ab initio* calculations are then used to obtain the vibrational frequencies for infrared intensities and Raman activities. Initially, a scaling factor of 1.0 is applied to produce the pure *ab initio* calculated frequencies, called *unscaled frequencies*. Since they are the result of *ab initio* calculations, the predicted frequency is always higher than the observed frequency (in accordance with the variational principle). To compensate, scaling factors of 0.88 for the CH stretches, 0.9 for the CH bends and heavy atom stretches, and 1.0 for all the other modes, such as torsional modes (rotation about single bonds), are used to calculate the scaled frequencies and the potential energy distributions.

The calculated Raman spectra are simulated from the *ab initio* calculations to generate scaled predicted frequencies and Raman scattering activities. The Raman scattering cross section, $\partial_j/\partial\Omega$, which is proportional to the Raman intensity, can be calculated from the scattering activities and the predicted frequencies for each normal mode [Amos, 1986; Polavarapu, 1990]. To obtain the polarized Raman scattering cross sections, the polarizabilities are incorporated into S_j by $S_j [(1 - \rho_j)/(1 + \rho_j)]$, where ρ_j is the depolarization ratio of the j th normal mode. The Raman scattering cross sections and the calculated scaled frequencies are used with a Lorentzian function to obtain the calculated spectrum. Infrared intensities are calculated based on the dipole moment derivatives with respect to the Cartesian coordinates. The derivatives are taken from the *ab initio* calculations and transformed to normal coordinates by

$$\left(\frac{\partial\mu_\mu}{\partial Q_i}\right) = \sum_j \left(\frac{\partial\mu_\mu}{\partial X_j}\right)L_{ji} \quad (32.4)$$

where Q_i is the i th normal coordinate, X_j is the j th Cartesian displacement coordinate, and L_{ji} is the transformation matrix between the Cartesian displacement coordinates and the normal coordinates.

The infrared intensities are then calculated by

$$I_i = \frac{N\pi}{3c^2} \left[\left(\frac{\partial\mu_x}{\partial Q_i}\right)^2 + \left(\frac{\partial\mu_y}{\partial Q_i}\right)^2 + \left(\frac{\partial\mu_z}{\partial Q_i}\right)^2 \right] \quad (32.5)$$

The literature contains several representative examples of predicted Raman and infrared spectra derived from representative compounds [Guirgis et al., 2002; Guirgis et al., 2001; Mohamed et al., 1999].

32.8 Research Issues and Summary

In many ways, computational chemistry is just beginning to show its potential as a tool for explaining reaction processes. However, the greatest potential applications for computational chemistry seem likely to come from predictions for probable outcomes in complex chemical systems. Experimental chemistry will always be important, since every prediction must be confirmed experimentally. However, theoretical predictions already serve to guide experiment, and computational chemistry raises the power of that predictive ability to a new level.

As an example of the future predictive power of computational chemistry, consider the evidence presented in Section 32.3.3 and Section 32.5.2.1 of this chapter. As a further example of the promise for the predictive power of computational chemistry and the increasingly important role that computational chemistry is likely to play in directing experimental work, we close with the following case study.

Case Study

This case study involves stereocartography [Lipkowitz et al., 2002]. The issue of **chiral** control in chemical processes is of enormous importance. The FDA now requires biological testing of both **enantiomers** of chiral agents. The synthesis of a chiral material adds significant cost and difficulty to any preparative procedure. For these reasons and others, the ability to control the chirality of a chemical process is crucial. Moreover, the ability to achieve that control in a catalytic manner has obvious financial implications to the chemical industry. A major limitation in catalytic processes is obtaining a fundamental understanding of how the catalyst achieves its effect of accelerating a process, and, in the case of a chiral reaction, how the catalyst differentiates (and thus accelerates) the rate of one chiral pathway from another.

Many catalysts are metal-based systems. From a computational standpoint, this makes the modeling situation very complex. The working premise of this particular protocol was the readily believable but previously unproven hypothesis that an effective catalysis in a chiral system is one in which the chirality of the catalyst is as close as possible to the reactive site of the catalyst. With this assumption, a computational paradigm was needed to evaluate the effectiveness of known chiral catalysts. This paradigm maps the “stereodiscriminating regions around a chiral catalyst — hence the term stereocartography.”

The first step was to make the center of mass of the catalyst at 0,0,0 on the Cartesian coordinate system, surrounded by a uniform three-dimensional grid. The second step was to put a transition state structure at grid points and compute the intermolecular energy (between transition state and catalyst) using molecular mechanics. The transition state–catalyst interaction was modeled 1,728 times at each grid point, using different alignments each time. For a typical analysis, this resulted in 950 million calculations! This is clearly a situation that calls for use of a highly parallel computational configuration, known as a *Beowulf cluster*.

To perform the analysis, parallel computing was employed “using a loosely networked cluster of SGI machines and on a small cluster of 26 AMD Athlon processors running a Linux operating system.” The software used for semiempirical calculations of the transition state structures was Spartan 5.0, available from Wavefunction, Inc., which uses PM3 with a transition metal parameter set. **AMBER**, in MacroModel 7.0, was used for MM calculations.

The catalyst structures were obtained from the Cambridge Structural Database (Wavefunction), with PM3 optimization when necessary (i.e., when the database structure was not identical to the catalyst). To achieve chiral discrimination, the **R** and **S** transition states both were modeled within the grid, and the difference map (by subtraction) of the **electrostatic potentials** of the two **diastereomeric** complexes was examined. In the difference map, stereodiscrimination was revealed by the presence of electrostatic potential — if that potential were close to the site of the chemical transformation, the hypothesis would be confirmed.

Using this method, the authors examined 18 catalysts that were well described experimentally. Strikingly, 17 of the 18 known catalysts were shown to obey the Lipkowitz hypothesis. This level of success will assuredly lead many experimenters to model their catalysts with the Lipkowitz method before going to the difficulty of synthesis and experimental evaluation of their effectiveness. The authors appear to have made great progress toward their goal of quantifying the factors that influence the chiral induction of the catalytic system “so that ligands for use as **asymmetric** catalysts could be improved upon, or better yet, be designed *de novo*.”

Defining Terms

- Ab initio** The computational construction of a molecule from its constituent atoms without any prior assumptions other than the identity, quantum mechanical properties, and predetermined connectivity of those atoms.
- Actinide** A series of *f*-block elements with increasing numbers of nuclear protons (atomic numbers 89–104) from actinium to rutherfordium.
- Activation energy** The energy needed to pass over the transition state when going from reactants to products.
- AMBER** A force-field method name that is an acronym for *assisted model building with energy refinement*.
- Anions** Negatively charged species, in which the total number of electrons exceeds the total number of protons.
- Anti** The disposition of two objects in reference to a plane so that the two objects are on opposite sides of the plane.
- Asymmetric** Without symmetry; *asymmetric* and *chiral* are synonyms.
- Axial** The location of a group that is directly attached to a six-membered ring structure and lies in a plane roughly perpendicular to that of the six-membered ring.
- B3LYP** An acronym for *Becke 3 term, Lee, Yang, and Parr*, an advanced variant of the density functional method that includes gradient correction factors for electron correlation potential energy.
- Basis sets** A set or collection of functions used to describe the atomic orbitals that are combined in the generation of a molecular orbital description of a compound.
- Born–Oppenheimer approximation** The assumption that because electron motion far exceeds nuclear motion, the electron motion is essentially independent of nuclear motion, so that the wave function is separated into two parts: one for the nucleus and one for the electrons.
- Chair structure** A conformation of the global energy minimum structure for cyclohexane (C₆H₁₂) that resembles a lounge chair (with a headrest and footrest), in which all opposing sides of the structure are parallel.
- Chime** A program developed by MDL for visualization of structural models on the Web.
- Chiral** A synonym of *asymmetric*; an object that is not identical to its mirror image.
- Conformations** Different structural representations of the same compound that differ only in the twist and turn of bonds (without breaking the bonds).
- Conjugation** An interaction of electron density in two or more adjacent systems. In a valence bond approach, adjacent pi bonds (or nonbonded electrons with a pi bond), with the pi electrons located in parallel, coplanar orbitals that can overlap each other, allow for interaction of the pi systems. Such an interaction imparts greater thermodynamic stability to the system than would be manifest if the adjacent electronic systems did not overlap (interact with) each other.
- Coordination number** The number of ligands that surround and are bonded to the central metal atom in a complexed structure.
- Covalent bonds** These occur when the electrons are shared evenly (but not necessarily equally) by each of two bonded atoms.
- d-block elements** The metallic elements in which highest-energy electrons are placed in the *d* orbitals of the atom.
- De novo** A *de novo* design is the construction of an entirely new structure based on new insights (such as computational models), rather than on the modification of an existing structure.
- Density functional theory (DFT)** Those *ab initio* methods that deal with the total electron density of the molecule.
- Diastereomeric relationship** A relationship between two objects that are not mirror images of each other but are still stereoisomers, meaning that they have different locations of atoms in space where the differences are not conformational. Diastereomers are expected to have different chemical and physical properties.

Diels–Alder reaction A reaction named after the two chemists who discovered it. It is a pericyclic process resulting in the formation of a cyclohexene structure from two species, one having a 2- π electron system and the other having a conjugated 4- π electron system.

Diffusion function A model for treatment of electrons that are at a considerable distance from the nucleus of the atom.

Effective core potential (ECP) A potential function that represents the nonvalence (nonbonding) electrons of an atom.

Electron configuration The manner in which electrons are added to atoms of increasing atomic number. The same protocol for electron configurations is applied to filling electrons into atomic and molecular orbitals.

Electron correlation The avoidance behavior that characterizes electrons; the electrons do not want to be near each other.

Electron spin resonance (ESR) A technique that uses the interaction between the nuclear magnetic spin of nuclei that exist as single electron (radical) species with an applied magnetic field to obtain spectroscopic data. ESR can be used to characterize the environment in which the atoms reside.

Electrostatic potential map The result of an interaction between a charge and the surface of a molecule, which reveals positions of affinity for both negative and positive species within the molecule.

Empirical methods Methods based on parameters assumed to be representative of atoms, bonds, and interactions in the target structure, employing classical mathematical relationships using those parameters to solve for structural energies.

Enantiomer The named relationship between two objects that have the same composition and connectivity but are mirror images of each other and are not identical. Enantiomers have different locations of atoms in space where the differences are not conformational. A classic example of an enantiomeric relationship is the set of right and left hands.

Equatorial Pertaining to the location of a group that is directly attached to a six-membered ring and lies in a plane roughly approximating that of the carbon atoms of that ring.

Excited state A state in which the ground state (low-energy) electronic configuration of the molecule has been altered so that one electron in the structure is elevated to a higher level of energy.

***f*-block elements** The lanthanide and actinide metallic elements in which highest energy electrons are placed into the *f* orbitals of the atom.

Formal oxidation When atoms react by either giving up or accepting electrons, the formal accounting of that process is denoted by the change in formal oxidation of an element relative to the number of electrons that the neutral atom would contain in a nonbonded state.

Frontier molecular orbitals The highest-energy molecular orbitals of a compound, typically taken as those that are integral to a conjugated system.

Group theory Mathematical methods commonly used to characterize the symmetry of compounds.

Half chair structure The global energy maximum structure for a cyclohexane (C₆H₁₂) compound, which resembles a chair with one end of the structure, either the headrest or the footrest, flattened out in a planar arrangement.

Hamiltonian The term *H* from the Schrödinger equation that serves as the operator for energy.

Hartree–Fock (HF) method A self-consistent *ab initio* procedure that models the total number of electrons in a system *N* by *N* wave functions. In Hartree–Fock, electron correlation is not considered, and the variation principle is assumed.

Heterogeneous Pertaining to a system of two or more different phases, such as a mixture of an insoluble solid and a liquid (e.g., sand in water) or a mixture of two insoluble liquids (e.g., oil and water).

Homogeneous Pertaining to a system of only one phase, such as a mixture of a soluble solid and a liquid (e.g., NaCl in water) or a mixture of two soluble liquids (e.g., ethanol and water).

Hückel calculations The mathematical treatment developed by Hückel to deal with compounds in which the electron interactions can be described as a matrix, with the sum of the squares of the coefficients of each column in the matrix representing electron density on one atom, and of each row the electron density on one orbital.

Hybridization A construct developed by Linus Pauling that became a central tool of valence bond theory to adopt blended atom orbitals (e.g., spherically symmetrical *s* orbitals and dumbbell-shaped *p* orbitals) to create hypothetical mixed atom orbitals (e.g., sp^3 , which denotes a mixing of one part *s* and three parts *p*) in order to account for observed bond angles and lengths.

Isomers Compounds that have the same elemental composition but differ from each other in some other respect. The three major types of isomers are constitutional (atoms have different connectivity), conformational, and configurational (atoms occupy different locations in space, and those differences cannot be resolved without breaking and remaking bonds).

Kinetics The study of the rates of chemical reactions.

Lennard–Jones 12-6 potential This is used to describe weaker interactions, such as van der Waals forces, and has the functional form $V_{LJ}(r) = 4\epsilon[(\frac{\sigma}{r})^{12} - (\frac{\sigma}{r})^6]$. The $\sim 1/r^{12}$ is a repulsive term that dominates at short distances, and the $\sim 1/r^6$ is an attractive term that dominates at large distances. The parameter ϵ is the depth of the well, and σ is related to the equilibrium bond distance $\sigma = 2^{1/6}r_e$.

Ligand An atom or a bonded grouping of atoms that forms a bond to a centrally located atom in a complex by donating its electrons to that atom.

Linear combination of atomic orbitals (LCAO) The process of combining the atomic basis functions to generate a wave function.

Many-body potential A potential energy function that includes many-body effects by changing the pair potential to incorporate interactions from nearby atoms.

Mechanism The description of bond-making and bond-breaking in a chemical process.

Merck molecular force field (MMFF) A version of a MM program developed by Merck Pharmaceutical Company to evaluate organic compounds of pharmacological potential.

Metallic Pertaining to elements that have a proclivity to give up valence electrons to other elements when combined with those elements to form compounds.

Metathesis Any reaction in which an atom (or group of atoms) in one reactant switches with another atom (or group of atoms) from another reactant in a chemical transformation.

Michaelis–Menton equation The expression of kinetics in biochemical systems is most often treated with the Michaelis–Menton equation in which a substrate (S) and an enzyme (E) react to form a product (P) by intermediate steps described as enzyme–substrate complexation (ES) and enzyme–product decomplexation, so that E + S are in equilibrium with ES, which is in equilibrium with EP, which is in equilibrium with E + P.

Molecular dynamics (MD) An application of a force–field method with classic equations of motion in a series of time steps. MD is useful to describe processes such as SIMS simulation or conformation searching.

Molecular mechanics (MM) A method that primarily uses a classical mechanics ball-and-spring approach to evaluate the structure of a compound.

Molecular orbitals Concept used to describe the distribution of electrons in a molecule when assuming that the orbitals no longer belong to the specific atoms of which the molecule is composed, but rather to the entire molecule.

Møller–Plesset method Electron correlation in *ab initio* methods that is based on perturbation theory.

Monte Carlo method A randomization of the three-dimensional locations of objects, generally used to seek a lower energy region that may not be accessible or evident by more regular manipulations of the same objects in a more orderly or logical manner.

Morse potential An empirical pair potential that describes the stretching of a chemical bond. The functional form is $V(r) = D_e(1 - e^{-\beta(r-r_e)})^2$, where r_e is the equilibrium bond distance, D_e is the depth of the well, and β is related to the curvature near the minimum.

Nuclear magnetic resonance (NMR) A technique that uses the interaction of nuclear magnetic spin of certain nuclei (like ^1H and ^{13}C) with an applied magnetic field to obtain spectroscopic data that can be used to characterize the environment in which the atoms reside.

- Nucleophilic behavior** The preference for an electron-rich species to bond to the positive nucleus of another species, other than hydrogen.
- Orbital** A three-dimensional volume of space which is the probable location for finding electrons. If the orbital belongs to an atom, it is called an *atomic orbital*; if it belongs to the molecule, it is called a *molecular orbital*.
- Pair potential** A potential energy function that describes how the potential energy between a pair of atoms depends on the distance between them.
- Pairwise additive assumption** The assumption that the interaction between each pair of atoms is independent of the other atoms in the system. The total potential energy of the system is assumed to be equal to the sum of the interaction between each pair of atoms: $V_{tot}(r_1, r_2, \dots, r_n) = \sum_i \sum_{j>i} V(r_{ij})$.
- Pericyclic processes** Processes (including the Diels–Alder reaction) with cyclic transition states that reflect the reorganization of sigma and pi bonds in the chemical transformation.
- Pi electrons** Those electrons positioned in orbitals that allow for side-to-side overlap. In valence bond theory, *p* orbitals are used most commonly to construct pi systems.
- Potential energy function** A mathematical function with a functional form that describes how the potential energy depends on the relative position of each atom in the system. The function represents the actual solution to the Schrödinger equation within the Born–Oppenheimer approximation for the physical system. The parameters of the functional form are fit to experimental data and also to data from *ab initio* calculations.
- Quantum mechanics** The physics of the very small. The rules of quantum mechanics govern atomic and molecular phenomena and determine the relative probabilities of electron locations.
- R** Denotes the spatial orientation of groups about a central atom in one of the pair of enantiomeric orientations, R and S.
- Radical species** Having a single, non-bonded electron.
- Raman spectroscopy** A technique for measuring a molecule's vibrational, rotational, or electronic energy, which depends largely on polarizability.
- Relativistic effects** As electrons get closer to the nucleus, their speeds approach the speed of light and the theory of relativity must be applied to them. This is especially important for atoms with larger atomic numbers.
- S** Denotes the spatial orientation of groups about a central atom in one of the pair of enantiomeric orientations, R and S.
- Saturated** A carbon compound is saturated if the carbons in the compound are bonded to as many hydrogen atoms as possible. Using the formula C_nH_{2n+2} , where *n* is the number of carbons, $2n + 2$ is the number of hydrogen atoms required for the compound to be classified as saturated.
- Schrödinger equation** Erwin Schrödinger (also spelled *Schroedinger*) developed the model of the hydrogen atom using wave functions upon which *ab initio* methods are founded. In this model, it is possible to solve for an electron's energy with great precision, but the electrons' locations can only be described probabilistically.
- Secondary ion mass spectrometry (SIMS)** Procedure that bombards a sample with primary ions, causing the sample to eject molecules and molecular fragments from the sample surface. The charged ejected particles (i.e., the secondary ions) are then analyzed by mass spectrometry.
- Self-consistent field (SCF)** A method of iterative refinement, starting from an arbitrary initial value and performing calculations of new values, replacing the initial value with the new values until the new (lower energy) and initial (higher energy) converge to an acceptable degree.
- Semiempirical method** A method that includes both quantum mechanics and empirical parameters to compute molecular structures and properties.
- Sigma electrons** Those electrons in a valence bond system that are positioned in end-to-end, overlapping atomic orbitals between two atoms. Typically, the atomic orbitals in such a bond have at least some percentage composition of *s*-type (symmetrically disposed around the atom) character.

- Spin** Electrons are described by many characteristic quantities, one of which is the spin quantum number, which can be either $+1/2$ or $-1/2$.
- Stiff equations** Sets of differential equations whose solutions vary over so great a span of values that their simultaneous integration is problematic by normal methods, such as Euler or Runge–Kutta.
- Syn** The disposition of two objects in reference to a plane so that the two objects are on the same side of the plane.
- Thermodynamic** Pertaining to the study or characteristics of energy flux in any chemical process.
- Torsion** The interaction of two bonds or groups about a central connecting bond (e.g., interactions of bonds A–B and C–D or groups A and D in a structure such as A–B–C–D).
- Transition metals** The collection of *d*- and *f*-block elements (including the actinides and lanthanides).
- Transition states** The high-energy structures (where the bonds are partially made or broken) that represent the lowest energy barrier that must exist between starting materials and products in reactions that create bonds.
- Twist boat conformation** A local energy minimum structure for cyclohexane (C_6H_{12}) that resembles a boat (with a bow, stern, and transom) whose sides are not parallel.
- Valence bond theory** A theory that describes molecules as a series of bonds made by the overlap and sharing of spin-paired electrons in the atomic orbitals between the atoms.
- Van der Waals force** The force between objects that arises from temporary electrostatic interactions of their surrounding electrons.
- Variational principle** Since an estimated wave function will never be equal to or lower than the actual energy, the result of a wave function calculation is used repeatedly as the approximation in successive calculations, until the approximate value converges with the calculated value.
- Vibrational frequency** The frequency of the vibration of atoms, which depends on the masses of the atoms that are bonded and the strength of the bond between them.
- Vital force** The theory that compounds from living systems, called *organic compounds*, can only be made by living systems, *in vivo* (in life), and not by humans, *in vitro* (in glassware).
- Wave function** The description of the probable distribution of electrons as a function of their *x*, *y*, *z* coordinates and spin.
- ZINDO** A program developed by Zerner that uses semiempirical quantum mechanical values to compute molecular spectra.

33.1 Introduction

Modern **astronomy/astrophysics** is a computationally driven discipline. During the 1980s, it was said that an astronomer would choose a computer over a telescope if given the choice of only one tool. However, just as it is impossible to separate “astronomy” from astrophysics, most astrophysicists would no longer be able to separate the computational components of astrophysics from the processes of data collection, data analysis, and theory. The links between astronomy and computational astrophysics are so close that a discussion of computational astrophysics is essentially a summary of the role of computation in all of astronomy. We have chosen to concentrate on a few specific areas of interest in computational astrophysics rather than attempt the monumental task of summarizing the entire discipline. We further limit the context of this chapter by discussing astronomy rather than related disciplines such as planetary science and the engineering-oriented aspects of space science.

33.2 Astronomical Databases

Physics and astronomy have been leaders among the sciences in the widespread use of and access to online access and data retrieval. This has most likely occurred because the relatively small number of astronomers is broadly distributed so that few astronomers typically reside in any one location; it also perhaps results because astronomy is less protective of data rights than other disciplines driven more by commercial

spin-offs. Astronomers regularly enjoy online access to journal articles, astronomical catalogs/databases, and software.

33.2.1 Electronic Information Dissemination

All major astrophysical journals are available electronically [Boyce et al. 2001]. Several electronic preprint servers are also available [Ginsparg 1996, Hanisch 1999]. Furthermore, the Astrophysical Data Service (ADS) [Kurtz et al. 2000] is the electronic index to all major astrophysical publications; it is accessible from a variety of mirror sites worldwide. The ADS is a data retrieval tool that allows users to index journal articles by title, keyword, author, astronomical object and even by text search within an article. The ADS is a citation index as well as a tool capable of accessing the complete text of articles and in many cases the original data, although it has not served its original purpose (as designed by NASA) of allowing for the integrated data management of all astrophysics missions.

Electronic dissemination plays an important role in the collection of astronomical data. Many variable sources (such as high-energy transients and peculiar **galaxies**) often exhibit changes on extremely short timescales. Follow-up observations require the community to rapidly disseminate source locations, brightnesses, and other pertinent information electronically (notification sometimes must go out to other observatories on timescales as short as seconds). There are a variety of electronic circulars available to the observational community. The primary source of these is the International Astronomical Union (<http://www.iau.org/>).

33.2.2 Data Collection

Astronomy is generally an observational rather than experimental science (although there are laboratory experiments that emulate specific astronomical conditions). Modern astronomical observations are made using computer-controlled telescopes, balloon instruments, and/or satellites. Many of these are controlled remotely, and some are robotic.

All telescopes need electronic guidance because they are placed on moving platforms; even the Earth is a moving platform when studying the heavens. From the perspective of the terrestrial observer, the sky appears to pivot overhead about the Earth's equatorial axis; an electronic drive is needed to rotate the telescope with the sky to keep the telescope trained on the object. However, the great weight of large telescopes is easier to mount altazimuthally (perpendicular to the horizon) than equatorially. A processor is needed to make real-time transformations from equatorial to altazimuth coordinates so that the telescope can track objects; it is also needed to accurately and quickly point the telescope. Precession of the equinoxes must also be taken into account; the direction of the Earth's rotational axis slowly changes position relative to the sky. Computers have thus been integrated into modern telescope control systems.

Additional problems are present for telescopes flown on balloons, aircraft, and satellites. The telescopes must either be pointed remotely or at least have the directions they were pointed while observing accessible after the fact. Flight software is generally written in machine code to run in real-time. Stability in telescope pointing is required because astronomical sources are distant; long observing times are needed to integrate the small amount of light received from sources other than the sun, moon, and planets.

As an example, we mention computer guidance on the Hubble Space Telescope (HST). HST has different sensor types that provide feedback to maintain a high degree of telescope pointing accuracy; the Fine Guidance Sensors have been key since their installation in 1997. The three Fine Guidance Sensors provide an error signal so that the telescope has the pointing stability needed to produce high-resolution images. The first sensor monitors telescope pitch and yaw, the second monitors roll, and the third serves both as a scientific instrument and as a backup. Each sensor contains lenses, mirrors, prisms, servos, beam splitters, and photomultiplier tubes. Software coordinates the pointing of the sensors onto entries in an extremely large star catalog. The guidance sensors lock onto a star and then deviations in its motion to a 0.0028-arcsecond accuracy. This provides HST with the ability to point at the target to within 0.007

arcseconds of deviation over extended periods of time. This level of stability and precision is comparable to being able to hold a laser beam constant on a penny 350 miles away.

To complicate matters, many telescopes are designed to observe in **electromagnetic spectral** regimes other than the visible. An accurate computer guidance system is needed to ensure that the telescope is correctly pointing even when a source cannot be identified optically, and that the detectors are integrated with the other electronic telescope systems. Many bright sources at nonvisible wavelengths are extremely faint in the visible spectral regime. Furthermore, telescopes must be programmed to avoid pointing at bright objects that can burn out photosensitive equipment, and sometimes must avoid collecting data when conditions arise that are dangerous to operation. For example, orbital satellites must avoid operating when over the South Atlantic Ocean — in a region known as the South Atlantic Anomaly, where the Earth's magnetic field is distorted — because high-energy ions and electrons can interact with the satellite's electronic equipment. This can cause faulty instrument readings and/or introduce additional noise.

There are other examples where computation is necessary to the data collection process. In particular, we mention the developing field of **adaptive optics**. This process requires the fast, real-time inversion of large matrices [Beckers 1993]. *Speckle imaging techniques* (e.g., [Torgerson and Tyler 2002]) also remove atmospheric distortion by simultaneously taking short-exposure images from multiple cameras.

Detectors and electronics must often be integrated by one computer system. Many interesting specific data collection problems exist that require modern computer-controlled instrumentation. For example, radio telescopes with large dishes cannot move, and sources pass through the telescope's field-of-view as the Earth rotates. Image reconstruction is necessary from the data stream because all sources in the dish's field of view are visible at any given time. Another interesting data collection problem occurs in infrared astronomy. The sky is itself an infrared emitter, and strong source signal-to-noise can only be obtained by constantly subtracting sky flux from that of the observation. For this reason, infrared telescopes are equipped with an oscillating secondary mirror that wobbles back and forth, and flux measurements alternate between object and sky. A third example concerns the difficulty in observing x-ray and gamma-ray sources. X-ray and gamma-ray sources emit few photons, and these cannot be easily focused due to their short wavelengths. Computational techniques such as Monte Carlo analysis are needed to deconvolve photon energy, flux, and source direction from the instrumental response. Very often, this analysis must be done in real-time, requiring a fast processor. In addition, the telescope guidance system must be coordinated with onboard visual observations because the visual sky still provides the basis for telescope pointing and satellite navigation.

33.2.3 Accessing Astronomical Databases

Database management techniques have allowed astronomers to address the increasing problem of storing and accurately cross-referencing astronomical observations. Historically, bright stars were given catalog labels based on their intensities and on the constellation in which they were found. Subsequent catalogs were sensitive to an increased number of fainter objects and thus became larger while simultaneously assigning additional catalog numbers or identifiers to the same objects. The advent of photographic and photoelectric measurement techniques and the development of larger telescopes dramatically increased catalog sizes. Additional labels were given to stars in specialty catalogs (e.g., those containing bright stars, variable stars, and binary stars). Solar system objects such as asteroids and comets are not stationary and have been placed in catalogs of their own.

In 1781, Charles Messier developed a catalog of fuzzy objects that were often confused with comets. Subsequent observations led to identification of these extended objects as star clusters, galaxies, and gaseous nebulae. Many of these extended astronomical sources (particular regions of the **interstellar medium**) do not have easily identified boundaries (and the observed boundaries are often functions of the **passband** used); this inherent fuzziness presents a problem in finding unique identifiers as well as a database management problem. Furthermore, sources are often extended in the radial direction (sources are three-dimensional), which presents additional problems because distances are among the most difficult astrophysical quantities to measure.

As astronomy entered the realm of multi-wavelength observations in the 1940s, observers realized the difficulty in directly associating objects observed in different spectral regimes. An x-ray emitter might be undetectable or appear associated with an otherwise unexciting stellar source when observed in the optical. Angular resolution is a function of wavelength, so it is not always easy to directly associate objects observed in different passbands.

Temporal variability further complicates source identification. Some objects detected during one epoch are absent in observations made during other epochs. Signal-to-noise ratios of detectors used in each epoch contribute to the source identification problem. Additionally, gamma-ray and x-ray sources tend to be more intrinsically variable due to the violent, nonthermal nature of their emission. Examples of sources requiring access via their temporal characteristics include supernovae, gamma-ray bursts, high-energy transient sources, and some variable stars and extra-galactic objects.

There are tremendous numbers of catalogs available to astronomers, and many of these are found online. Perhaps the largest single repository of online catalogs and metadata links is VisieR (<http://vizier.u-strasbg.fr/viz-bin/VizieR>) [Ochsenbein et al. 2000]. Online catalogs also exist at many other sites, including HEASARC (High Energy Astrophysics Science Archive Research Center at <http://heasarc.gsfc.nasa.gov/>), HST (Hubble Space Telescope at <http://www.stsci.edu/resources/>), and NED (NASA/IPAC Extragalactic Database at <http://nedwww.ipac.caltech.edu/>).

Large astronomical databases exist for specific ground-based telescopes and orbital satellites. Some of these databases are large enough to present information retrieval problems. Examples of these databases are 2MASS (Two Micron All Sky Survey) [Kleinmann et al. 1994]; DPOSS (Digitized Palomar Observatory Sky Survey) [Djorgovski et al. 2002]; SDSS (Sloan Digital Sky Survey) [York et al. 2000]; and NVSS (The NRAO VLA Sky Survey) [Condon et al. 1998]. Databases span the range of astronomical objects from stars to galaxies, from active galactic nuclei to the interstellar medium, and from gamma-ray bursts to the cosmic microwave background. Databases are often specific to observations made in predefined spectral regimes rather than specific to particular types of sources; this reflects the characteristics of the instrument making the observations.

33.2.4 Data File Formats

The astronomic community has evolved a standard data format for the transfer of data. The Flexible Image Transport System (FITS) has broad general acceptance within the astronomic community and can be used for transferring images, spectroscopic information, time series, etc. [Hanisch et al. 2001]. It consists of an ASCII text header with information describing the data structure that follows. Although originally defined for nine-track, half-inch magnetic tape, FITS format has evolved to be generic to different storage media. The general FITS structure has undergone incremental improvements, with acceptance determined by vote of the International Astronomical Union.

Despite the general acceptance of FITS file format, other methods are also used for astronomical data transfer. This is not surprising, given the large range of data types and uses. Some data types have been difficult to characterize in FITS formats (such as solar magnetospheric data). Satellite and balloon data formats are often specific to each instrument and/or satellite.

Due to the large need for storing astronomical images, a wide range of image compression techniques have been applied to astronomy. These include fractal, wavelets, pyramidal median, and JPEG (e.g. [Louys et al. 1999]).

33.3 Data Analysis

Mathematical and statistical analyses are the driving forces behind the use of computation in astrophysics.

Data analysis and theoretical software can be accessed at a variety of sites worldwide. A few of the most well-known sites include the Astrophysics Source Code Library (<http://ascl.net/>), the UK Starlink site (<http://star-www.rl.ac.uk/>), and the Astronomical Software and Documentation Service at STScI, (<http://asds.stsci.edu>). Data analysis tools written in RSI's proprietary IDL programming language are

available at the IDL Astronomy User's Library (<http://idlastro.gsfc.nasa.gov/homepage.html>). IDL has become a computing language of choice by many astronomers because it has been designed as an image-processing language, it has been written with mathematical and statistical uses in mind, it can handle multidimensional arrays easily, and it has many built-in data visualization tools.

33.3.1 Data Analysis Systems

Some 20 years ago, a myriad of different data analysis systems existed within astronomy. Typically, each institution (or sometimes individual groups within an institution) had its own data analysis package, and compatibility between these packages was limited or nonexistent. In the fall of 1981, however, astronomers at Kitt Peak National Observatory began development of the Image Reduction and Analysis Facility (IRAF), intended to serve as a general-purpose, flexible, extendable data reduction package. IRAF has grown beyond its original use primarily by ground-based optical astronomers to encompass space-based experiments as well at wavelengths ranging from x-ray to infrared.

IRAF is currently a mature system, with new releases occurring roughly annually, and is operated by about 5000 users at 1500 distinct sites. It is supported under a number of different computer architectures running UNIX or UNIX-like (e.g., Linux) operating systems. Oversight of IRAF development is formalized, with a Technical Working Group and various User's Committees overseeing evolution of the software. Numerous large astronomical projects have adopted IRAF as their data analysis suite of choice, typically by providing extensions to the basic system. These projects include the x-ray "Great Observatory" Chandra, the Hubble Space Telescope, PROS (ROSAT XRAY Data Analysis System), and FTOOLS (a FITS utility package from HEASARC).

The IRAF core system provides data I/O tools, interactive graphics and image display tools, and a variety of image manipulation and statistical tools. Commonly available "packages" that are part of the standard installation include tools for basic CCD data reduction and photometry, and support one-dimensional, two-dimensional, echelle, and fiber spectroscopy. Most tasks can be operated in either interactive or batch mode.

IRAF supports the FITS file format, as well as its own internal data type. In addition, extensions exist to handle other data types. Currently, those include STF format (used for HST data), QPOE format (used for event list data such as from the x-ray and EUV satellites), and PLIO for pixel lists (used to flag individual pixels in a region of interest). IRAF uses text files as database or configuration files, and provides a number of conversion tools to produce images from text-based data. Binary tables can be manipulated directly using the TABLES package.

Other general-purpose data reduction packages coexist with IRAF. These include the Astronomical Image Processing System (AIPS), and its successor (AIPS++), developed at the U.S. National Radio Astronomy Observatory (NRAO), and is still the image analysis suite of choice for radio astronomy. Image processing has been a very important subdiscipline within computational astrophysics, and we mention a number of image reconstruction methods with special applications to astronomy: the Maximum Entropy Method (e.g., [Lasenby et al. 2001]; the Pixon Method [Piña and Puetter 1993]; and Massive Inference [Skilling 1998]). XIMAGE and its relatives (XSPEC and XRONOS) serve a similar function for the x-ray astronomy community. A significant number of optical astronomers use Figaro, developed at the Anglo-Australian telescope. Figaro is particularly popular throughout Australia and the United Kingdom. Recently, Figaro has been adapted to run within the IRAF system, allowing users to have the best of both worlds. While there is no formal software system operating under IDL, the profusion of astronomical programs available in that proprietary language makes it worthy of mention.

One of the most significant drivers for development of mission-independent data analysis software within astronomy has been NASA's Applied Information Systems Research Program (AISRP). This program has encouraged the development of software to serve community-wide needs and has also fought the recurrent tendency for each project to develop its own software system, but instead to write software "packages" within the IRAF or IDL architecture. Of course, a general data analysis system is not the best solution for all specialized needs, particularly for space-based astronomy. In these cases, many missions have developed their own packages, and not all of these exist within an IRAF/AIPS/XIMAGE/IDL framework.

33.3.2 Data Mining

For many years, both NASA and ESA (the European Space Agency) have collected and preserved data from observatories in space. Similar activities are underway (although with varying degrees of success) at ground-based observatories. Most of these archives are available online, although the heterogeneous nature of user interfaces and metadata formats — even when constrained by HTML and CGI — can make combining data from multiple sources an unnecessarily involved process. In addition, astronomical archives are growing at rates unheard of in the past: terabytes (TB) per year are now typical for most significant archives. Two recently established databases that illustrate the trend are the MACHO database (8 TB) and the Sloan Digital Sky Survey (15 TB).

The simplest kinds of questions one might ask of these kinds of data sets involve resource discovery; for example, “Find all the sources within a given circle on the sky,” or “List all the observations of a given object at x-ray wavelengths.” Facilities such as SIMBAD [Wenger et al. 2000]; VisieR [Ochsenbein et al. 2000]; NED [Mazzarella et al. 2001]; and ASTROBROWSE [Heikkila et al. 1999] permit these kinds of queries, although they are still far from comprehensive in their selection of catalogs and/or data sets to be queried. One problem arises from the nature of the FITS format, which is poorly defined as far as metadata are concerned; XML may provide a solution here, but astronomers have yet to agree on a consistent, common set of metadata tags and attributes.

Difficulties due to heterogeneous formats and user interfaces are being addressed by a number of so-called **virtual observatory** projects, such as the U.S. National Virtual Observatory (NVO), the European Astrophysical Virtual Observatory (AVO), and the British Astrogrid Consortium. The most basic intent of all these projects, which are coordinated with one another at some level, is to deliver a form of integrated access to the vast and disparate collection of existing astronomical data. In addition, all intend to provide data visualization and mining tools.

In its most encompassing form, astronomical data mining involves combining data from disparate data sets involving multiple sensors, multiple spectral regimes, and multiple spatial and spectral resolutions. Sources within the data are frequently time-variable. In addition, the data are contaminated with ill-defined noise and systematic effects caused by varying data sampling rates and gaps and instrumental characteristics. Finally, astronomers typically wish to compare observations with the results of simulations, which may be performed with mesh scales dissimilar to that of the observations and which suffer from systematic effects of their own. It has been observed [Page 2001] that data mining in astronomy presently (and in the near future) focuses on the following functional areas:

1. Cross-correlation to find association rules
2. Finding outliers from distributions
3. Sequence analysis
4. Similarity searches
5. Clustering and classification

Despite the difficulties outlined above, the nature of astronomical data — which are generally freely available and in computer-accessible form — has led to numerous early applications of data mining techniques in the field. As far back as 1981, FOCAS (Faint Object Classification and Analysis System) [Jarvis and Tyson 1981] was developed for the detection and classification of images on astronomical plates for the automatic assembly of catalogs of faint objects. Neural nets and decision trees have also been applied for the purposes of discriminating between galaxies and stars in image data [Odewahn 1992, Fayyad 1996] and for morphological classification of galaxies [Storrie-Lombardi 1992].

More recently, projects such as JPL's Diamond Eye [Roden et al. 1999] have begun to experiment with more general data mining enterprises. In this particular case, users interact with data mining servers via a Java applet (and thus need not have any particular data mining expertise themselves). Algorithms being tested include adaptive recognition (and its application to dynamic events) and ad hoc queries. Another current program is SKICAT (http://www-aig.jpl.nasa.gov/public/mls/skicat/skicat_home.html), which is an integrated software system applying image processing, database management, and AI classification

to large image database analysis. The basic image processing routines detect objects and measure a set of features (surface brightness, extent, morphology, etc.) for each object. Algorithms such as GID3*, O-Tree, and RULER are used to produce decision trees and classification rules based on training data, and these classifiers are then applied to the new data.

The greatest near-term successes of data mining are likely to arise from its application to large but coherent data sets. In this case, the data has a common format and noise characteristics, and data mining applications can be planned from the beginning. Perhaps the most ambitious of such ongoing projects are the Sloan Digital Sky Survey (SDSS) [York et al. 2000] and 2MASS (e.g. [Nikolaev et al. 2000]). SDSS uses a dedicated 2.5-meter telescope to gather images of approximately 25% of the sky (some 10^8 objects), together with spectra of approximately 10^5 objects of cosmological significance. Pipelines have been developed to convert the raw images into astrometric, spectroscopic, and photometric data that will be stored in a common science database, which are indexed in a hierarchical manner. The science database is accessible via a specialized query engine. The SDSS has required Microsoft to put new features into its SQL server; in particular, Microsoft has added a tree structure to allow rapid processing of queries with geographic parameters. The Two Micron All Sky Survey (2MASS) is another high-resolution infrared sky survey that contains massive amounts of data for discrete as well as nebulous sources.

The key problem in astronomical data mining will most likely revolve around interpretation of discovered classes. Astronomy is ruled by instrumental and sampling biases; these systematic effects can cause data to cluster in ways that mimic true source populations statistically. Because data mining tools are capable of finding classes that are only weakly defined statistically, these tools enhance the user's ability to find "false" classes. Subtle systematic biases are present (but minimized) even in controlled cases when data are collected from only one instrument. The astronomical community must be careful to test the hypothesis so that class structures are not produced by instrumental and/or sampling biases before accepting the validity of newly discovered classes.

33.3.3 Multi-Wavelength Studies

Multi-wavelength studies have become increasingly important in astronomy, as new spectral regimes (x-ray, extreme UV, and gamma ray) have opened to practitioners, and astronomers have become aware that most problems cannot be adequately addressed by studies within any one spectral band. Such studies are now recognized as essential to the understanding of objects ranging from the Sun and stars, through x-ray bursters and classical novae, to the interstellar medium and active galactic nuclei. The computational requirements peculiar to multi-wavelength astrophysics essentially fall into one of two categories, where the distinction is in the time rather than the spectral domain.

In the first case, we have situations in which the timescales associated with the phenomena under study are long compared with typical observational timescales. One such case is in studies of the interstellar medium (ISM), which is important in astrophysics because galactic gas and dust clouds are the source of new generations of stars. The ISM becomes more enriched as generations of stars die and return heavy elements to it. In the study of the ISM, one can identify three characteristic temperature scales: <100 K, $\approx 10^4$ K, and $\approx 10^7$ K; these temperatures necessitate observations at radio/infrared, optical/UV, and x-ray wavelengths, respectively (e.g., [Zhang et al. 2001]). In each case, the strength of its emission or absorption depends on the local density, composition, metallicity, temperature, and distribution of ambient photons. Because this causes the interstellar medium (and to a lesser extent the intergalactic medium) to interfere with observations of other galactic and extragalactic sources, stellar, galactic, and extragalactic astronomers are interested in knowing the radiative properties of the interstellar medium, which is by definition nebulous and three-dimensional, as well as knowing where this material is located. An example of code used to locate the interstellar medium in the visual spectral regime can be found at <http://ascl.net/extinct.html> [Hakkila et al. 1997]. Because the characteristic evolutionary timescale of the ISM is long by human standards, simultaneous (and even contemporaneous) multi-wavelength observations are unnecessary. In this milieu, catalogs and databases come into their own, and archival multi-wavelength research is possible, focusing on spatial rather than temporal correlations.

An idea of the numerous databases and collections of online data available on the ISM can be found at http://adc.gsfc.nasa.gov/adc/quick_ref/ref_ism.html.

A different situation occurs with variable sources such as gamma-ray bursters, and extremely short-duration and high-energy events occurring at cosmological distances. The source of the bursts is as yet unknown, and they may be created by mergers of a pair of neutron stars or black holes, or by a hypernova, a type of exceptionally violent exploding star. Gamma-ray bursts and their afterglows have been detected across the electromagnetic spectrum, and further study of these objects clearly calls for multi-wavelength studies (e.g. [Galama 1999]). However, unlike the case obtaining for the ISM, gamma-ray bursts have timescales ranging from milliseconds up to approximately 10^3 seconds, and thus coordinated and simultaneous (or near-simultaneous) multi-wavelength observations are essential. In this case, the computational demand is more on rapid deployment of various computer-controlled telescopes (both on the ground and in space) than on correlation analyses of existing databases. Thus, systems such as GCN (GRB Coordinates Network) have been developed [Barthelmy et al. 2001] to distribute locations of GRBs to observers in real-time or near-real-time, and to distribute reports of the resulting follow-up observations.

33.3.4 Specific Examples

33.3.4.1 Cosmic Microwave Background (CMB) Data Analysis

One of the main goals of CMB data analysis is to derive the power spectrum of the temperature fluctuations, which correlates directly to fluctuations in the density of matter in the early Universe. The precise spectrum of matter perturbations depends acutely on cosmological parameters and, hence, CMB data is an excellent diagnostic for determining the parameters of cosmological models. However, the task of constructing the power spectrum is daunting because the raw CMB signal has instrument noise, as well as noise from the interstellar medium and other astrophysical objects, imposed upon it. To further complicate matters, all these sources of noise are often correlated.

Analysis proceeds by first creating a physical map from the time series of instrument pointings. A pixel map is first constructed by dividing up the area of sky surveyed. For the COBE experiment [Smoot et al. 1992], only a few thousand pixels were necessary; while for the PLANCK Surveyor satellite (<http://astro.estec.esa.nl/SA-general/Projects/Planck/>), tens of millions of pixels are required. Thus, the main step in creating the map is the separation of noise, which can be done under the assumption that the time-series of noise signals is drawn from a Gaussian distribution. Linear algebra methods are used to calculate the pixel-pixel noise correlation, which is then used to construct the map. Brute-force methods are inefficient and exploiting sparse matrix methods is the only way to do the calculation efficiently. Nonetheless, the calculation is sufficiently large that massively parallel computing is necessary, and a general analysis package (MADCAP) has been developed [Borrill 1999].

Having constructed the map, the next step is to calculate the power spectrum. This is a significantly more difficult process than map creation, because each pixel contains information about the signal on all scales within the map. Further, the power spectrum that produces the signal must be derived from a maximum likelihood analysis, which in turn requires an iterative process. The steps involved in the iterative process are extremely computationally costly because correlation matrices and numerical derivatives must be calculated multiple times. Estimates of the total number of flops required to analyze the PLANCK data set are close to 10^{24} , which would take almost 1000 years on the Earth Simulator alone. Even smaller data sets, such as MAXIMA-2, require tens of petaflops. Ultimately, analysis of the larger data sets requires the development of new analysis methods.

33.3.4.2 Gamma-Ray Burst Data Analysis

Gamma-ray bursts (GRBs) are short bursts of primarily gamma-radiation having fluxes and spectra that evolve on short timescales. Evidence suggests that GRBs are produced when relativistic shock waves collide with each other and with the ambient interstellar medium. The source of the shocks is currently presumed to be a *hypernova*; a supernova variant in which a significant portion of the collapsing stellar core's energy is focused into shocked bipolar accelerated particle beams. GRBs exhibit a wide variety of complex behaviors

and yet there is evidence of multiple GRB classes. Class identification is as important in astrophysics as in other sciences; the properties of distinct GRB classes can lead to a better general understanding of GRB physics as well as to a better understanding of the different sources and environments producing the classes. However, class identification is not helpful if the mechanisms responsible for the producing the classes cannot be determined.

Data mining techniques have proven useful in the study of GRB classes. Data mining techniques are needed to identify clusters in the GRB attribute space because individual GRB behaviors overlap. Some overlap results from the large intrinsic range of GRB behaviors, some is due to distinctly different properties of GRB classes, and some is due to observational and instrumental bias. Bias can cause phantom classes to appear by creating clustering where no distinct source populations exist.

A reference to data mining techniques applied to GRBs can be found in [Hakkila et al. 2003]. GRB data mining has thus far been used primarily with the large GRB database collected by BATSE (the Burst And Transient Source Experiment on NASA's Compton Gamma-Ray Observatory) because this experiment has well-documented properties [Paciesas et al. 1999]. Data mining tools identify three distinct GRB classes rather than two known historically. Detailed analyses find that the newest (third) GRB class does not represent a separate source population; it is, instead, produced by observational biases resulting primarily from low signal-to-noise observations and from the instrumental trigger characteristics [Hakkila et al. 2003]. This successful result indicates that scientific data mining can be used not just to determine that classes exist, but also to determine *why* they exist.

33.3.4.3 Time Series Analysis

Astronomers make use of time series analysis techniques for a variety of purposes, including studies of variable stars and cataclysmic variables [Gilliland et al. 1998, Kiss et al. 2001]; pulsating or oscillating stars [Buzasi et al. 2000, Poretti et al. 2002]; asteroid rotation rates, active galactic nuclei [Pronik et al. 1999]; and detection of extrasolar planets [Brown et al. 2001]. Typically, astronomical time series suffer from relatively low signal-to-noise ratios, uneven sampling, and numerous gaps, at times leading to severe aliasing at the 1 day^{-1} frequency and difficulties in estimating a traditional autocorrelation function. In addition, some applications (e.g., AGN studies and planetary detection) are dominated by nonsinusoidal signals or pulses.

Historically, the primary tools used to support these efforts have been discrete Fourier transforms and periodograms [Scargle 1982]. Both of these estimators of the autocorrelation function can be defined in such a way as to satisfactorily represent unevenly sampled data, and small gaps in the time series can be handled using clever binning or interpolation techniques, but these necessarily distort the data and lead to the loss of information. Early efforts to deal with the difficulties raised by irregular sampling and gaps focused on applying the CLEAN algorithm [Roberts et al. 1987] to apply a nonlinear deconvolution in the frequency domain. Unfortunately, CLEAN, originally developed for use by radio astronomers, suffers from nonuniqueness as well as the tendency to fail when aliasing problems are severe. In some cases, aliasing can be minimized or eliminated by experimental design (e.g., GONG), but more often astronomers are confronted with this fundamental problem and this has driven numerous recent efforts in the area.

Recent developments in this area focus on the application of nonlinear, nonstationary techniques and Bayesian methods. The wavelet transformation shows great promise [Abry et al. 1995; Scargle 1997] because, unlike the DFT, it can be used to construct power spectrum estimators that are nearly independent of the signal shape and amplitude in the presence of noise. Such estimators are likely to find increasing use in the planetary-detection and AGN modeling communities. Perhaps an even more useful application of wavelets is in the denoising of power spectra, a technique pioneered by the solar physics community. Bayesian methods are also increasing in popularity, as they are well-suited to finding change points in long series of time-tagged data such as is typically obtained from high-energy astrophysics experiments [Scargle 1998].

A rapidly growing difficulty is the size of power spectra produced by astronomical experiments. Helioseismological observations can easily give rise to time series with in excess of 10^7 points, and asteroseismological observations are rapidly approaching this level [Schou and Buzasi 2001]. Achieving the maximum time resolution inherent in data such as time-tagged x-ray photon lists can require estimators with in excess

of 10^9 points [Ransom et al. 2002]. Furthermore, upcoming space-based experiments such as Eddington and Kepler will give rise to data sets that are so large as to mandate the use of automated techniques.

33.4 Theoretical Modeling

Prior to the advent of computers, theoretical modeling consisted largely of solving idealized systems of equations for a given problem. Very often, to make problems tractable, simplifying assumptions such as spherical symmetry and linearization of the problem would be necessary. Rapid numerical solutions of equations avoid the need for simplifying assumptions, but at a cost: one can no longer achieve an elegant formula for the solution to the problem, and insight often derived from manually solving the equations is lost.

33.4.1 The Role of Simulation

Although computation is commonplace in theoretical modeling, perhaps the most heavily computationally biased aspect is *simulation*. Simulation can be viewed as an extension of finding numerical solutions to a given equation set; however, the set of equations is often enormous in size (such as that produced by the gravitational interaction problem between a large number of bodies). Simulation also often involves visualizing the “data set” to help understand the phenomenon being studied, and the systems under investigation are almost always cast as an Initial Value Problem.

The roots of simulation in astrophysics can be traced back to at least the 1940s. Driven by a desire to understand the clustering of galaxies, Holmberg built an analog computer consisting of light sources and photocells to simulate the mutual interaction of two galaxies via gravity. Today, almost all simulation is conducted on digital computers. Development of fast, efficient algorithms for solving complex equation sets can often lead to programs containing tens of thousands of lines of code. Although it has been the tradition for individual researchers to develop codes in isolation, the past few years have seen the appearance of collaborations of researchers who work together on large coding projects. This trend is likely to continue and it is probable that in the near future researchers will converge to using a handful of readily available simulation packages (e.g., NEMO, <http://bima.astro.umd.edu/nemo/>).

33.4.2 The Gravitational n -body Problem

Although Newton’s Law of Universal Gravitation has been supplanted by **General Relativity**, Newton’s Law remains highly accurate for a very large number of astrophysical problems. However, solving the interaction problem for any number of bodies (n bodies) is difficult because at first appearances, the number of operations scales as n^2 . However, provided that small errors in the force calculation are acceptable (RMS errors typically less than 0.5%), then approximate solutions can be found using order $n \log n$ operations. Roughly speaking, the algorithms used by researchers fall into two categories: treecodes [Barnes and Hut 1986] and grid (FFT) methods [Hockney and Eastwood 1981]. Treecodes are usually about an order of magnitude slower than grid codes for homogeneous distributions of particles, but are potentially much faster for very inhomogeneous distributions. To date, the largest gravitational simulations conducted contain approximately 1 billion particles, and have been used to coarsely simulate volumes representing as much as 10% of the entire visible universe [Evrard et al. 2002].

33.4.3 Hydrodynamics

Hydrodynamic modeling — or equivalently, computational fluid dynamics — plays an extremely important role in astrophysics. Although most astrophysical **plasmas** are not fluids in the everyday sense, the physical description of them is the same. Modern hydrodynamic methods fall into two main groups: Eulerian (fixed) descriptions and Lagrangian (moving) descriptions. Eulerian descriptions can be broadly decomposed into finite difference and finite element methods. In astrophysics, the finite difference method is by far the most common approach. Lagrangian descriptions can be decomposed into (1) “moving mesh”

methods where the grid deforms with the flow in the fluid, and (2) particle methods, for which Smoothed Particle Hydrodynamics (SPH) is a popular example [Gingold and Monaghan 1977].

Because shocks play an important role in the evolution of stars and the ISM, a significant amount of research has focused on “shock capturing methods.” Most early approaches to shock capturing, and indeed a number of methods still in use today, provide stability by using an artificial viscosity to smooth out flow discontinuities (shocks). Although these methods work well, they often introduce additional, unwanted dissipation into the simulation. Perhaps the best alternative approach is the Godunov’s Method [Godunov 1959], which is a simple example of a first-order method where the Riemann shock tube problem is solved at the interface of each grid cell. More modern algorithms have extended this idea to higher-order integration schemes, such as the Piecewise-Parabolic Method [Collela and Woodward 1984].

33.4.4 Magnetohydrodynamics and Radiative Transfer

Magnetic fluid dynamic modeling (MHD) is the focus of a large amount of research in computational astrophysics [Falgarone and Passot 2003]. The system of equations for MHD is that of hydrodynamics plus the addition of coupling terms corresponding to magnetic and electric forces and Maxwell’s equations that constrain and evolve the magnetic and electric fields. Because of the severe complexities arising from the divergenceless nature of the magnetic field, most MHD methods are finite difference; and although particle methods have been used, quite often they produce significant integration errors.

Modern methods, as in hydrodynamics, often cast the problem in terms of a system of conservation laws. It is usual to look at variation along a given axis direction and to recast the problem in terms of “characteristic variables” that are constructed from eigenvalues and the primitive variables, such as density, pressure, and flow speed. Such recasting aids the development of the numerical method because timestepping can be viewed as propagating the system an infinitesimal amount along a characteristic. This formulation often allows development of stable integration schemes that produce accurate numerical solutions even when large time steps are used.

Radiative transfer (RT), the study of how radiation interacts with gaseous plasmas, is an extremely difficult problem. It bears parallels to gravity in that all points within a system can usually affect all others, but is further complicated by the possibility of objects along any given direction producing non-isotropic attenuation. The radiation intensity is a function of position, two angles for direction of propagation, and frequency — a total of six independent variables. There are many different approaches to solving RT, ranging from explicit ray tracing to Monte Carlo methods, as well as characteristic methods [Peraiah 2001]. Much of the modern research effort focuses on deriving useful approximation methods that ease the computational effort required.

33.4.5 Planetary and Solar System Dynamics

Recent advances in telescope instrumentation have led to a cascade of discoveries of extra-solar planets and, at the time of writing, more than 100 extra-solar planets are known. Consequently, there is now a large amount of interest in studying planet and solar-system formation. Solar-system formation occurs during star formation, and the inherent differences in the planets are due to a differentiation process that enables different elements to condense out of the solar nebula at different radii.

Planets form by hierarchical merging processes within the disk of the solar nebula. Dust grains form the first level of the hierarchy and planets the last, while objects of all mass scales and sizes exist in between. It should be noted that representing this variation of masses and sizes within a simulation is impossible because resolution is always limited by the available computing power and memory. Theoretical models of the agglomeration process must include hydrodynamics and gravity, although currently there is debate about the role of hydrodynamics in gas giant planet formation. At present, theory can be roughly divided into two approaches: (1) the study of stability properties of the solar nebula disk from an analytic perspective, and (2) the simulation of the process from a first principles perspective. Simulations with a million mass elements, designed to follow the agglomeration process in the inner part of the solar system,

were conducted in 1998 [Richardson et al. 2000]. More recent hydrodynamic simulations [Mayer et al. 2002] using the SPH technique have shown that gas giant planets can form extremely rapidly because of instabilities in protoplanetary disks.

The realization that our Solar System contains many small asteroids and meteorites capable of causing severe damage to the Earth has renewed interest in solar system dynamics. Calculating accurate orbits for these systems is difficult because they often have chaotic orbits. Chaotic systems place great demands on numerical integrations because truncation errors can rapidly pollute the integration. Thus, the integration schemes used must be highly accurate (often quadruple precision is used), and much effort has been devoted to “long-term” integrators (such as “symplectic integrators,” see [Clarke and West 1997]) that preserve numerical stability over long-periods of simulation time. The chaos observed in long-term simulations of the solar system inspired a new theory [Murray and Holman 1999] that demonstrates that the Solar System is chaotic (Uranus could possibly be ejected) but the timescale for this is extremely long (10^{17} years).

33.4.6 Stellar Astrophysics

Among the first astrophysical problems to be addressed using modern computational methods were models of stellar interiors [Heney et al. 1959; Cox et al. 1960] and atmospheres [Kurucz 1969]. One simplifying assumption needed for early stellar codes was that of Local Thermodynamic Equilibrium, which meant that stellar structural variations were not expected to occur on short timescales. Such assumptions are no longer necessary: stellar interior and atmosphere codes have become increasingly complex as computers and computational techniques have evolved. Theoreticians have been able to study rapid evolutionary phases and complex atmospheric processes in stars. Some of the difficult problems currently being addressed include the evolution of rotating stars [Meynet and Maeder 2002]; radial and nonradial stellar pulsations [Buchler et al. 1997; Crsico and Benvenuto 2002]; stellar magnetospheres [Wade et al. 2001]; evolution of stars in binary systems [Beer and Podsiadlowski 2002]; and supernovae [Woosley et al. 2002].

33.4.7 Star Formation and the Interstellar Medium

One of the greatest challenges in astrophysics is understanding the star formation process. Star formation is an enormously difficult problem because it encompasses gravity, hydrodynamics, radiative transfer, and magnetic fields. Further, the difference in density between between the initial gas cloud from which the star forms and the final star itself is 21 orders of magnitude, or equivalently, a change in physical scale of 7 orders of magnitude.

One of the most significant questions in this field is: Why do most stars form in binary systems? To address this question, numerical simulations have been run that follow the fragmentation of a large cloud of gas. The methods used have been primarily Lagrangian ones (such as SPH), although Adaptive Mesh Refinement (AMR) techniques [Berger and Collela 1989] are becoming more popular. The reason for the growth of interest in AMR is that recent results have demonstrated a severe error in a large body of numerical simulations of the cloud fragmentation process: they lacked resolution to adequately follow the balance between gravitational forces and local pressure forces [Truelove et al. 1997]. Simulations currently suggest that turbulent fragmentation plays a critical role in determining the formation of multiple star systems and that a filamentary structure is the main mechanism for transferring mass to the protostellar disk [Klein et al. 2000]. A similar process seems to govern formation of the first stars in the Universe [Abel et al. 2002].

Studying the interstellar medium presents different challenges. Traditionally, the ISM is understood as having a series of distinct phases that determine local star formation [McKee and Ostriker 1977], with regulation of the phases provided by heating and cooling mechanisms. Stellar winds and supernovae are the primary heating mechanism, while radiative cooling is the dominant cooling mechanism for the hot gas phases. The supernovae and winds also constantly stir the ISM, which in combination with rapid radiative cooling, serve to make it a highly turbulent medium. Turbulent media are difficult to understand because motions on very large scales can quickly couple to motions on much smaller scales,

and thus accurate modeling requires resolution of large and small scales [Mac Low 2000]. Because of this range of scales, achieving sufficient resolution to be able to accurately model turbulence is difficult, and a number of researchers rely on two-dimensional models to provide sufficient dynamic range. Recent simulations have shown that self-gravity alone, without the stirring provided from supernovae explosions, is sufficient to produce the spectrum of perturbations expected from analytical descriptions of turbulence [Wada et al. 2002]. In the near future, three-dimensional simulations with a similar resolution to two-dimensional models will be possible, although the incorporation of MHD turbulence makes large-scale three-dimensional simulations a formidable challenge.

33.4.8 Cosmology

The study of the Big Bang and quantum gravity epoch is still largely conducted analytically, although some aspects of this research lend themselves to computer algebra. Following these earliest moments, the Universe undergoes a series of phase transitions (or “symmetry breaking”) as the forces of nature separate out of the “Unified Field” [Kolb and Turner 1993]. Computation has been used to examine the nature of the phase transitions that occur as each of the forces separates. For example, the Electroweak phase transition has been extensively examined using lattice calculations to explore whether the phase transition is first (most probable) or second order [Kajantie et al. 1993]. Numerical simulations have also investigated how non-uniform symmetry breaking can lead to the formation of defects [Ach’ucarro et al. 1999].

Computation is used extensively in the study of **Big Bang Nucleosynthesis** (BBN) and the relic Cosmic Microwave Background (CMB). However, at present, CMB data analysis probably represents the biggest challenge computationally. Theoretical modeling of BBN dates back to the 1940s [Alpher et al. 1948], and a very detailed numerical approach to solving the coupled set of equations describing the reaction network was developed comparatively early [Wagoner et al. 1967]. Currently, there are a number of BBN codes available, and considerable effort has been put into reconciling results from different codes. CMB modeling is comparatively straightforward because the equations describing the evolution of a thermal spectrum of radiation in an expanding Universe are not overly complex. However, because the CMB spectrum we measure has foreground effects superimposed upon it (such as clusters of galaxies), a large amount of effort is expended simulating the effect of foreground pollution [Bond et al. 2002].

The theoretical modeling of large-scale structure in the Universe has relied heavily on computation. Because on large-scales “dark matter” dominates dynamics, only gravity need be included, and a Newtonian approximation can be used without significant error. Particle-based algorithms are used to evolve an initially smooth distribution of particles into a clustered state representative of the Universe at its current epoch. The first simulations with moderate resolution (3×10^5 mass elements) of the distribution of galaxies were conducted in the early 1980s [Efstathiou and Eastwood 1981]. Simulations have played a leading role in establishing the accuracy of the **Cold Dark Matter** (CDM) model of structure formation [Blumenthal et al. 1984]. In this cosmological model, structures are formed via a hierarchical merging process. Simulation has also shown that dark matter tends to form cuspy halos that have a universal core profile [Navarro et al. 1997], while the large-scale distribution of matter is dominated by filamentary structures.

33.4.9 Galaxy Clusters, Galaxy Formation, and Galactic Dynamics

The modeling of clusters of galaxies and galaxy formation relies on the same codes as the study of large-scale structure, with the addition of hydrodynamics to model the gas that condenses to form stars and nebulae within galaxies. Typically, the hydrodynamic methods used are either Eulerian grid-based algorithms or Lagrangian particle-based methods [Frenk et al. 1999], although, as in star formation, AMR methods are being adopted. Modeling of galaxy clusters is comparatively straightforward because the intracluster gas tends toward hydrostatic equilibrium. However, simulations have shown that the gas in galaxy clusters shows evidence of an epoch of preheating [Eke et al. 1998].

Galaxy formation is an exceptional difficult problem to study numerically because the evolution of the gas is strongly affected by supernovae explosions that occur on scales smaller than the best simulations

can currently simulate [White 1997]. The physics is also technically challenging because galaxy formation occurs in the very nonlinear regime of gravitational collapse while simultaneously being a radiation hydrodynamics problem (although an optically thin approximation for the gas works very well). Only within the past few years has a sufficient understanding evolved to enable simulations of galaxy formation to produce moderate facsimiles of the galaxies we observe [Thacker and Couchman 2001]. Nonetheless, the very best simulations continue to lack both important physics and sufficient resolution to describe the galaxy formation process in great detail.

The first large-scale numerical studies of galactic dynamics were conducted in the 1960s [Hockney 1967]. At least initially, and to a large extent today, most n -body simulations are used to confirm analytic solutions derived from idealized models of galactic disks [Binney and Tremaine 1987]. Typically, these simulations begin with a model of a given galaxy, which usually consists of a disk of stars and an extended dark halo, which is then perturbed in some fashion to mimic the phenomenon under study. Recently, it has been highlighted that accurate modeling of galactic dynamics in CDM universes is exceptionally difficult due to coupling between the substructure in the larger galactic halo and the galactic disk [Weinberg and Katz 2002]. Traditionally, researchers believed that approximately 1 million particles were sufficient to model galaxies reasonably; however, these new results have pushed that estimate at least an order of magnitude higher. Although researchers in this field use codes similar to those in large-scale structure, specialist codes, which are designed to reduce numerical noise, have been developed (e.g., the Self Consistent Field code of Hernquist and Ostriker [1992]).

33.4.10 Numerical Relativity

General relativity calculations are extremely computationally demanding because not only is the theory exceptionally nonlinear, but there are a number of elliptic constraint equations that must be satisfied at each iteration. Further, the rapid change of scales that can accompany collapse problems often requires adaptive methods to resolve. There are also other subtleties related to the boundary conditions around black holes that present severe intellectual challenges. Currently, the strongest science driver behind these calculations is the need to calculate the gravitational wave signal of cataclysmic events (such as binary black hole coalescence), which may be detectable with the LIGO gravitational wave detector (<http://www.ligo.caltech.edu/>). Because of the large amount of computation involved in computing space-time geometry, and the comparatively low amount of communication between processors, numerical relativity is an ideal candidate for Grid-based computation. The CACTUS framework has been developed to aid such calculations (<http://www.cactuscode.org>).

Relativity calculations are most often mesh based (although spectral methods are used occasionally). Before determining the evolution equations for the space-time, a gauge must first be decided upon, and the most common gauge is the so called “3 + 1 formalism,” where the space-time is sliced into a one-parameter family of space-like slices. Other formulations exist, such as the characteristic formalism, and in general the gauge is chosen to suit the problem being studied. Initial conditions for the space-time are provided and then the simulation is integrated forward, with suitable boundary conditions being applied. Building upon this body of research, the first calculation of the gravitational waveform from binary black-hole coalescence was performed in 2001 [Alcubierre et al. 2001].

33.4.11 Compact Objects

The study of compact objects such as white dwarf and neutron stars presents a formidable theoretical challenge. These systems exhibit extreme density, in turn requiring detailed nuclear physics as well as relativistic descriptions. Compact objects are widely believed to be the source of energy behind GRBs, with energetic scenarios, such as sudden mergers, driving a highly relativistic “fireball” shock wave that produces an extreme amount of gamma-ray radiation during collisions with other shock waves or the interstellar medium [van Putten 2001].

Neutron star collisions have been simulated for similar reasons to black holes: the calculation of their gravitational wave spectrum [Calder and Yang 2002]. Neutron stars are also the beginning point of core collapse (Type II) supernovae, and the simulation of the ignition process has attracted much attention. Fully general relativistic models are now beginning to appear [Bruenn et al. 2001]. Of particular interest is how the neutrinos drive a wind shortly after collapse begins [Burrows et al. 1995].

Type I supernovae occur when white dwarfs accrete sufficient mass to exceed the Chandrasekhar limit and subsequently undergo collapse. The physics is challenging because the process occurs far from equilibrium and entails radiative transfer as well as hydrodynamic instabilities. As in studies of Type II supernovae, to date most calculations use a two-dimensional approximation [Niemeyer et al. 1996] and Eulerian approaches; however, some explorations have used SPH in three-dimensions [Bravo and Garcia-Senz 1995]. The push toward full, high-resolution three-dimensional calculations is gathering momentum [Reinecke et al. 2002]. Such simulations are necessary to fully understand instabilities and include more accurate physics. However, the computational challenge is significant and, ultimately, progress awaits the development of 100-Teraflop computers.

33.4.12 Parallel Computation in Astrophysics

Parallel computing in astrophysics is often used to examine problems that simply cannot be addressed on a desktop computer, regardless of how long one could wait. The primary driver in this case is the large amount of memory available in parallel computers as compared to serial ones: the largest parallel computations simply do not fit into a desktop. The secondary use of parallel computation is to speed up data analysis, which involves performing the same analysis on many subsets of data. In this case, parallel computers significantly help in lowering the data reduction time.

More than 20% of the total cycles at the U.S. National Center for Supercomputing Applications are devoted to astrophysics, which is second only to materials science in terms of resource usage. Astrophysicists have a history of developing unique and ingenious parallel algorithms to solve the problems they face. Indeed, a number of research problems in astrophysics, such as binary black-hole coalescence and the formation of galaxies, are considered to be computational “Grand Challenges” by the National Science Foundation. These problems have computing demands that are similar to the nuclear ignition codes in the Accelerated Strategic Computing Initiative, which is part of the U.S. Government Stockpile Stewardship Program.

Parallel codes for distributed memory platforms are most often developed using the Message Passing Interface (MPI). Prior to the standardization of MPI, the Parallel Virtual Machine (PVM) API was very popular, and PVM remains the most common mechanism for parallelizing simple codes. Higher-performance APIs, such as the remote direct memory access provided provided by MPI-2, are yet to receive significant attention, primarily because vendors have failed to provide full support for this emerging standard. All of these APIs can lead to a significant increase in the size of a parallel program compared to the serial one. It is not uncommon for parallel codes to be over twice the length of serial ones. Codes written using these APIs have the potential to scale to many hundreds of processors.

Shared memory parallel codes are most often developed using the standardized OpenMP API. This API is particularly simple to use because it enables simple parallelization of codes using “pragmas” that are inserted into the code before iterative loops. The iterations within the loop, provided that they meet certain data independence requirements, can then be distributed to different CPUs, thereby speeding up execution times. The OpenMP API often does not lead to significantly longer parallel programs, but is limited in terms of scalability by the requirement of running on shared memory computers, which typically have a maximum of around 32 processors.

Over the past few years it has become increasingly apparent that although the physics being simulated by two codes is often quite different, the underlying data structures being used, such as grids or trees, are quite similar. This has led to the development of skeleton packages in which researchers need only add the numerical implementation of their equations and the communication between processors is handled by the package. CACTUS and PARAMESH are examples of this type of framework. However, most researchers seem reluctant to rely on these packages and instead develop an optimized communication layers themselves.

It is unclear what role “The Grid” will play in the development of theoretical modeling. Grid technologies have an inherently large latency, which makes simulation of elliptic-like problems (where the solution at one point depends on all others) particularly difficult. Relativistic problems appear to be comparatively well-suited to a grid environment due to the exceptionally large amount of computation involved in tensor calculations. So far, demonstration calculations run on a Grid environment using CACTUS are the best example of an effective Grid application. The potential of The Grid in astrophysics will probably be realized through extensive data analysis (akin to the SETI@home model) and data mining.

33.5 Research Issues and Summary

In this section we first highlight a number of key areas in computational astrophysics that will receive increasing attention in the future. No significance should be attached to the ordering of the items.

1. *Development of a Virtual Observatory.* A Virtual Observatory is a geographically distributed, Web-based repository of space-based and ground-based digital sky surveys, observatory and mission archives, and astronomy data and literature services. Virtual Observatories will provide powerful data analysis, visualization, and data mining toolkits for the effective and rapid scientific exploration of the resulting massive data sets. Virtual Observatories are to be enabled by technology, but driven by science.
2. *Planet formation.* Models need to include both hydrodynamics and dust to better understand the formation process in both the inner and outer solar system. Increasing resolution and space-borne optical interferometry will require detailed theoretical support from simulations to analyze observations.
3. *Star formation.* Following the full collapse of a gas cloud through to nuclear ignition remains an enormously challenging theoretical proposition. There are also a large number of questions about the formation of stars in groups, especially globular clusters, that will require key insights from simulations.
4. *Galaxy formation.* Progress is limited by both a lack of numerical resolution and an incomplete understanding of the physics of the process. It is currently unclear how to model the extremely important effect of heating from supernovae on protogalactic collapse. New discoveries will depend heavily on the growth of understanding of the star formation process.
5. *CMB data analysis.* New approximation algorithms are required to reduce the enormity of the analysis calculations for high-resolution data sets. Brute force and larger computers are not the answer, as even Petaflop computers will take over a year to analyze upcoming data sets.
6. *Black-hole coalescence.* With the growth of gravitational wave astronomy, calculating wave forms for binary systems will become increasingly important. These calculations have the potential to exploit the growth of “The Grid” computing environment.
7. *Supernovae ignition.* Current models can only simulate with adequate resolution in two-dimensions. A 100-fold improvement in computational power is needed to enable full three-dimensional calculations.
8. *Visualization.* The increasing complexity of data sets makes analysis more and more difficult. Haptic interfaces and/or multidimensional representation will be necessary to understand the phenomenological aspects of the next generation of astronomical data sets and simulations.
9. *Data mining tools that incorporate measurement error.* Efforts are being undertaken to include measurement errors in the performance of data mining tools. Pattern recognition algorithms currently define classes without regard to data quality; poorly measured data can smear out true clusters that would be easily visible if the data were limited to that of high quality. In some cases, poor-quality measurements can cause data to artificially cluster (e.g., when an upper flux limit is used in lieu of a measurement). Because the scientific method is statistical in nature, computational tools for science are needed that better reflect statistical uncertainties.

10. *Autonomous spacecraft/instrumentation operation.* Autonomous spacecraft are being designed to carry out day-to-day operations independent of ground control. Some of these operations include navigation and the scheduling and execution of observations and experiments. Support technologies for autonomous spacecraft include robotics, artificial intelligence, and control theory. This approach will reduce mission operation costs while simultaneously allowing orbital satellites to work dynamically rather than passively.

Astrophysics is gradually and irreversibly becoming a computational science. Astronomical data are being stored in and retrieved from progressively larger databases; data and metadata are being used by larger audiences. The analyses of such data are aided by pattern recognition algorithms and improved data visualization tools. Theoretical modeling has developed beyond the point where elegant calculations using relatively simple assumptions suffice; detailed models with many physical parameters are often required to adequately explain the detailed observations made by the newest orbital and ground-based telescopes spanning the electromagnetic spectrum. Parallel computation is often used in carrying out time-consuming calculations. High precision is needed to accurately calculate model parameters, and computationally intensive statistical tools are required to evaluate theoretical model efficacies. Astrophysics is thus evolving, and the new generation of astrophysicist is increasingly well-versed in the use of computational tools. This can only help us better understand the structure, evolution, and nature of the universe.

Defining Terms

Adaptive optics: An active form of observing light (rather than a passive one) in which lasers are fired at the sky from the telescope site, and the reflected laser light is used to differentially correct observed starlight for atmospheric refraction and convection.

Astrophysics: The study of the physical properties, structure, kinematics, dynamics, and evolution of celestial objects.

Big Bang nucleosynthesis: The epoch of the early Universe when the nuclei of atoms were formed. Theories of this epoch reproduce observations of elemental abundances exceptionally well, strongly supporting the Hot Big Bang theory.

Cold dark matter: Hypothesized sub-atomic particles that contribute roughly 30% of the mass in the Universe. Although in the early Universe these particles interacted vigorously, their influence is now seen only via gravitation. Theories that include the effects of these particles match observations exceptionally accurately.

Cosmic microwave background: Relic electromagnetic radiation left over from 300,000 years after the Big Bang. The distribution of radiation is very close to being homogeneous and isotropic, but carries small perturbations on it that correspond to perturbations of the matter density in the early Universe.

Cosmology: The branch of astrophysics dealing with the structure and evolution of the Universe on the largest scales.

Electromagnetic spectrum: Classification of light by wavelength (which is inversely related to energy). Ranging from light with the shortest wavelength (and largest energy) to that with the longest wavelength (and smallest energy), the electromagnetic spectrum includes gamma-ray, x-ray, ultraviolet, visible, infrared, and radio.

Galaxy: A large, gravitationally bound ensemble of stars, gas, and dust. Galaxies are traditionally classified as spiral, elliptical, irregular, or peculiar, based on their morphological structure. Our *Milky Way* galaxy is a large spiral galaxy containing more than a hundred billion stars.

General relativity: Einstein's theory of gravitation, which casts gravity not as a force, but rather as a consequence of warping in the local space-time continuum. The theory relies strongly upon geometrical concepts of distance and curvature.

Interstellar medium (ISM): The material between the stars. It is composed primarily of hydrogen and helium gas, with 1 to 2% heavy elements chemically mixed to form larger molecules ("dust"). Dense, cool molecular clouds are the seeds of star formation.

- Passband:** An electromagnetic regime defined by the spectral response of a particular filter and/or instrument.
- Plasma:** An ionized gas. A plasma behaves differently than a normal gas (which can often be modeled as a fluid) because a treatment of electromagnetic theory is needed to address the electrical charges found within it.
- Supernova:** A massive stellar explosion during which a star can briefly brighten to almost a billion times its original luminosity. Such events can be seen at enormous distances, although maximum luminosity usually lasts only for tens of days.
- Virtual observatory:** Proposed publicly accessible metadatabase of archived ground-based, balloon, and satellite astronomical observations. The database will also be associated with a variety of search engines and data mining tools.

34.1 Introduction

The past decade has witnessed the emergence of computational biology, in many forms, as a discipline in its own right. The application of mathematical and computational tools to all areas of biology is producing exciting results and providing insights into biological problems too complex for traditional analysis. In all areas of the life sciences, computational tools — from databases to computational models — have become commonplace in all laboratory settings. There is not a pharmaceutical or biotechnology company that does not have a computational biology or informatics group. Likewise, computational biology has emerged as an established academic field. Talent shortages and the inherent interdisciplinary nature of the field, however, have limited the rate of development of the academic sector.

The emergence of large-scale biological research efforts, such as the *Drosophila* and Human Genome Projects among other genome efforts, has contributed to the continued landslide of complex data. What sets biology apart from other data-rich fields is the *complexity* of its data, and the emergence of the fields of proteomics and systems biology has brought even more focus to that problem. Whereas a few years ago, biology was generally viewed as a scientific “cottage industry,” with data being generated in a highly distributed mode, the recent move to large-scale projects has accelerated the generation of widely shared data. Still, biology has failed to agree on standard formats or syntax, leading to significant losses of data utility and requiring extraordinary efforts to use shared information. The new paradigm of *Discovery Science*, as contrasted with the traditional *Hypothesis-Driven* investigation, is seriously limited by the lack of widely used standards.

Thus, all areas of the biological sciences have urgent needs for the development of organized and accessible storage of biological data which incorporates the use of standardized syntax and file formats. The emergence of XML as a self-defining and common data format has been embraced by many in the life sciences. This has been accompanied by the use of SOAP and other tools to deploy data exchange via

Web Services. While this may be considered a form of biological database development, this approach is an attempt to enhance traditional database technology such as transaction-oriented relational database systems, which are often inadequate to serve many areas of the biological sciences. It is clear that collaboration between computer scientists and biologists continues to be necessary to design information platforms which accommodate the needs for variation in the representation of biological data, the distributed nature of the data acquisition system, the variable demands placed on different data sets, and the absence of adequate algorithms for data comparison, all of which are characteristic of biological science.

The continued advances in commercially available hardware and a greater emphasis on hardware clusters and grids are beginning to have a profound effect on computational biology. While in the past, traditional general-purpose hardware was inadequate for many of the most computationally intense problems, this condition has essentially disappeared as high-performance general-purpose instruments, commodity clusters, and grids have become more widely available. However, not only hardware limitations have affected the productivity of the computational biologist. There is a continuing need for new algorithm development to cover many tasks, especially real-time data analysis and comparisons between objects and images. Imaging technology is central to almost all of biology, and data representation through image construction remains an elusive but astoundingly powerful tool.

During the past decade there were dramatic advances in instrumentation and related methodologies for both light and electron microscopy. The advances lie not simply in higher resolution, but rather in a broader size range of structures that can be analyzed, more powerful methods for putting together the pieces of three-dimensional puzzles of cell form, and the addition of dynamic details of biological form and function, ranging from the subcellular to the physiological level. These approaches are computationally demanding. Computational resources have been expanding to meet these needs but remain inadequate for dealing with the massive data flow. As new experiential and computational approaches emerge in a few laboratories around the world, and as the ability to combine data from multiple instruments expands, the demand for better hardware and software continues. However, it is important that new software be developed within the context of the experimental research driving the needs; that is, there must be close collaboration between those developing the software and the groups carrying out research on static and dynamic structures.

X-ray crystallography and *NMR* are the major experimental methods for deducing macromolecular structures at atomic resolution. Both methods produce extremely large amounts of data and are entirely dependent upon the availability of powerful computers and sophisticated processing algorithms for the interpretation of raw data. In addition, there are fundamental scientific problems in both areas that require major computational advances. Substantial opportunities exist for combining structural information from several experimental techniques. This may provide the basis for a structural solution where only partial data is available from any single technique. With improved computational tools, combining physical data from a variety of sources has become more common. These developments will allow solutions to be obtained for structural problems which would otherwise be intractable. Analysis of errors in structures based upon experimental data from several sources also represents a significant computational challenge.

Advances in x-ray and NMR data analysis will lead directly to rapid developments in the field of protein-folding and structure-function prediction, which will be synergistic with developments in other areas of biology itself, and especially computational biology. Common problems of data representation, search strategy, pattern recognition, and data visualization appear in many fields. There is a particularly exciting synergistic relationship between the protein-folding field and the fields of structure determination by x-ray crystallography and 2-D NMR. Each field will benefit from rapid advances in the others. Improved folding algorithms provide a new way to attack the phase problem in crystallography, and new, more carefully refined protein structures provide rich new insights into protein folding.

Computational neurobiology is one of the most rapidly developing areas of computational biology. It gives us the hope of interpreting the mass of anatomical and physiological information about the nervous system, much of it derived from diagnostic testing, that is now available in functional terms. Better integration and interpretation of these data will permit neurobiology to make contact with other fields such as psychology and artificial intelligence. This work is making specific, testable predictions in the

areas of sensory perception (visual, olfactory, and auditory), memory, learning, and motor control. Above all, it will lead to the integration of all these aspects to provide an eventual understanding of the total functioning of the nervous system. Such integration can be expected to provide new insights that will lead to improvements in the treatment of diseases of the nervous system at all levels, from neuropharmacology to psychotherapy.

The area of *genome analysis* has been, and continues to be, a major focal point in computational biology, and much progress has been made over the past few years. The sequencing of the human, mouse, rat, and fruit fly genomes in the past few years has challenged computational biologists and statisticians in many areas. While robust approaches to both **linkage mapping** and **physical mapping** were developed in the past, a new set of genetic challenges emerged from the genome sequencing effort. The human genome contains a wide variety of gene variations, or *polymorphisms*, that are responsible for the unique character of each individual, including inherited disease. A single human genome contains millions of these polymorphisms, and the detection and statistically valid association of a particular polymorphism with a given trait is now a major problem in computational genomics.

In many cases this analysis requires the ability to analyze tens of thousands of markers in family pedigrees. To be fully useful in a meaningful quantitative sense, this analysis will require powerful computer simulation and modeling. Major algorithmic advances have been made in the area of sequence assembly and clone assembly in physical mapping. As biologists continue to pursue the rapid sequencing of many genomes, the most common strategy is to use “shotgun sequencing,” which relies on the assembly of random fragments. While powerful assembly algorithms have been developed, many in the field still consider this an important problem.

Common to all of the problem areas mentioned is the need for good visualization of data. Visualization is necessary because the map and sequence analysis phase for a molecular biologist is equivalent to exploratory analysis for a statistician. It is at this point that the experimentalist gains the feeling for, and understanding of, a physical or linkage map or sequence, which may then guide many months of experimental work. The complexity inherent in biological systems is so great that very sophisticated methods of analysis are required. These are the tools that must be readily accessible to molecular and cellular biologists untrained in computer technology.

Ecology and evolutionary biology encompass a broad range of levels of biological organization, from the organism through the population to communities and whole ecosystems. This complexity demands computational solutions. The need for enhanced computational ability is most evident when one attempts to couple large numbers of individual units into highly interactive and largely parallel networks, whether at the tissue, community, or ecosystem level of organization. The proliferation of information from remote sensing introduces the need for geographical information systems that provide a framework for classifying information, spatial statistics for analyzing patterns, and dynamic simulation models that allow the integration of information across multiple spatial, temporal, and organizational scales.

What follows is an examination of several specific areas of computational biology, with particular emphasis on those areas related to molecular biology, and a short development of the experimental paradigm and highlights of the current computational challenges regarding the requirements for further development of that area. There are common themes that appear in several of the sections, and these themes deserve special attention because they appear to be limiting the development of the entire field, regardless of the specific area of research. (This review will not attempt to cover the important areas of computational neuroscience and ecology and evolutionary biology in any further detail. Both fields are rich in computational challenges and theory and, like some of the areas covered here, deserve a chapter of their own.)

34.2 Databases

Biology is inherently information-rich because of the complexity and variety of living systems. Understanding these systems requires information about their organization, structure, and function at a multitude of levels, from the macroscopic to the molecular. Moreover, each species (and in many species, each organism)

represents the potential for a unique solution to the problems of life processes and the organism's interaction with the environment. The full understanding of biology requires extending organismic complexity to include the relationships of species and organisms in their ecological niches, as well as the evolution of the biosphere over time.

Historically, much of this information was accessible to scientific inquiry only at high levels of abstraction, so that the inherent richness of information was not reflected in the volume of data available. This situation has changed dramatically in a number of biological fields, among them molecular biology, neurobiology, ecology, and taxonomy. This change has been made especially dramatic by the ubiquitous use of the World Wide Web (WWW). Emerging scientific paradigms will require even more data, organized into large and dynamic databases to support ongoing biological research. Indeed, some aspects of modern biology (e.g., the various genome projects, systems biology or protein structure–function studies) are now utterly dependent upon database and computer technology. In many cases, current data collections are not well organized for ease of retrieval or error correction but remain central to work in a given field. For example, several important macromolecular databases are maintained as flat files, poorly delimited and not accessible to ad hoc queries because of the absence of well-structured fields. Because of the importance of such data, investigators around the world struggle to find solutions to ready access and query. The reliance of modern molecular biology on databases is exemplified by the heavy dependence on the collection of DNA-sequence data (GenBank, EMBL, and DDBJ). These databases contain the definitive public domain DNA sequence data. However, because of the difficulty in the use of such data, and the large-scale generation of proprietary data, a new group of commercial data sets has become available (e.g., the Celera Discovery System, Incyte's LifeSeq, Gene Logic's GeneExpress, etc.).

As a result of this need, a substantial number of people now devote their careers to data management and computational analysis in biological disciplines. However, despite significant and vigorous efforts, the present generation of biological databases will fail in the next decade without significant continued development. They were not (and could not have been) designed to deal with the volume, complexity, and diversity of the data that will need to be accessible for future biological research.

The explosion of data is derived, in large part, from the desire of increasing numbers of investigators to have shared data repositories. The pressure on databases is severe in a quantitative sense, but is equally daunting in terms of the diversity and the interrelationships that must be represented among the data. These problems are further complicated by the way data is generated in biological research, which is geographically dispersed and, more importantly, lacks any meaningful standardization. Taken together, these problems pose unique transdisciplinary challenges for database design. Indeed, it is important to note that a single technology is not yet in hand that can support the design of adequate databases for much of the biology of the next decade. In fact, the application of the term "database" itself tends to be misleading. Database technology and theory as it currently exists is an inadequate paradigm for what is needed now and in the future to represent and organize biological information. For example, biological data includes mixtures of measurements, images, and interpretation, including extensive collections of metadata and derived data. Ideally, each of these data types would be available to ad hoc queries. At present, only a few extended relational systems have addressed these needs, and without complete success. The most recent focus has been to define this data in an XML format that enables the development of a variety of solutions to access and analysis, including access through Web services models.

Biologists have become increasingly sophisticated in their use of computers and in their abilities to state their research requirements in terms of informational and computational strategies. Biological science is now posing questions that not only require computational solutions, but also provide problems of fundamental interest to computer science researchers, thus creating the possibility of effective interdisciplinary work. Fortunately, there is a growing community of transdisciplinary workers whose expertise is centered at the interface of biology and computing, and who can provide much of the insight into how the two fields can interact productively.

One of the principal challenges in scientific computing in the next decade will be the development of database systems that can handle the inherent complexity of biological information and the marriage

of those systems with visualization tools that enable laboratory scientists to interpret and understand the data and analytical results. The existence and availability of such databases will transform the way the science is done, and make possible completely new paradigms of biological research. Meeting this challenge will require the construction of databases in fields where none are available, significant research and development in database and knowledge-base technology, and the provision of a robust and widely available computational infrastructure for biological science through new algorithmic approaches to data analysis and tools to embed database access into analysis and modeling.

34.2.1 Access and Communication

The emergence of the World Wide Web has revolutionized access to biological databases. Because the subdomains of biology are fragmented, it has been necessary to develop many distinct and customized databases. The fact that there is little semantic consistency between these databases has raised a significant barrier to linking them through standard query mechanisms. Several investigators have built hypertext-based linkages between a number of different databases, bringing together a richer data resource. One representative of the several available systems is the Biology Workbench developed at the San Diego Supercomputer Center and the University of California, San Diego (<http://workbench.sdsc.edu/>). Another approach to database linking through a common interface was developed by the European Molecular Biology Laboratory (EMBL) and has been commercialized and further refined by Lion Biosciences (<http://www.lionbioscience.com/solutions/products/srs>). The tool, termed SRS (sequence retrieval system), enables a scientist to use common terms to query a variety of databases and then to establish links between them based on common features and cross references. However, it does not enable *ad hoc* SQL queries across all data sources.

As powerful as the WWW-based systems are, they still lack the potential for supporting complex *ad hoc* queries that would be achieved through a true federation of biological databases. The need for such a federation has been recognized most acutely in the genomics community, and the outlines for such a federation were developed several years ago [Robbins 1994]. It was suggested that for minimum technical linkage, all of the participating databases present similar **APIs** (application programming interfaces) to the Net. All of the databases in the federation should also be relational systems that support SQL queries. Ideally, these databases should (1) be self-documenting, (2) be stable, and (3) conform to agreed-upon federation-wide semantics. The problem with this strategy is that in many cases it places the goals of the federation in conflict with the rapidly changing nature of biological research and the needs of the specialty user community. To cope with these problems, several systems have been developed to integrate heterogeneous databases. The two most common are DiscoveryLink developed by IBM and discoveryHub developed by GeneticXchange. Both approaches utilize an intelligent broker architecture with a series of wrappers that describe the specific databases they are linking. Neither has fully solved the problem of the semantic inconsistency of biological databases; however, discoveryHub has attempted to approach this problem through a semantic translator.

34.2.2 Representation/Data Modeling

To enhance the continued development of shared data resources, we must increase database expressiveness, study representation of biological knowledge, and automate modeling of database schemas. Biological knowledge is extremely rich and diverse; it includes raw experimental data (images, numbers, symbols); interpretations of experimental data (descriptions of biological objects with complex properties and internal structures); descriptions of experimental methods (complex procedures); and theoretical knowledge (documents, equations, descriptions of processes such as gene expression). Existing database technology provides a small number of simple representational primitives (such as relations); allowing databases to capture only a small piece of this rich biological semantics. Research is needed to provide richer representational capabilities, and to study how to represent the wide range of biological knowledge. Further, because biological databases will model a large number of complex entities, biological database schemas

will be correspondingly complex. Researchers must investigate automated methods of managing database schemas to increase the efficiency of the database design process.

34.3 Imaging, Microscopy, and Tomography

Image reconstruction with light and electron microscopy and other imaging techniques is a powerful tool for the characterization of biological structures in three dimensions over a wide range of scales. Biological structures amenable to one or more techniques of imaging include single macromolecules and macromolecular assemblies, subcellular organelles, whole cells, and tissues. Characterization of the spatial organization of biological structures is critical for determining the functionality of these structures. Many fundamental problems in biology are open to study by microscopy and other imaging techniques. The advances in computer-controlled scanning microscopies, high-resolution atomic-force microscopy, and cryoelectron microscopy have substantially expanded the level of detail that can be attained by these methods.

The continuing advances and widespread applications of **transmission electron microscopy** at conventional, intermediate, and high voltages (with and without energy filtration), as well as confocal light microscopy, are leading to the production of vast amounts of data that need to be processed to extract the structural information and biologically important details. Each of these techniques can produce three-dimensional images of biologically important structures. Successes in these studies do not imply that the technical problems have been solved; currently, there remain substantial computational challenges to meet before achieving the goal of making efficient use of these techniques. These challenges include developing improved image processing and reconstruction algorithms.

In transmission electron microscopy, there have evolved three distinct methodologies for producing three-dimensional information: (1) electron crystallography of two-dimensional lattices and the processing of images of symmetric structures; (2) the analysis of multiple images of isolated asymmetric macromolecular assemblies; and (3) electron tomography, or three-dimensional reconstruction from a tilt series of images obtained from a single structure. Confocal light microscopy (CLM), a tool used in cell biology, produces three-dimensional images by scanning light focused to a single point over a three-dimensional grid in the specimen, and then imaging the light onto a point detector. Compared to conventional microscopies, CLM has a somewhat higher resolution and a much smaller depth of field, minimizing mixing of image data from different depths in the specimen.

The success of these methods has been substantial (Fernandez et al., 2002). This has stimulated the development of a comprehensive user-oriented facility, the National Center for Microscopy and Imaging Research (NCMIR). Generally known as the *Telescience Portal*, it is used by molecular and cell biologists, electron microscopists, and computer scientists around the world. The portal links instruments and computers at laboratories in Europe, North America, and Asia over a dedicated IPv6 network. NCMIR's central instrument is a state-of-the-art 400,000-volt intermediate-voltage transmission electron microscope equipped with charge-coupled detectors (CCDs) and can be operated under complete computer control and via the Internet. Because of its design, the instrument is able to penetrate thicker samples than conventional electron microscopes and is therefore particularly good at 3-D reconstruction. In collaboration with Japanese scientists, the portal also provides network-base access to a 3-MeV ultrahigh-voltage electron microscope. These resources are also linked to high-performance computing facilities in Taiwan and San Diego. Thus, the Portal is an applications environment supplying centralized access to all of the tools necessary for high-level electron tomography. A full description of the Telescience Portal and a related facility (the Biomedical Informatics Research Network (BIRN)) is available at <http://www.ncmir.ucsd.edu>.

Use of these imaging techniques entails three fundamental problems. The first is the vast quantity of data being produced that requires complex processing. This is a problem common to all imaging techniques within and outside biology. For example, cryoelectron-microscopic analysis of icosahedral viruses involves sample preparation followed by microscopy followed further by a series of computational steps, many of which are very computation-intensive [Cheng et al. 1995]. Because of the limited computing power available, only a limited number of independent images can be analyzed. However, three-dimensional images are intrinsically complex, and the amount of information required to characterize an image in

detail is very high. For example, construction of the three-dimensional image of a molecule from electron-microscope images of single particles routinely requires thousands of particle images. This means that the actual time to produce a three-dimensional image is weeks to months, due in large part to the user-mediated steps that remain in the analysis. For efforts like this to prove maximally fruitful, it is crucial that each step be automated as much as possible.

The second fundamental problem common to all imaging techniques is the existence of a point spread function due to the instrumental broadening that is intrinsic to each form of imaging. For example, transmission electron microscopy loses a cone of data in the Fourier transform of the image, and the restoration of this cone represents a difficult, open problem. In **scanning confocal microscopy**, the point spread function is greatly extended in the direction parallel to the optical axis, and narrowing it could improve the resulting three-dimensional images.

Third, the results of any imaging method must be quantitated and displayed. The problems of image enhancement and visualization are completely general, although each technique may benefit more from specific display modes than others. Quantitative comparison of images also provides substantial challenges, especially in the presence of noise. Comparison of two images of flexible objects (e.g., cells or chromosomes) represents a substantially greater challenge.

One of the recurring problems common to all imaging techniques is the existence of artifacts due to incomplete data collection. These artifacts may seriously interfere with the interpretation of the reconstruction, and may even lead to incorrect conclusions. This problem is most serious in electron microscopy, where a full range of viewing angles is not usually accessible, and data corresponding to a cone or wedge in Fourier space cannot be collected. In confocal microscopy, the resolution in the z -direction (parallel to the optical axis) is much lower than in the x and y directions, as reflected by a nonisotropic instrumental point spread function.

Although several restoration algorithms have been in existence for some time, only the recent increases in computational speed have made their practical implementation possible. Two algorithms with potential application to signal restoration have attracted special attention due to their success in other fields — projection onto convex sets (POCS) [Bellon and Lanzavecchia 1995] and maximum entropy (ME) [Schneider et al. 1995]. Both methods are extremely computation-intensive, making their application to realistic-sized image volumes ($64 \times 64 \times 64$ or $128 \times 128 \times 128$) extremely demanding. The full development of these algorithms into something useful for detailed images of biological systems will require many computation cycles, to allow many different parameter values to be tested (ME) or a variety of different constraints to be used (POCS). Thus, a serious attempt to make three-dimensional image restoration viable for biological images will always require the highest available computational speed, along with advances in the theory and design of algorithms.

34.4 Determination of Structures from X-Ray Crystallography and NMR

The three-dimensional structures of proteins and nucleic acids are essential elements in the pathway relating gene sequence to function. The problem of predicting three-dimensional structure from a sequence remains unsolved at present. X-ray crystallography and NMR are the major experimental methods for deducing these structures at atomic resolution. While the rate at which these structures are being determined has increased dramatically, it lags significantly behind the rate at which new sequences are being accumulated. Each newly determined structure increases our knowledge in two ways. First, it adds to the database of known structures that can be used in knowledge-based methods in subsequent structure determinations of other macromolecules. Equally important, each new structure provides insights into the fundamental biological processes that support all life.

NMR and x-ray crystallography both produce extremely large amounts of raw data and are entirely dependent upon the availability of powerful computers and sophisticated processing algorithms for the interpretation of those data. In addition, there are fundamental scientific problems in both areas that

require major computational advances. Both NMR and crystallography make use of constraint refinement to optimize the fit of experimental data to working models, and both fields use large scale-simulations to correlate the molecular models to known biological properties. Like investigators in three-dimensional microscopy, crystallographers and NMR spectroscopists are using maximum-entropy reconstruction as a major tool in computational analysis.

34.4.1 Determination of Macromolecular Structures from NMR Data

NMR methods for determining three-dimensional structures of macromolecules in solution have become increasingly important over the past several years. Major limitations on the speed and ease of analyzing the NMR data include the difficulty of assigning individual resonances in the spectra to particular protons in the molecule and then of calculating the full three-dimensional structure using distance geometry, molecular dynamics, or algorithms. For example, when determining the structure of a 100–150-residue protein, it may take as much as two weeks of NMR spectrometer time to collect the raw data, two or three days to calculate the spectra, and months or years to fully interpret the results. The complexity of this process depends on both the size of the protein and the extent of peak overlap within the spectra. Because this is the critical bottleneck in obtaining the structural information, it limits the size of molecules that can be considered. One critical element is the solubility of biological macromolecules. The balance between solubility and the sensitivity of modern NMR equipment places the current lower limit on concentration at around 0.5 mM. Many proteins, especially those of high molecular mass, aggregate at such high concentrations, leading to broad spectral lines of no value in structural studies. The solution to this problem lies with the development of enhanced computational approaches, such as maximum-entropy reconstruction of specially collected data sets. This approach requires approximately 100 times the computational work of traditional discrete-Fourier-transform processing. The refinement of this approach will require the continued collaboration of structural biologists and computer scientists [Schmieder et al. 1995]. Future advances in algorithms, software development, and the availability of more powerful computers will make a major impact on the time required to interpret NMR data.

A critical step in interpreting the data is to use the relationships between protons signified by two-dimensional (or three-dimensional) crosspeaks to assign the resonances to particular protons in the molecule. Assignment is frequently the rate-limiting step in structure determination. There are a number of different strategies for assignment, and approaches to automate this process are under active investigation. It is clear that several approaches will be necessary to deal with the problems associated with ambiguous data. Both the **sequential** and **mainchain-directed** assignment procedures make use of patterns of *J*-correlated and distance-correlated relationships. In both cases, the procedure is still largely manual, although there have been recent attempts to automate parts of the analysis. The development of computer-assisted or fully automatic pattern recognition techniques would make a major impact on the time required to make the assignments, as well as the size of molecules that can be studied. This is particularly true as the complexity of the original NMR data increases.

Once protons have been assigned, a three-dimensional structure can be estimated using the peak areas from the **NOESY** spectrum to determine distance constraints. Extensive computing is required to calculate structures using distance geometry, molecular dynamics, or **Kalman filtering** techniques. Several refinements of the structure are needed, and a family of structures is usually generated. Recently, back-calculation of the NOESY spectrum has been used to try to refine the structure. The value of this procedure and the effect of using different techniques to calculate NMR structures still need to be established. However, both the development and application of this technique require major computing power.

34.4.2 X-Ray Structure Determination of Macromolecules

X-ray crystallography provides a fine example of how the availability of affordable supercomputers has dramatically sped up the rate at which x-ray structures can be determined. There are four major phases in crystal structure determination: crystal growth, solution of the phase problem, interpretation of the

resulting electron density in terms of an atomic model; and refinement of the atomic model. Up until very recently, the refinement of protein structures using x-ray data required substantial manual intervention and took one or more years to get to a satisfactory stage. With the incorporation of **simulated annealing** methods into the refinement procedure, the time required for this phase continues to decrease as more computational power becomes available. It should be noted that while the established protocols for simulated annealing can now be run fairly comfortably on workstations, the original development and testing of the method required the availability of supercomputers such as the Cray.

The fundamental problem in protein crystallography is the **phase problem**, which, with the improvement in refinement techniques, has become the major bottleneck in the structure determination process. The current method of multiple isomorphous replacement (MIR) relies on measuring data using crystals of the protein soaked in different metal compounds. The soaking procedure does not always yield suitable crystals, and in some cases the lack of metal derivatives delays the determination of the structure. Attempts to solve the phase problem without resorting to MIR or other experimental techniques fall into two classes:

1. *Ab initio phasing.* This does not rely on any additional experimental information other than that provided by the x-ray data set on the native protein crystal. Methods that have been successful for small molecules break down in the range of 100 atoms or so, well below the range of 1000 atoms or more in protein molecules. The availability of more computing power is gradually leading to the extension of some of these methods to larger polypeptides, and intensive computational effort may yield success for the smaller proteins (approximately 50 amino acids). The *ab initio* solution of virus structures may be aided by taking advantage of their high degree of noncrystallographic symmetry. If an adequate starting model is available, then these techniques allow the extension of phases directly over a wide resolution range [Rossman et al. 1985]. Novel approaches, such as those based on maximum entropy, may also provide computational tools that will have a substantial impact on obtaining phases for diffraction data.
2. *Use of prior knowledge.* In cases where the three-dimensional structure of a closely related protein is known, the phase problem can be solved using the known structure as a starting point for refinement (*molecular replacement*). Computation-intensive methods such as simulated annealing have proved particularly valuable here, because significant distortions may have to be introduced into the starting structure and the optimization procedure needs to escape from the local minimum of the starting structure. The inclusion of prior knowledge into phase determination is likely to become extremely important in the near future, because it is becoming clear that proteins are built up from smaller subunits or segments that are commonly shared between large numbers of proteins. As the database of known structures increases, it should be possible to use segments of structures in search procedures to solve the phase problem. There is a need here to develop and apply novel search procedures and pattern recognition algorithms, many of which will also be applicable in the next stage of the structure determination.

Noisy electron density maps are difficult to interpret manually because of false or missing connections in the electron density. It is not uncommon for a structure determination project to arrive at this stage rapidly, once crystals are obtained, and then to spend a long time getting a better electron density map (the phase problem). Computing is essential in two ways. First, phase bias from the model must be minimized by optimizing relative contributions from calculated and observed diffraction data. Second, rapid interactive refinement of difficult-to-interpret regions must be performed to help to solve the problem. This requires high-speed supercomputing and a fast network link between the supercomputer and a high-performance graphics workstation.

Even in the case of a well-defined electron density map, fitting an atomic model to these maps is a time-consuming process. The problem lies in automatic recognition of characteristic patterns of macromolecular structure, such as alpha helices, that cannot be achieved by existing algorithms. Because of the complexity of the three-dimensional pattern recognition, further advances in methodology and computing speed are required.

34.5 Protein Folding

Protein folding, recognized for many years as one of biology's core problems, remains a focus of much work and attention. Folding converts the linear, one-dimensional information of the amino acid sequence into the biologically active three-dimensional structure. Folding may be thought of as a final unsolved aspect of the genetic code, and it is clear that progress on the folding problem will have tremendous theoretical and practical implications for biology. As described above, there have been dramatic advances in crystallography and two-dimensional NMR, and the virtual explosion of protein sequence data reemphasizes the importance of working on the folding problem. Even limited progress in this area could have a tremendous payoff, especially because of the recognition that such diseases as cystic fibrosis, Alzheimer's, Creutzfeldt-Jacob (human form of Mad Cow), and many others are protein folding-related problems [Dobson 1999, Fink 1998, Hammarström et al. 2003]. The *protein folding problem* can be considered either as:

- The problem of understanding the actual kinetic pathway by which a protein folds, or
- The problem of predicting the final folded conformation.

Obviously, a detailed structural understanding of folding intermediates would lead to a prediction of the final folded structure. However, experimental studies of folding intermediates have been very difficult because the intermediates are present in vanishingly small amounts. The rich database of known structures provides an excellent guide regarding the final folded conformation and can serve to guide theoretical work. In addition, there is an evolving literature regarding fruitful experimental approaches [Hammarström et al. 2003].

At first glance, the protein folding problem may seem to have a tantalizing simplicity (a given string of 100 amino acids contains all the data needed to determine the final folded structure), but the problem is extraordinarily complex. If each residue in a polypeptide chain can adopt ten distinct conformations, then the protein could adopt 10^{100} distinct structures, which leads to an extraordinarily difficult search problem. Many different strategies have been used in approaching the folding problem. Some methods have relied on detailed physical models of the polypeptide chain and have tried to carefully simulate the interactions (hydrogen bonds, van der Waals contacts, electrostatic interactions, etc.) that stabilize the chain. Other methods rely on the structural database that has accumulated over the past decades. In some sense, it appears that "structure is more conserved than sequence," so that the structural database is a useful guide when modeling new proteins.

Current approaches to the folding problem can generally be placed into one of two methods: direct determination of the folded conformations, or a template-based method. Direct methods seek to determine the lowest acceptable energy point in a suitably defined conformational space. Template-based methods compare the sequence of the unknown with a collection of solved structures and select a limited number of highly scored possibilities [Luthy et al. 1992, Sali et al. 1994].

One core problem with direct methods is the difficulty of searching through the astronomical number of possible structures. A naive calculation may suggest that there are 10^{100} conformations, yet it is clear that only "a few" of these are of low enough energy to be plausible structures or plausible folding intermediates. The multiple-minima problem arises repeatedly in studies of folding. Both physical approaches (based on a detailed molecular potential surface) and pattern recognition schemes (based on analogy) encounter the same problems with multiple minima.* Stochastic search algorithms have proved especially useful in handling problems with multiple minima, and the method of **simulated annealing** is frequently used. This method corresponds to a simulation of the molecular dynamics under the influence of random thermal forces. Other search algorithms involve buildup or stochastic buildup based on genetic algorithms. To estimate the difficulty of the multiple-minima problem in protein folding, it is possible to draw upon

*The same search problem occurs in other parts of computational biology, including sequence comparison problems in genomics, neural networks, and immune-network modeling.

some parts of statistical physics for help. Simple lattice models have been used to estimate excluded-volume effects after polymer collapse, and these models indicate that the number of allowed conformations may be far smaller than suggested by the initial naive estimates. This result is very encouraging because it suggests that the search problem can focus on a much smaller region of conformational space.

Detailed atomic models have been used to study protein folding and stability. The models are based upon well-understood principles of physical chemistry and have been used in conjunction with molecular dynamics and Monte Carlo methods to study the underlying forces that determine the stability of folded proteins. The application of free-energy perturbation theory has been a particularly exciting development. These approaches are beginning to provide a much better understanding of the key forces involved in protein folding and stability, such as the true role of electrostatic interactions and the origin of the hydrophobic effect. Continued close interactions between experimental biologists and computational/theoretical researchers have also been extremely important for this field. Theory can help design new experiments, and better data can allow the refinement of basic physical models.

Although not directly linked to the protein folding problem, an extremely important area of computational biology involves the molecular modeling of protein function. A molecular understanding of enzyme catalysis can now be approached through a combination of molecular dynamics and quantum chemistry. There have been many applications of this approach, and important insights about the mechanism of triose phosphate isomerase have recently come from such simulations. Another exciting area is the recent development of computational approaches to modeling electron transfer. This a fundamental and inherently quantum-mechanical process involved in energy transduction and photosynthesis. Signal transduction is another extremely important and active area of research. This involves problems of docking and protein-protein recognition. Allosteric transitions are a frequent consequence of such interactions, and new methods for studying protein motions on long timescales are being developed [Gilson et al. 1994].

Much information has been derived from the ability to clone and express a protein of choice, followed by deliberate mutation of individual residues or larger segments. Perhaps the simplest application of folding that can be envisioned would be to predict the structural perturbation caused by a single-residue mutational change in a protein of known structure [Hammarström et al. 2003]. However, frequently, such mutations do not result in major rearrangements of the chainfold, as shown by the work of Kossiakoff [Eigenbrot et al. 1993] and others. While the structural effect of single-site changes has been successfully predicted in some cases [Desjarlais and Berg 1992], there are many conspicuous failures, and clearly more work is needed. At the level of larger segments, attempts to predict antibody hypervariable loops have also met with partial success [Tramontano and Lesk 1995; Pan et al. 1995]. Recent experiments suggest that deletion of entire loops can be tolerated while partial deletions of the same segments are not. Such results suggest the existence of quasi-independent modules, which would simplify calculations.

34.6 Genomics

Genomics is the study of DNA and its products at the genome level. This includes both experimental and theoretical aspects of the problem. For the computer scientist, the interest lies in the discrete domains and output of the system; for the biologist, the goal is to reveal the function of a sequence, either of the DNA or, more commonly, of the protein gene product. The biological effort includes genetic mapping, physical mapping (restriction maps, ordered clones, x-ray diffraction maps, cytogenetic maps, and sequence assembly), and sequence analysis including polymorphism identification and location. There is a natural division of the work into two major computational areas: support for the construction and representation of various maps, and analysis of the data produced. This overlaps at the boundary with computation involved in the analysis of protein folding and interacts with work to assign function to gene products. The systematic effort to map genomes in the presence of variability and error also mandates the use of new computational techniques to assist in the design of efficient experiments. Beyond this, there are four major areas in which the use of computers is indispensable: database searching for DNA sequence analysis, maximum-likelihood calculations for genetic linkage mapping, DNA sequence assembly, and general bookkeeping (e.g., laboratory information management systems).

34.6.1 Genetic Mapping

Genetic mapping deals with the inheritance of certain genetic **markers** within the pedigree of families. These markers can be genes, sequences associated with genetic disease (polymorphic regions, often single nucleotide changes), or arbitrary probes determined to be of significance [e.g., single nucleotide polymorphisms (SNPs), sequence tagged sites (STs), or expressed site tags (ESTs)]. The sequence of such markers and their probabilistic distance (traditionally measured in centimorgans and now in many cases in megabase pairs) along the genome can often be determined with fair accuracy by the use of maximum-likelihood methods. Inheritance of traits across the pedigrees of multiple families is determined by a number of techniques that essentially hybridize each family member's genome against the predetermined probes. Eventually, the genetic map most likely to produce the observed data is constructed. Only a few years ago, the knowledge of the mathematics involved and the computational complexity of algorithms based on that mathematics limited analysis to no more than five or six markers. As knowledge of approximations to the formulas and likelihood estimation has improved, software capable of producing maps for 60 markers or more [Magness et al. 1993, Matise et al. 1994] has been developed. Early advances in this area include the identification of a large number of SNP and EST probes as well as software capable of tractably producing maps based on hybridization pedigree data [Cinkosky and Fickett 1993]. Further progress in this area has used mathematical methods such as combinatorics, graph theory, and statistics, and computer science methods such as search theory. Although significant progress has been made over the past few years, considerable effort is still required to make genetic linkage maps effective tools for genetic research.

The human genome contains a wide variety of gene variations that are responsible for the unique character of each individual, including inherited disease and genetic susceptibility to disease. These variations also predict a variety of responses to external factors such as chemicals and drugs. These variations are of several types and two individuals may vary by as many as 5 million locations. The association of these variations with specific traits is a significant mathematical and computational challenge. Furthermore, tools to address more complex situations (such as manic-depressive disease, which is likely to involve multiple genes) are badly needed.

34.6.2 Sequence Assembly

The recent successes in sequencing the fruit fly [Adams et al. 2000], mouse [Waterston et al. 2002] and human [Lander et al. 2001, Venter, et al. 2001] genomes were derivative of a rapid sequencing and **sequence assembly** technique that was intensely computational. The assembly technique is referred to as a "shotgun assembly" process. Shotgun assembly is an example of an inverse problem: starting with a set of sequence reads randomly sampled from a target, reconstruct the order and position of those fragments in the original target. In this case, fragments of a genetic sequence are randomly sampled, and then experiments are performed on the fragments to determine which pairs of fragments come from overlapping regions [Iris 1994]. This overlap information is then used to piece together, or assemble, the fragments into an ordered layout of the fragments that covers the original genetic sequence (see [Venter et al., 2001] pp. 1308–1319 for a complete description and an example). This problem can be solved using multiple strategies but relies on the existence of multiple data types to establish a physical scaffold onto which the assembly is placed. For example, the Celera whole genome assembler (WGA) has a five-stage process: Screener, Overlapper, Unittigger, Scaffold, and Repeat Resolver. This is a very computer-intensive process, taking days with current state-of-the-art hardware. Every overlap computed was statistically a 1-in- 10^{17} event and, therefore, not a coincidental event.

The sequence assembly problem has been extensively examined and several solutions have been applied. Venter et al. [2001] assembled the human genome using the Celera WGA as described above, while a somewhat different assembly approach was taken by Kent and colleagues for the public version of the genome [Lander et al. 2001]. As additional large genomes are solved, the assembly problem will continue to be further refined and computational efficiencies achieved. This continues to be an exciting and productive interface between computer scientists, mathematicians, algorithmists, and bioinformaticists.

The assembly problem is further compounded by the fact that all the data is inaccurate (e.g., digest lengths are off by up to 10%, electrophoretically determined sequences contain 0.5% incorrect base assignments, etc.). One approach to dealing with these problems has been developed by Phil Green, the author of the Phred [Ewing et al. 1998, Ewing and Green 1998] and Phrap programs (<http://www.phrap.org>). Phred reads DNA sequencer trace data, calls bases, assigns quality values to the bases, and writes the base calls and quality values to output files. Phrap is a program for assembling shotgun DNA sequence data. Key features are that it allows the use of entire reads (not just trimmed high-quality parts); uses a combination of user-supplied and internally computed data quality information to improve accuracy of assembly in the presence of repeats; constructs contig sequences as a mosaic of the highest quality parts of reads (rather than a consensus); and, provides extensive information about assembly (including quality values for contig sequences) to assist in troubleshooting. It is able to handle very large datasets and was influential in the subsequent development of more complex assemblers.

Additionally, the data is partial, not all regions of the original are represented in the sample, and the orientation of fragments is frequently unknown. Other issues involve the amount and type of information gathered to infer overlaps. More information implies more confidence in the veracity of an overlap, but some false positives will occur by chance. Consequently, it is likely that when building a scaffold from ordered clone libraries, a variety of different experiments yielding heterogeneous types of information will be performed and must be used simultaneously to detect overlaps. A key analysis problem is to accurately assess the statistical significance of overlaps under some stochastic model. Another issue involves how much to sample. Statistical and biological considerations show that for large problems with moderate overlap information, one will never achieve coverage without an impractical amount of sampling. This is the gambler's dilemma: at some point one must stop rolling the dice and move to another strategy to complete an assembly project.

While preliminary solutions to genome analysis have been of great use, many challenges remain, including:

1. The scale of the problems is such that they are computationally demanding. Better algorithms and the exploitation of parallelism are required.
2. Each assembly problem has a somewhat different combinatorial structure due to variations in the experimental methods used to infer overlaps. There is clearly a central generalized assembly problem, but each variation requires its own optimization to best leverage the combinatorial structure. However, many of these projects are one-time efforts. The challenge is to build software that is both general and efficient.
3. The resulting assemblages are large, and software is needed that permits one to visualize and navigate a solution. Further engineering is required to allow investigators to manipulate solutions according to their expert knowledge, and to maintain versions of the data and a record of the work.
4. Finally, the central assembly problem involves NP-hard combinatorial problems for which heuristics work well on typical data. But as the scale and number of the problems to be solved increase, we will need ever more trustworthy solutions [Goldberg et al. 1995].

34.6.3 Sequence Analysis

Database searching has become an essential part of modern molecular biology. Database searching is our most effective means of identifying a potential biochemical function of a newly sequenced protein or gene. It is hard to imagine the number of hours of trial and error that are eliminated by the advent of this technique.

34.6.3.1 Matching a Defined Pattern

The need for speed in database searches has led to using heuristic methods. Current research topics in this area include the improvement of the sensitivity of searching, which can be severely reduced by the overall nucleotide composition of the genomes involved. Database searches are generally conducted with a global alignment algorithm that finds the "best" alignment over the entire length of both sequences. Recent

advances in our understanding of domain structure of proteins and the intron–exon organization of genes has made it very desirable to develop a fast, sensitive local alignment search algorithm to identify regions within a pair of sequences that show the highest similarity. Currently, the most promising approach to this is an implementation of one of the rigorous dynamic programming local alignment algorithms on very highly parallel hardware [Lim et al. 1993].

Several other searching techniques are widely used by experimental molecular biologists as aids for guiding and interpreting experiments. These include things as simple as finding the highly hydrophilic and hydrophobic regions in a protein sequence or regions capable of forming helices on the surface of a protein. Finding specific patterns of codon usage in a newly sequenced gene can yield insights into its expression, and finding the intron–exon junction is necessary before the correct protein sequence can be derived from a genomic DNA sequence. There are several important research topics in searching for signals. First is the need for procedures for easily and clearly specifying very arbitrary, complex patterns in a sequence. Faster algorithms for finding these patterns are needed as well. In many cases, the patterns, or biological signals, that are being sought are too complex to be readily identified by visual inspection of sequences. This is especially true if some variation is permissible in the signal pattern. Thus, another important research topic is better algorithms for selecting the most likely patterns to be associated with a signal in a sequence. For example, given several genes known to contain exons, from a single organism, how do we discover the pattern that signals the beginning and end of each exon? A variety of tools have been applied in the large genome projects [Adams et al. 2000, Lander et al. 2001, Venter et al., 2001] and further refinement is still needed.

34.6.3.2 Alignment

Sequence alignment is an important type of searching. It is, basically, the search for the most similar juxtaposition of sequences or regions within sequences. Good alignments are necessary if our inferences about the homology of genes are to be accurate. Even more crucially dependent on good alignments are methods for reconstructing phylogenies based on sequence data [Steel et al. 1994]. Finally, some problems in identifying signal patterns are appreciably simplified given well-aligned sequences. Fortunately, the state-of-the-art in pairwise sequence alignment is well-advanced. There are rigorous algorithms for both global and local alignments of pairs of sequences. These algorithms allow both flexible and sophisticated treatment of insertion/deletion gaps. One possible topic for research in this area is the context-sensitive treatment of these gaps. This would include cases where an insertion/deletion would change the reading frame of a coding region in a gene sequence or change the relative positions of amino acids known to be essential to protein function.

Multiple sequence alignment techniques are not as far advanced as the pairwise techniques. The rigorous pairwise algorithm can be, and has been, extended to multiple sequence problems. However, this approach requires computer time and memory proportional to the product of the lengths of the sequences. Recent advances have reduced this requirement by a large constant factor. However, even with this improvement, this approach soon exhausts even the fastest present-day computers. If a phylogeny of the sequences is available independent of the sequences themselves, it can be used to convert a sequence alignment problem into a series of pairwise problems. However, because a frequent reason for doing a multiple sequence alignment is to generate a phylogeny, this is not a general solution. Thus, a variety of heuristic algorithms are used for most multiple sequence alignment problems.

Several kinds of research are needed here. First, faster and more rigorous algorithms are required. Where algorithms are not completely rigorous, we need to characterize their performance so that we know how close to an optimal solution we can come. We also need to identify what sequence features might cause an algorithm to perform badly.

Defining Terms

API: Application programming interface. An API provides a wide and varied set of functions, messages, and structures that give applications access to the features and capabilities of the underlying

operating system. The API consists of a set of standard interfaces to such features as window management, graphics device interface, system services, multimedia services, and remote procedure calls.

Clone assembly: The essence of experimental physical mapping is the ordering and placement of fragmented regions of chromosomes in an overlapping contiguous stretch of DNA that covers the entire chromosomal interval. The DNA fragments are derived from the original DNA and each fragment propagated independently (cloned) to obtain working quantities. Fragment overlaps are determined by hybridization experiments with unique DNA sequences that will permit the unique identification of a chromosomal region. This is a computationally difficult problem.

Kalman filtering: A digital-image averaging procedure for the enhancement of the signal-to-noise ratio in noisy images. The Kalman filter is a recursive version of the true averaging procedure, and takes the form $y_1 = (i - 1)y_i - 1/i$, in which the filter parameters are not constant but vary with the frame number i so that the latest averaged image y_n always equals $(x_1 + x_2 + \dots + x_n)/n$. This gives a straightforward average over n frames, with a maximum signal-to-noise ratio, without having to prespecify n .

Linkage and linkage mapping: The proximity of two or more markers (e.g., genes, DNA sequences) on a chromosome; the closer the markers are, the lower the probability that they will be separated during repair or replication, and therefore, the greater the probability they will be inherited together. A map of the relative positions of genetic markers on a chromosome, determined on the basis of how often they are inherited together, is referred to as a linkage map.

Marker: An identifiable physical location on a chromosome (e.g., a specific identifiable sequence such as a restriction-enzyme cutting site, or a gene) whose inheritance can be monitored. Markers can be expressed regions of DNA (genes) or a segment of DNA with no known coding function but whose inheritance can be followed with molecular techniques.

Mainchain-directed alignment: A technique for predicting protein structure from NMR data, based on aligning only mainchain residues and ignoring sidechain structures at the primary alignment stage. This technique ignores the complexity of the sidechain packing but suffers from distortions based on the effects of sidechain groups.

NOESY: Nuclear Overhauser Effect (NOE) Enhancement Spectroscopy. The NOE is a consequence of relaxation of dipole-coupled spins induced in magnetic resonance. The enhancement factor in NMR is the deviation from thermal equilibrium induced in one of a pair of dipole-coupled spins following the selective radiation of one of the pairs.

Phase problem: In x-ray diffraction structure determination, a collimated beam of monochromatic x-rays is directed through an object. The x-rays are scattered in all directions by the electrons of every atom in the object. The magnitude of the scattering is proportional to the size of the electron complement of atoms in the target. Because of the variable composition of the target, the scattering of x-rays appears continuous. However, when regular structures are radiated, and known heavy-metal ions are included, it is possible through a series of least-squares calculations to reassemble the phased waves of the diffracted x-rays and compute a clean electron density map.

Physical map: A map of the locations of identifiable regions on DNA (e.g., specific identifiable sequences or genes), *regardless of inheritance*. Distance is measured in base pairs. The physical map with the highest possible resolution is the entire nucleotide sequence of the chromosome.

Scanning confocal microscopy: A technique that — unlike conventional light microscopy, which focuses an optical image of a specimen on the image plane of a collection system — involves the physical scanning of the specimen with a diffraction-limited point of light. In some cases, this may be a one- or two-dimensional array of points. In such microscopy, the result of the interaction of the scanned light beam(s) with successive regions of the specimen is measured and recorded. With such instruments, digital signal processing may significantly enhance the signal-to-noise ratio, yielding three-dimensional images of extraordinary quality.

Sequence assembly: One of the most common methods of sequencing DNA is “shotgun” sequencing, in which a DNA strand is read as a series of random substrings of length 350 to 500. The reconstruction

of the sequence of the whole molecule from these random strings is referred to as sequence assembly. There is great complexity in this process, because the reactions to produce the sequencing substrate may be obtained from either strand. Therefore, when comparing two fragments, one must take into account that they could be derived from the same strand or from different strands; in the latter case, it is necessary to take the reverse complement of one of them before making the comparison.

Sequential alignment: A technique for evaluating the degree of secondary structure alignment by sequential evaluation of the root-mean-square deviation between backbone atoms. This involves identification of secondary structure, application of a clustering function to locate collections of such structures, and examining the more extended alignments outside of the initial regions.

Simulated annealing: This technique is a derivative of the Metropolis algorithm and applies statistical mechanics to optimization to many-body systems. In brief, the Metropolis algorithm is used to provide a simulation of a number of atoms in equilibrium at a given temperature. In each step of the algorithm, an atom is given a small random displacement, and the resulting change ΔE in the energy of the system is computed. If the $\Delta E \leq 0$, the displacement is accepted and the value is the basis for the next round. Through a series of probabilistic and cost functions, the algorithm optimizes at a given temperature. The simulated annealing procedure applies this function to a system that has been “melted,” and the temperature is lowered until the system is frozen. It is essential that at each stage the system proceed long enough to reach a steady state.

SOAP: SOAP is a lightweight protocol for exchange of information in a decentralized, distributed environment. It is an XML-based protocol that consists of three parts: an envelope that defines a framework for describing what is in a message and how to process it, a set of encoding rules for expressing instances of application-defined datatypes, and a convention for representing remote procedure calls and responses. SOAP can potentially be used in combination with a variety of protocols.

Stochastic search algorithm: A form of optimization searching based on random sampling (Monte Carlo) methods where points v from a set V are chosen at random with probability $1/|V|$. The minimum values of $f(v)$ are recorded as the random sampling proceeds, and the sampling does not terminate arbitrarily, as might occur in a deterministic search. Simulated annealing is an example of a stochastic algorithm.

Transmission electron microscopy (TEM): A technique in which a suitably prepared sample is placed in a beam of electrons being controlled in an electric field. A moving electron has a wavelength that is inversely proportional to its momentum (mass times velocity). Therefore, the higher the accelerating voltage of the TEM, the smaller the wavelength and the higher the resolution. The modern TEM consists of an electron source, an imaging lens, and an image-recording system, all housed in a column under high vacuum. Electrons are emitted from a heated tungsten filament held at a large negative potential and accelerated through voltages greater than 80 kV. The column is equipped with condenser electromagnetic lenses for focusing.

Web Services: A Web service is a software system identified by a URI (Uniform Resource Identifiers, a.k.a. URLs, are short strings that identify resources on the Web), whose public interfaces and bindings are defined and described using XML. Its definition can be discovered by other software systems. These systems can then interact with the Web service in a manner prescribed by its definition, using XML-based messages conveyed by Internet protocols.

Further Information

The Journal of Computational Biology is a regular source of computational molecular biology. Additional journals related to computational biology are in the late planning stages. The *Journal of Structural Biology* and *Proteins: Structure, Function and Genetics* is also a source of current work. For a comprehensive treatment of the mathematics of molecular biology, the reader is directed to *Introduction to Computational Biology: Maps, Sequences and Genomes*, by Michael Waterman, published by Chapman & Hall, 1995.

IV

Graphics and Visual Computing

Graphics and Visual Computing is the study and realization of complex processes for representing physical and conceptual objects visually on a computer screen. Fundamental to all graphics applications are the processes of modeling objects abstractly and rendering them on a computer screen. Also important are object identification, light, color, shading, projection, and animation. The reconstruction of scanned images and the virtual simulation of reality are also of major research interest, as is the ultimate goal of simulating human vision itself.

Computer Graphics System
Scene Specification • Rendering • Storage and Display
- 35.3 Research Issues and Summary

35.1 Introduction

The name *three-dimensional computer graphics* has been used freely in the computer graphics community for many years now [Foley et al. 1990, Glassner 1995, Hill 1990, Rogers 1985, Watt and Watt 1992]. It is something of a misnomer, because the graphics themselves are not in any sense three-dimensional (3-D). Rather, the way that the graphics are generated is dependent upon the construction of a virtual 3-D model in the computer, which is then imaged via a virtual camera, usually implying a simulation of a real physical illumination process. The term *three-dimensional* merely emphasizes the fact that a simulation of a 3-D world underlies the image-making process and also that the images produced often display the kinds of foreshortening distortions apparent in photographs or perspective drawings of real 3-D scenes. This chapter is devoted to outlining the various aspects of the process of generating 3-D computer graphic images. It is meant to give the reader an overview, or “big picture,” that can be filled in by reading [Chapter 36](#) through [Chapter 43](#) of the handbook, which provide more detailed information on specific aspects of the process.

35.2 Organization of a Three-Dimensional Computer Graphics System

A three-dimensional graphics system can be thought of as having three major components, each of which performs a distinct and clearly defined key role in the process of image generation. These three components are responsible for *scene specification*, *rendering*, and *image storage and display*. [Figure 35.1](#) gives a schematic view of the process used in 3-D graphics, showing the role that each of these components plays. Each of these major components can itself be broken down into groups of important subcomponents.

FIGURE 35.1 The 3-D graphics process.

35.2.1 Scene Specification

The *scene specification* section of a 3-D graphics system is responsible for providing an internal representation of the virtual scene that is eventually to be imaged. This requires both an interface to allow user specification and modification of the scene definition and a set of internal data structures that store and organize the scene so that it can be accessed by the user interface and the rendering system. This can be a highly interactive program, providing access to a variety of modeling tools via an interactive user interface; it may be script-driven, providing a scene description language that the user communicates in; or it can be as simple as a program that reads basic geometric information from a tightly formatted scene description file. In any case, the scene specification system will need to support some concept of a geometric coordinate system and provide some way of describing the geometry of the scene to be imaged. Scene description systems also will provide a way in which the user can specify what (virtual) materials objects are made of and how the scene is lit.

35.2.1.1 Coordinate Systems

Key to the geometric structure of a 3-D graphics system is a compact means for storing and utilizing descriptions of **local coordinate systems**. The local coordinate systems are used in the definition of the various components of a model describing the geometry and other characteristics of the scene, much as the local coordinates used on a plan are used in describing the design of a real object. For example, the coordinates on the plan for a complete airplane will necessarily be much different from the coordinates used on the plan for the airplane's wheel assembly.

Consistent with the usual representation of 3-D coordinates in mathematics and engineering, most current books, articles, and implementations of 3-D graphics systems use right-handed coordinate systems [Foley et al. 1990]. This gives a natural organization with respect to the display screen, with the x -coordinate measuring horizontal distance across the screen, the y -coordinate measuring vertical distance up the screen, and the z -coordinate providing the third spatial dimension as distance in front of the screen. However, in the early development of computer graphics, coordinate systems were often left-handed [Foley and van Dam 1982]. In screen space, the difference is that the positive z or depth coordinate is measured into the screen. Of course, for modeling, a local coordinate system can be positioned and oriented anywhere in space and is not usually aligned with the screen. Figure 35.2 shows the ordering of right-handed and left-handed coordinate systems.

A local coordinate system is usually defined in terms of a small set of intuitive geometric operations — the **affine transformations**. These are:

1. Translation — a change in the position of the origin of the local system
2. Scaling — a change in the scale of measurement in the local system
3. Rotation — a change in the orientation of the local system
4. Shear — transformation from an orthogonal coordinate system to a nonorthogonal system or vice versa via shearing deformations

FIGURE 35.2 Right- and left-handed coordinate systems.

FIGURE 35.3 A clown described by a hierarchy of local coordinate frames.

All of these elements of the local-coordinate-system definition are specified with respect to the origin, scale, orientation, and shear of some external reference system, which might itself be specified relative to some other external system. In this way, local coordinates can be nested within each other, providing the possibility for models to be described in a **hierarchical** fashion. For example, the simple clown model of Figure 35.3 is described in terms of a hierarchy of coordinate frames, which allows for the design and modeling of the head, eye, nose, and hat in their own separate local coordinate frames but then places the two eyes, the nose, and the hat on the head with respect to the head's frame. Finally, the assembled head is placed and oriented in the scene with respect to a local reference frame for the scene. The reference frame at the top of such a hierarchy is usually referred to as the **global coordinate system**.

The basic geometric unit is the 3-D point, which is typically represented in a 3-D graphics system as a 3-vector and stored as an array of three elements, representing the x , y , and z components of the point. Orientation vectors, like normals to surfaces and directions in space, are also represented by 3-vectors. Thus, the point (x, y, z) is given by the vector

$$\begin{bmatrix} x \\ y \\ z \end{bmatrix}$$

(or in some systems by its transpose $[x \ y \ z]$).

A local-coordinate-system is usually specified by a four-dimensional (4-D) *homogeneous transformation matrix* of the form

$$M = \begin{bmatrix} a_{11} & a_{12} & a_{13} & a_{14} \\ a_{21} & a_{22} & a_{23} & a_{24} \\ a_{31} & a_{32} & a_{33} & a_{34} \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

which specifies a transformation from the local coordinate system to its reference coordinate system. In other words, applying the transformation M to a point specified in the local coordinate system will yield the same point specified in the reference coordinate system. Another way of thinking of the same transformation matrix M is that when applied to the reference coordinate system it aligns it with and scales it to the local coordinate system. The 4-D homogeneous form of the transformation matrix M allows the unification of translation with scaling, rotation, and shear in a single matrix representation.

The transformation implied by matrix M is actually implemented by a three-step process. Assuming that 3-D geometric points are represented as column vectors in the local coordinate system, they are transformed into the reference coordinate system by:

1. Extending the 3-D point \mathbf{p} into a 4-vector \mathbf{v} in homogeneous space by giving it a fourth, or w , coordinate of 1:

$$\mathbf{p} = \begin{bmatrix} x \\ y \\ z \end{bmatrix} \implies \mathbf{v} = \begin{bmatrix} x \\ y \\ z \\ 1 \end{bmatrix}$$

2. Premultiplying this extended vector by the matrix M yielding a transformed 4-vector \mathbf{v}' :

$$M\mathbf{v} = \mathbf{v}' = \begin{bmatrix} x' \\ y' \\ z' \\ 1 \end{bmatrix}$$

3. Converting the resulting 4-vector \mathbf{v}' into the transformed 3-D point \mathbf{p}' by discarding its w -coordinate:

$$\mathbf{v}' = \begin{bmatrix} x' \\ y' \\ z' \\ 1 \end{bmatrix} \implies \mathbf{p}' = \begin{bmatrix} x' \\ y' \\ z' \end{bmatrix}$$

Inspection of matrix M will show that it is defined to always send the original w -coordinate to itself, thus making the third step legitimate. (In earlier computer graphics systems, it was usual for points to be represented by row vectors instead of column vectors and for step 2 to be done by *postmultiplying* the homogeneous row vector \mathbf{v} by the transpose of matrix M .)

The basic transformations of translation, rotation, scaling, and shear are given by the following matrices, which assume that points are represented as column vectors in a right-handed coordinate system and that transformations will be done by premultiplication of the vector (extended to homogeneous coordinates) by the matrix. Use of left-handed coordinates instead of right-handed coordinates will affect the rotations only as indicated below. If row vectors and postmultiplication are being used to represent points and their transforms, the matrices must be transposed.

- *Translation* by Δx in the x -direction, Δy in the y -direction, and Δz in the z -direction:

$$T(\Delta x, \Delta y, \Delta z) = \begin{bmatrix} 1 & 0 & 0 & \Delta x \\ 0 & 1 & 0 & \Delta y \\ 0 & 0 & 1 & \Delta z \\ 0 & 0 & 0 & 1 \end{bmatrix}, \quad T(\Delta x, \Delta y, \Delta z) \begin{bmatrix} x \\ y \\ z \end{bmatrix} = \begin{bmatrix} x + \Delta x \\ y + \Delta y \\ z + \Delta z \end{bmatrix}$$

- *Scaling* of s_x in the x -direction, s_y in the y -direction, and s_z in the z -direction:

$$S(s_x, s_y, s_z) = \begin{bmatrix} s_x & 0 & 0 & 0 \\ 0 & s_y & 0 & 0 \\ 0 & 0 & s_z & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}, \quad S(s_x, s_y, s_z) \begin{bmatrix} x \\ y \\ z \end{bmatrix} = \begin{bmatrix} s_x x \\ s_y y \\ s_z z \end{bmatrix}$$

- *Rotation* through angle θ around the x , y , or z axis, with right-handed rotation around the axis taken as a positive rotation (i.e., aligning the thumb of the right hand with the axis, the fingers grasp the axis in the direction of positive rotation; note that if left-handed coordinates are being used, the signs of the *sine* terms in R_x and R_y should be reversed, but R_z is unaffected):

$$R_x(\theta) = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos \theta & -\sin \theta & 0 \\ 0 & \sin \theta & \cos \theta & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}, \quad R_x(\theta) \begin{bmatrix} x \\ y \\ z \end{bmatrix} = \begin{bmatrix} x \\ y \cos \theta - z \sin \theta \\ y \sin \theta + z \cos \theta \end{bmatrix}$$

$$R_y(\theta) = \begin{bmatrix} \cos \theta & 0 & \sin \theta & 0 \\ 0 & 1 & 0 & 0 \\ -\sin \theta & 0 & \cos \theta & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}, \quad R_y(\theta) \begin{bmatrix} x \\ y \\ z \end{bmatrix} = \begin{bmatrix} x \cos \theta + z \sin \theta \\ y \\ -x \sin \theta + z \cos \theta \end{bmatrix}$$

$$R_z(\theta) = \begin{bmatrix} \cos \theta & -\sin \theta & 0 & 0 \\ \sin \theta & \cos \theta & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}, \quad R_z(\theta) \begin{bmatrix} x \\ y \\ z \end{bmatrix} = \begin{bmatrix} x \cos \theta - y \sin \theta \\ x \sin \theta + y \cos \theta \\ z \end{bmatrix}$$

- *Shear* parallel to the (x, y) plane as a function of z , or parallel to the (y, z) plane as a function of x , or parallel to the (z, x) plane as a function of y :

$$H_{xy}(h_{xz}, h_{yz}) = \begin{bmatrix} 1 & 0 & h_{xz} & 0 \\ 0 & 1 & h_{yz} & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}, \quad H_{xy}(h_{xz}, h_{yz}) \begin{bmatrix} x \\ y \\ z \end{bmatrix} = \begin{bmatrix} x + h_{xz}z \\ y + h_{yz}z \\ z \end{bmatrix}$$

$$H_{yz}(h_{yx}, h_{zx}) = \begin{bmatrix} 1 & 0 & 0 & 0 \\ h_{yx} & 1 & 0 & 0 \\ h_{zx} & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}, \quad H_{yz}(h_{yx}, h_{zx}) \begin{bmatrix} x \\ y \\ z \end{bmatrix} = \begin{bmatrix} x \\ y + h_{yx}x \\ z + h_{zx}x \end{bmatrix}$$

$$H_{zx}(h_{xy}, h_{zy}) = \begin{bmatrix} 1 & h_{xy} & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & h_{zy} & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}, \quad H_{zx}(h_{xy}, h_{zy}) \begin{bmatrix} x \\ y \\ z \end{bmatrix} = \begin{bmatrix} x + h_{xy}y \\ y \\ z + h_{zy}y \end{bmatrix}$$

More complex coordinate transformations, involving combinations of the basic transformations, can be obtained by specifying them as a sequence of operations, each described by a 4-D transformation matrix. The product of these matrices will yield a compound transformation matrix that has the same effect as each transformation applied separately. For example, a rotation of 30° around the x axis followed by a translation to the point $(10, 20, -10)$ would be given by

$$M = T(10, 20, -10)R_x(30^\circ)$$

FIGURE 35.4 A biparametric surface.

35.2.1.2 Geometric Modeling

Virtually all 3-D graphics systems provide the ability to work with simple geometric primitives that can be specified as lists of 3-D points. These primitives include points, lines, and polygons. Points can be arranged together to indicate a *sampled* surface, lines to form a *wireframe* representation, and polygons to form *polyhedral* surfaces. More sophisticated modelers will provide **parametric surfaces**, which are defined via an underlying piecewise polynomial formulation [Rogers and Adams 1990, Bartels et al. 1987]. Polynomial coefficients are adjusted to give the surface a specific shape, and these coefficients are often given intuitive form by encoding them via simple geometric devices, such as control polyhedra.

A typical surface formulation is a *biparametric surface*, which describes a surface in three spatial dimensions (x, y, z) via a set of three functions of two parameters u and v :

$$x = X(u, v), \quad y = Y(u, v), \quad z = Z(u, v)$$

This concept is illustrated in Figure 35.4. The rectangular grid on the left of the figure, defined in the (u, v) parametric coordinate system, is mapped, via the functions X , Y , and Z , into a 3-D surface like that shown on the right. A set of points on a parametric surface can be obtained algorithmically by looping over a collection of sample points on the (u, v) plane. Simple geometric primitives and parametric surfaces are described more fully in [Chapter 36](#).

Implicit surfaces are a common alternative to parametric surfaces. Here, surfaces are defined as the set of points satisfying a mathematical expression of the form

$$F(x, y, z) = 0$$

Thus, these surfaces are defined implicitly. Any point (x, y, z) in 3-D space can be tested to determine whether or not it is above [$F(x, y, z) > 0$], below [$F(x, y, z) < 0$], or on [$F(x, y, z) = 0$] the surface. However, it is not generally easy to algorithmically generate a set of points guaranteed to be on the surface, without resorting to iterative search or relaxation techniques. Implicit formulations are especially useful for defining solids, where the implicit equation can be evaluated to determine whether a point is inside, outside, or on the surface of the solid. For example, the well-known equation for a sphere of radius r centered at the point (x_0, y_0, z_0) can be written implicitly as

$$(x - x_0)^2 + (y - y_0)^2 + (z - z_0)^2 - r^2 = 0$$

Implicit techniques can be generalized to describe surfaces or solids defined algorithmically in the form of a programmed function. This technique is useful in describing a variety of natural-looking forms [Ebert 1994]. Functional techniques are described in [Chapter 37](#).

Some geometric data come naturally in the form of a set of scalar values distributed in a 3-D field. For example, data from medical scanners, such as MR or CT devices, consist of a set of material density values distributed on a regular lattice within a volume of space. This type of data has its own specialized set of modeling and visualization techniques that are described thoroughly in [Chapter 41](#).

FIGURE 35.5 Texture and bump maps.

35.2.1.3 Materials

In the context of a 3-D graphics system, a **material** is an attribute of a geometric object that provides a description of how the surface of the object will appear when viewed from a particular direction under a particular illumination. In physical terms, what we need to define here is how a surface reflects (or transmits) light as a function of incident angle, reflection (or refraction angle), and wavelength. A function providing these relationships is known as the material's **bidirectional reflectance distribution function** or BRDF.

In practical terms for computer graphics applications, it is usually enough to approximate the BRDF for a material with a collection of parameters and maps. A usual material specification system will provide parameters for the specification of a material's color, diffuse reflectance factor, specular reflectance factor, specularity, transmissivity, and refraction index. These factors and their use in lighting calculations are described in detail in [Chapter 38](#).

A material specification will also often include the capability to provide both **texture maps** and **bump maps**. A texture map provides a pattern of color that is to be applied to the surface of an object during the rendering process. These can be anything from a digital image that will be projected onto the surface, to a regular geometric pattern like a checker-board or polka-dot design. A bump map is a pattern of perturbations to the normal vector to a surface that simulates the effect that bumps would have on the appearance of the surface. Figure 35.5 illustrates texture and bump maps. Some systems also provide for **displacement maps**, which are used to locally perturb both the surface normal and the surface itself. It is usual to relate texture and other map coordinates directly to the parametric coordinates of a parametric surface. For nonparametric surfaces, specific texture coordinates must be provided by the user or by some algorithmic technique. For example, many modelers allow the user to provide texture coordinates along with 3-D geometric coordinates for each vertex in a polygonal surface.

Within the field of computer graphics, color is becoming as complex a topic as it is in physics, psychology, and art. However, from the point of view of usual practice, color is most often represented in 3-D graphics systems in one of two related color systems, the *RGB* and the *HSV* systems.

The RGB or "red-green-blue" system is the usual system used for storage or display of color. This is because this color system relates directly to the three-electron-gun RGB organization of color CRT displays. An RGB color is stored as a triple of three numbers giving the relative amount of each of the three color primaries — red, green, and blue. Because the RGB system organizes color into three *primaries*, and allows us to scale each primary independently, we can think of all of the colors that are represented by the system as being organized in the shape of a cube, as shown in [Figure 35.6](#). We call this the RGB color cube or the RGB color space (when we add coordinate axes to measure R, G, and B levels). Note that the corners of the RGB color cube represent pure black and pure white; the three primary colors red, green, and blue; and the three secondary colors yellow, cyan, and magenta. The diagonal from the black corner to the white corner represents all of the gray levels. Other locations within the cube correspond with all of the other colors that can be displayed.

The HSV or "hue-saturation-value" color system represents colors using three measures that relate directly to how artists often think about color. It provides separate measures of *hue* (corresponding to

FIGURE 35.6 RGB color cube.

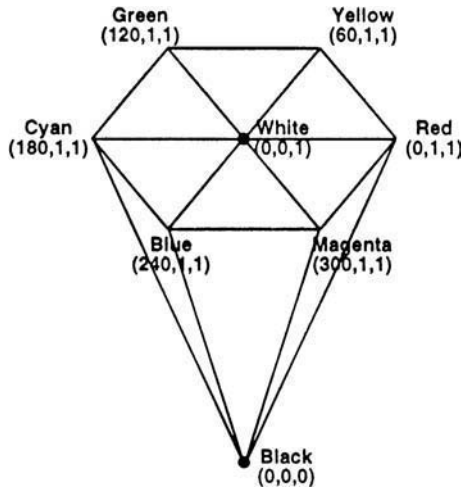

FIGURE 35.7 HSV color cone.

dominant color name), *saturation* (purity of color), and *value* (brightness on gray scale). Its structure is derived directly from the RGB system, and in fact there is a simple translation from RGB to HSV and back. If the RGB color cube of Figure 35.6 is viewed along its white–black diagonal, it presents a hexagonal silhouette. “Peeling” off layers of the face of the RGB cube visible along the white–black diagonal and projecting these cross sections onto a flat surface result in a series of smaller and smaller hexagonal cross sections. If these cross sections are then stacked up, they form a hexagonal cone. The HSV system is the cone-shaped space derived in this way, shown in Figure 35.7. Figure 35.8 shows how the coordinates of the HSV color space are organized. The hue or *h* coordinate is an angular measurement (usually in degrees) around the face of the cone, with red at 0° , green at 120° , and blue at 240° . The saturation or *s*-coordinate is measured from the center of the face of the cone out to its perimeter, with 0 at the center corresponding with gray and 1 at the perimeter corresponding with a fully saturated color of the chosen hue. The value or *v*-coordinate is measured from the apex of the cone to its face along the central axis, with 0 at the apex corresponding with no illumination (black) and 1 at the face corresponding with full illumination.

35.2.1.4 Lights

The purpose of lights in a 3-D graphics system is to provide the illumination source for the simulated shading calculations done by the renderer in making an image. Thus, all light sources must define a

FIGURE 35.8 HSV parameterization of hue, saturation, and value.

FIGURE 35.9 Infinite and point light sources and variants.

color of the illumination that they provide, usually specified in RGB or HSV coordinates. Note that this illumination color combines the notions of the intensity of the light and its chromatic attributes. Lights are arranged in a scene along with geometric objects but usually carry no geometric properties other than their position and, for directional lights, a direction of orientation. Some rendering algorithms work with light sources with other geometric properties such as shape and area, but most 3-D graphics systems work with only two types of lights — **infinite lights** and **point lights**. Figure 35.9 illustrates infinite and point light sources and some of their variants.

An infinite light is one that is so far away from the geometry being illuminated that light rays can be assumed to be parallel to each other, like the rays of light from the sun illuminating the earth. For this type of light, no position needs to be specified. All that matters geometrically is the direction of the light rays.

A point light source is assumed to have no area, with light emitted in all directions from the geometric position of the light. Simple variants of point light sources include the addition of conic or other shading devices with the light specification, so that the light shines only in a particular direction. A further variation is to have the intensity of light rays fall off gradually as a function of angular distance from the central directional axis of the light. With these variations, a point light can provide a reasonable approximation to an unshaded incandescent bulb, a shaded desk or studio lamp, a flashlight, or a spotlight.

35.2.2 Rendering

Rendering is simply the process of transforming a 3-D scene description into a two-dimensional (2-D) image. It is generally done by a simulation of the physical process that occurs in a camera when a picture is recorded on film. Making this process algorithmic, so that it can be simulated efficiently and accurately in a computer, is the essence of the rendering problem. [Chapter 38](#), describes practical approaches to rendering in some detail, so a brief synopsis will suffice here.

Briefly, the main steps in the rendering process are:

1. Point of view — orienting the 3-D scene as if it were being viewed from a particular point in space,
2. Projection — associating points in the 3-D scene with their images on a 2-D virtual image plane or screen by projecting the 3-D scene description onto the plane,
3. Visible-surface determination — deciding which surfaces projected onto the image plane would actually be visible from the present viewpoint,
4. Sampling — fixing a set of sample points across the virtual image plane, usually corresponding in some way with the pixels that will be used to store the calculated image, and associating these sample points with visible points on the scene's 3-D geometry,
5. Shading calculation — determining, for these sample points, what color would be reflected or transmitted to the viewpoint from the geometry visible at the sample point, taking into account the scene's geometry, lighting, and materials,
6. Image construction — from the shaded samples, determining and storing colors for each pixel in the output image.

These steps are not necessarily completed in this order. Nevertheless, every renderer will have to solve each of these problems in some way.

35.2.2.1 Camera

The role of the virtual camera in a 3-D graphics system is to provide both a point of view from which to render an image and the basic parameters of the mathematical projection that will be used to form the virtual image. The camera's position and orientation are specified sometimes as part of the scene description system and sometimes elsewhere. Nevertheless, it is typical for the camera to be positioned in the global coordinate system, usually with some positioning controls that correspond to the operation of a real studio camera. Often, a camera is positioned by one set of controls and aimed by another set. Aiming is usually made easier by the option to select a **center of interest**, which is a reference point in the scene toward which the camera will orient itself.

Theoretically, cameras can have any projection characteristics, corresponding to the entire variety of lens types, either real or imagined. However, practical 3-D graphics implementations usually implement only the standard parallel or perspective projections that are common in architectural and design drafting.

A perspective projection is one in which all light rays coming from the scene converge at a common point, known as the **center of projection**. If a projection plane is interposed between the scene and the center of projection, the point at which a ray from the scene through the center of projection intersects the projection plane is the *image* of that point. [Figure 35.10](#) shows the geometry of this projection. The parallel projections can be considered as special cases of the perspective projections, where the center of projection is infinitely far from the scene and virtual screen. Thus, rays between points on the scene and the center of projection are parallel to each other when intersecting the screen.

FIGURE 35.10 Geometry of a perspective projection.

In order to completely specify the perspective projection, the position of the camera (i.e., the center of projection), the direction in which the camera is aimed (i.e., its central ray of projection), the camera's up direction, the distance of the virtual screen from the center of projection along the central projection ray, and the width and height of the virtual screen must be known. This assumes that the virtual screen is centered on the central ray of projection, with its surface normal aligned with the central ray (i.e., it is perpendicular to the central ray). It is also possible to build fancier cameras, where the screen can be moved off center and oriented skewed to the central ray.

35.2.2.2 Renderer

The renderer in a 3-D graphics system is essentially the engine that drives the picture-making process. We can think of the renderer as viewing the scene through the lens of the virtual camera and constructing an image of what it sees, by first sampling points on the scene geometry and calling on the shader to calculate colors for each sample, and then combining these sampled colors into the pixels of the image. There are so many approaches to rendering, and the subject is so complex, that we will direct the interested reader to [Chapter 38](#) for more information.

35.2.2.3 Shader

The shader is the algorithm that uses the information collected by the renderer about a point sample on the scene geometry, its material attributes, and the available lighting to calculate a color for the sample. Generally this is done by a more or less approximate physical simulation of how light is reflected toward the camera from the position on the surface at which the sample is being taken. Again, the reader is referred to [Chapter 38](#) for more detailed information on shading and how it is done in a typical graphics system.

35.2.2.4 Image Construction

The final step in the rendering process is the construction of a digital image from the set of shaded samples across the virtual screen. This is done in any of a variety of ways, all of which are forms of low-pass filtering and resampling, providing a smooth blending and interpolation of the color samples into image pixel values [Wolberg 1990]. In practical terms, the digital image pixel grid is superimposed over the virtual screen, so that its pixels become associated with locations on the screen. Then the color of each pixel in the grid is calculated by taking a weighted average of the shaded samples in the vicinity of the pixel.

35.2.3 Storage and Display

For a 3-D graphics system to be useful, there must be a way to turn the results of calculations into tangible images that can be both viewed and stored for archiving and transmission. Thus, a 3-D graphics system is organized around a model of a digital image data structure, one or more image file formats, and a notion of the kind of display device that will be used to view images.

35.2.3.1 Image

The *pixmap* is the basic data structure for in-memory storage of digital images. A pixmap is simply a 2-D array of pixel values, with each pixel's value stored in units of one or more bits. Typical pixel sizes are 1, 8, 24, and 32 bits.

A pixmap that allocates only one bit per pixel is known as a *bitmap* and can be used to store only monochrome images (i.e., each pixel is either full on or full off). Pixmap with 8 bits per pixel can be used to store up to 256 levels of gray for a shaded gray-tone image, or, if the image is colored, the 8 bits are usually used to index a *lookup table*, which is simply an array containing up to 256 RGB colors that are used in the image. Pixmap of this type are limited to pictures with a palette of no more than 256 distinct colors, although these colors can be drawn from a much larger set of possible colors. The size of this set is determined by the number of bits per entry in the lookup table. This scheme is often supported by hardware as described below in the discussion of *framebuffers*.

Pixmap with 24 bits per pixel normally allocate 8 bits, or one byte, to each of the three RGB color primaries, giving a color resolution of 256 levels per primary, or 16,777,216 distinct colors. This color resolution is well beyond the ability of the human eye to distinguish color differences, so that even color gradations in these images appear to be as smooth as they would be in a continuous-tone color image.

On a high-end graphics computer, it is not unusual to allocate more than 24 bits per pixel in a pixmap. The extra space can be used to store colors at higher than 8-bit resolution, which is often handy to avoid roundoff errors in image-processing operations. A common configuration is a 32-bit pixel, where only 8 bits are used for each color primary, and the additional 8 bits are used to store an *alpha* value. The alpha value is used in image-compositing operations as a measure of pixel opacity. For purposes of compositing images together, pixels with high alpha values are treated as if they were opaque and pixels with low alpha values are treated as if they were transparent. Other uses for extra bits in a pixmap are to store aspects of the geometric information of the original model, such as surface normal, object id, material type, 3-D position, etc. This information can be used in postprocessing of the image to do things like modify shading, or to add embellishments to the image that give a notion of the underlying form and structure of the geometry of the imaged objects.

35.2.3.2 Display Devices

The display device most frequently used in conjunction with a 3-D graphics system is the *CRT* or *cathode-ray tube*. A CRT works on exactly the same principle as a simple vacuum tube. A schematic diagram of the organization of a monochrome CRT is shown in Figure 35.11. Electrons traveling from the negatively charged cathode toward the positively charged plate are focused into a beam by focusing coils. The plate end of the CRT is a glass screen coated with phosphor. The grid control voltage adjusts the intensity of the beam and thus determines the brightness of the glowing phosphor dot where the beam hits the screen.

FIGURE 35.11 Schematic diagram of a CRT.

FIGURE 35.12 Raster scan pattern.

Steering or deflection coils push the beam left/right and up/down so that it can be precisely directed to any desired spot on the screen.

A color CRT works like a monochrome CRT, but the tube has three separately controllable electron beams or *guns*. The screen has dots of red-, green-, and blue-colored phosphors, and each of the three beams is calibrated to illuminate only one of the phosphor colors. Thus, even though beams of electrons have no color, we can think of the CRT as having red, green, and blue electron guns. Colors are made using the RGB system, as optical mixing of the colors of the tiny adjacent dots takes place in the eye. Typically, the colored phosphors are arranged in triangular patterns known as *triads*, and an opaque *shadow mask* is positioned between the electron guns and the phosphors to ensure that each gun excites only the phosphors of the appropriate color.

A CRT can be used to display a picture in two different ways. The electron beam can be directed to “draw” a line-drawing on the screen — much like a high-speed electronic Etch-a-Sketch. The picture is drawn over and over on the screen at very high speed, giving the illusion of a permanent image. This type of device is known as a *vector display* and was quite popular for use in computer graphics and computer-aided design up until the early 1980s. By far the most popular type of CRT-based display device today is the *raster display*. These work by scanning the electron beam across the screen in a regular pattern of *scanlines* to “paint” out a picture, as shown in Figure 35.12. The resulting pattern of scanlines is known as a **raster**. As a scanline is traced across the screen by the beam, the beam is modulated proportional to the intended brightness of the corresponding point on the picture. After a scanline is drawn, the beam is turned off and brought back to the starting point of the next scanline. As opposed to a vector display, which essentially makes a line drawing on the screen, a raster display can be used to paint out a shaded image.

The NTSC broadcast TV standard that is used throughout most of America uses 585 scanlines with 486 of these in the visible raster. The extra scanlines are used to transmit additional information, like control signals and closed-caption titling. The NTSC standard specifies a *framerate* of 30 frames per second, with each *frame* (single image) broadcast as two *interlaced fields*. The first of each pair of fields contains every even-numbered scanline, and the second contains every odd-numbered scanline. In this way, the screen is *refreshed* 60 times every second, giving the illusion of a solid flicker-free image. Actually, most of the screen is blank (or dark) most of the time. High-quality color CRTs for computer graphics greatly exceed the resolution and framerate of the NTSC standard, offering noninterlaced framerates of 60 or more frames per second with 1000 or more scanlines per frame.

35.2.3.3 Framebuffers

A *framebuffer* is the hardware interface between the pixmap data structure of a digital image and a CRT display. It is simply an array of computer memory, large enough to hold the color information for one

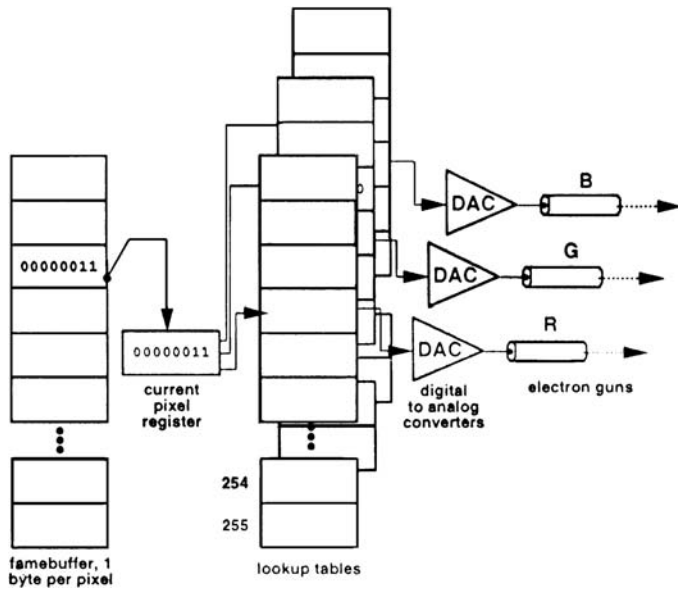

FIGURE 35.13 8-bit color framebuffer with lookup table.

or more frames (i.e., screenful) and display hardware to convert the current frame into control signals to drive a CRT. The color framebuffer schematized in Figure 35.13 holds an 8-bit per pixel color image in a pixmap. The circuitry that controls the electron gun on the CRT loops through each row of the image array, fetching each pixel value in turn and using it to index an array of 256×3 high-speed hardware registers arranged as a lookup table. The values fetched from each of the three indexed registers are converted to voltages by digital-to-analog converters (DACs) and used to control the grid voltages of the CRT's three RGB electron guns. The timing has to be such that the memory fetches and conversion to grid voltages are synchronized exactly with the trace of the beam across the corresponding screen scanline, so that the correct position on the screen is associated with the appropriate pixel from the framebuffer.

A full-color-resolution framebuffer is shown in schematic form in Figure 35.14. This type of device will have at least 24 bits per pixel (8 bits per color primary), driving three color guns, either directly or (as shown in the figure) through a separate lookup table per color primary. In this case, the lookup table is not used to increase the color resolution but instead can be used to correct nonlinearities or to obtain certain effects like overlay planes or pseudocoloring. Higher-end framebuffers may have more than 24 bits allocated per pixel, for hardware handling of such tasks as image compositing, depth buffering for hidden-surface resolution, double buffering for real-time animated display, and overlays.

35.2.3.4 Image Files

Due to the potential for using huge amounts of space, image file storage is a very important issue in computer graphics. A TV-resolution image has about $\frac{1}{3}$ million pixels — so a full-color RGB TV image will contain $3 \times \frac{1}{3} = 1$ million bytes of color information. Now, at 1800 frames (or images) per minute in a computer animation, we can expect to use up most of a 2-gigabyte disk for each minute of animation. Fortunately, we can do somewhat better than this by various file compression techniques, but disk storage space remains a crucial issue. Related to the space issue is the speed-of-access issue — that is, the bigger an image file, the longer it takes to read, write, and display.

For purposes of this overview, we will look closely at only a very simple, but very widely used image file format that has no intrinsic notion of compression. The *PPM*, or *portable pixmap*, format was devised to be an intermediate format for use in developing file-format conversion systems [Murray and vanRyper

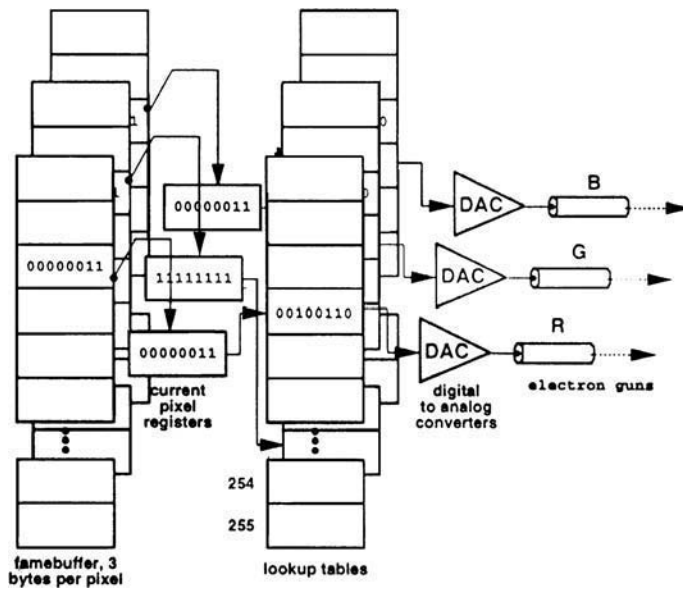

FIGURE 35.14 24-bit color framebuffer with three lookup tables.

1994]. Anyone familiar with computer graphics knows that the number of popular image file formats is immense. These include GIF, Targa, RLA, SGI, PICT, RLE, RLB, and many more. Converting images from one format to another is one of the common tasks in computer graphics, because different software packages and hardware units require different file formats. If there were N different file formats, and we wanted to be able to convert any one of these formats into any of the other formats, we would have to have $N \times (N - 1)$ conversion programs. The PPM idea is that we have one format that serves as a common source or target for all format conversions. We then write only N programs to convert all other formats into PPM and N more programs to convert PPM files into all other formats. In this way, we need write only $2 \times N$ programs to build a complete image conversion library.

The PPM format is not intended to be an archival format, so it does not need to be too storage-efficient. Although it is one of the simplest formats, PPM will nevertheless serve to illustrate some common features of image files. Most file formats are variants of the following organization. The file will typically contain some indication of the file type (which has come to be known as the format's *magic number*), a block of header or control information, and the image description data. Most (but not all) formats have a magic number, which identifies the file type. Often the magic number is not a number at all but rather a string of characters. The header block contains various descriptive information necessary to interpret the data in the image data block or can contain such archival information as creation date, image name, etc. The image data block is some form of encoding of the pixmap that describes the image. Some formats are much more complex than this, but this is the basic layout of a high percentage of formats.

In the PPM format, the magic number is either P1, P2, P3, P4, P5, or P6. P1 and P4 indicate that the image data are in a bitmap. These files are called PBM (portable bitmap) files. P2 and P5 are used to indicate gray-scale images or PGM (portable graymap) files. P3 and P6 are used to indicate full-color PPM (portable pixmap) files. The lower numbers — P1, P2, P3 — indicate that the image data are stored as ASCII characters; i.e., all numbers are stored as character strings. This has the advantage that you can read the file in a text editor. The higher numbers — P4, P5, P6 — indicate that image data are stored in a more compact binary encoding. We will look here only at P6-type files.

The header for a PPM file consists of the information shown in Figure 35.15, stored as ASCII characters in consecutive bytes in the file. In the header, all whitespace is ignored, so the program that writes the file can freely intersperse spaces and line breaks. The image width and height determine the length of a

(b) Dump of start of PPM P6 red-cube image file

FIGURE 35.16 Red cube image and corresponding PPM P6 image file data: (a) red cube on a mid-gray (0.5 0.5 0.5) background, (b) dump of start of PPM P6 red-cube image file.

scanline and the number of scanlines. The maximum color value cannot exceed 255, but it may be less if less than 8 bits of color information per primary are available.

The PPM P6 data block begins with the first pixel of the top scanline of the image (upper left-hand corner), and pixel data are stored in scanline order from left to right in 3-byte chunks giving the R, G, B values for each pixel, encoded as binary numbers. There is no separator between scanlines, and none is needed, as the image width given in the header block exactly determines the number of pixels per scanline. Figure 35.16a shows a red cube on a mid-gray background, and Figure 35.16b gives the first several lines of a hexadecimal dump of the contents of the corresponding PPM file. Each line of this dump has the hexadecimal byte count on the left, followed by 16 bytes of hexadecimal information from the file, and ends with the same 16 bytes of information displayed in ASCII (nonprinting characters are displayed as !). Except for the first line of the dump, which contains the file header information, the ASCII

information is meaningless, because the image data in the file are binary encoded. A line in the dump containing only a * indicates a sequence of lines all containing exactly the same information as the line above.

35.3 Research Issues and Summary

In this chapter, we have taken a quick, broad-brush look at 3-D graphics systems, from scene specification to image display and storage. The attempt has been to lay a basic foundation and to provide certain essential details necessary for further study. A practical example of the implementation and use of a 3-D graphics system appears in [Chapter 43](#).

As research in graphics tends to be specialized, readers are directed to the research issues and summary sections of [Chapter 37](#) through [Chapter 42](#) of this handbook for information on important and interesting open research areas. However, we note here some broad areas of research that are both timely and important to the development of the field. In the area of rendering, there are two areas that seem to be generating much current interest: extending solutions to the global illumination problem to handle a wider variety of material types and developing nonphotorealistic techniques. The entire fields of virtual reality and volumetric modeling are just getting off the ground and promise to be strong research areas for many years. Within the subfield of computer animation, three areas are of very strong current interest. These are physically based modeling and simulation [Barzel 1992], artificial-intelligence and artificial-life techniques for character animation and choreography, and higher-order interactive techniques that exploit the capabilities of new 3-D position and motion tracking devices. Finally, in the area of modeling, there is much room for improvement in interactive modeling tools and techniques, again possibly exploiting 3-D position and motion trackers. And there is a continuing search for compact, powerful ways to represent natural forms.

Defining Terms

Affine transformation: A coordinate-system transformation where each transformed coordinate is a linear sum of the three original coordinates plus a constant.

Bidirectional reflectance distribution function: A function defined for a reflecting material that, given arrival and departure directions, gives the fraction of light energy of a particular wavelength arriving at a surface from the arrival direction that is reflected from the surface in the departure direction.

Bump map: A pattern of surface normal displacements, simulating the undulations of a bumpy surface, that is to be mapped onto a geometric surface during rendering.

Center of interest: A point in space toward which the virtual camera is always aimed.

Center of projection: The point in space at which all rays of projection for a perspective projection converge. This often is considered to be the position of the virtual camera.

Displacement map: A pattern of surface position displacements to create the undulations of a bumpy surface that is to be mapped onto a geometric surface during rendering.

Global coordinate system: A coordinate system with respect to which all other coordinate systems in the definition of a 3-D scene are defined.

Hierarchical model: A geometric model defined within a set of nested reference coordinate frames, whose references form a directed tree or acyclic graph from a set of leaf frames, where basic geometric objects are defined, to a root frame in which the entire scene is defined.

Homogeneous coordinate system: In a 3-D graphics system, this is a 4-D coordinate system into which points are transformed before being multiplied by a homogeneous transformation matrix. The system is called homogeneous because all 3-D points lie on the same hyperplane perpendicular to the fourth coordinate axis. Typically, this coordinate is 1 for all points.

Implicit surface: A surface defined implicitly as the set of points satisfying an equation of the form $F(x, y, z) = 0$.

Infinite light: A light source taken to be infinitely far from the model being illuminated, so that all of its rays reaching the model can be considered to be parallel.

- Local coordinate system:** A coordinate system defined with respect to some reference coordinate system, usually used to define a part or subassembly within a scene definition.
- Material:** The collective set of properties of the surface of an object that determines how it will reflect or transmit light.
- Parametric surface:** A surface defined explicitly by a set of functions of the form $X(\mathbf{u}), Y(\mathbf{u}), Z(\mathbf{u})$ that returns (x, y, z) coordinates of a point on the surface as a function of the set of parameters \mathbf{u} . Most commonly, $\mathbf{u} = (u, v)$, which yields a biparametric surface parametrized by the parametric coordinates u and v .
- Pixel:** A square or rectangular uniformly colored area on a raster display that forms the basic unit or picture element of a digital image.
- Point light:** A light source that radiates light uniformly in all directions from a single geometric point in space.
- Projection:** A transformation typically from a higher-dimensional space to a lower-dimensional space. In computer graphics the most commonly used projection is the camera projection, which projects 3-D scene geometry onto the plane of a 2-D virtual screen, as one of the key steps in the rendering process.
- Raster:** An array of scanlines, painted across a CRT screen, which taken together form a rectangular 2-D image. Often the term raster is used to refer to the 2-D array of pixel values stored digitally in a framebuffer.
- Surface normal:** A vector perpendicular to the tangent plane to a surface at a point. If the surface is planar, the three coefficients of the surface normal vector are the three scaling coefficients of the plane equation.
- Texture map:** A pattern of color to be mapped onto a geometric surface during rendering.
- Transformation matrix:** For a 3-D system, this is a 4×4 matrix that, when multiplied by a point in homogeneous coordinates, gives the coordinates of the point in a transformed homogeneous coordinate system. The 4-D homogeneous form of the matrix allows the unification of 3-D translation, rotation, scaling, and shear into one operator.

Further Information

The reader seeking further information on three-dimensional graphics systems should refer first to [Chapters 36](#) through [43](#) of this Handbook, which provide much of the detail that this overview intentionally skips. The Further Information sections of these chapters provide pointers to the best source books on each of the specialized topics covered.

Beyond this volume, the primary source book for a broad coverage of the field is *Computer Graphics Principles and Practice* by Foley, van Dam, Feiner, and Hughes, published by Addison–Wesley. For a host of practical information and implementation tips, the five-volume series *Graphics Gems*, published by Academic Press, is an invaluable source. Information on image file formats can be found in the *Encyclopedia of Graphics File Formats* by Murray and vanRyper, published by O'Reilly. Fine practical guides to image-processing techniques are *The Image Processing Handbook* by Russ, published by CRC Press, and *Digital Image Processing* by Gonzalez and Woods, published by Addison–Wesley. The mathematics of computer graphics is given a very lucid treatment in *Mathematical Elements of Computer Graphics* by Rogers and Adams, published by McGraw–Hill, and there is no better reference to practical approaches to the implementation of numerical algorithms than *Numerical Recipes* (in various computer-language editions) by Press, Teukolsky, Vetterling, and Flannery, published by Cambridge University Press. Finally, the recent two-volume set *Principles of Digital Image Synthesis* by Glassner, published by Morgan Kaufmann, provides an excellent comprehensive coverage of the theoretical groundings of the field.

Persons interested in keeping up with the latest research in the field should turn to the ACM SIGGRAPH Conference Proceedings, published each year as a special issue of the ACM journal *Computer Graphics*. Other important conferences with published proceedings are *Eurographics* sponsored by the European Association for Computer Graphics, *Graphics Interface* sponsored by the Canadian Human–Computer Communications Society, and *Computer Graphics International* sponsored by the Computer Graphics Society. The IEEE journal *Computer Graphics and Applications* provides an applications-oriented view of recent developments, as well as publishing news and articles of general interest. ACM's *Transactions on Graphics* carries significant research papers, often with a focus on geometric modeling. Other important journals include *The Visual Computer*, IEEE's *Transactions on Visualization and Computer Graphics*, and the *Journal of Visualization and Computer Animation*.

36.1 Introduction

Geometric primitives are rudimentary for creating the sophisticated objects seen in computer graphics. They provide uniformity and standardization in addition to enabling hardware support.

Initially, definition of geometric primitives was driven by the capabilities of the hardware. Only simple primitives were available, e.g., points, line segments, triangles. In addition to the hardware constraints, other driving forces in the development of a geometric primitive have been either its general applicability to a broad range of needs or its satisfying ad hoc, but useful applications. The triangular facet is an example of a primitive that is simple to generate, easy to support in hardware, and widely used to model many graphics objects. An example of a specific primitive can be drawn from flight simulation in the case of *light strings*, which are instances of variable-intensity, directional points of light used to model airport and city lights at night. It is not a common primitive, but it is supported by a critical and profitable application.

As hardware and CPU increased in capability, the sophistication of the primitives grew as well. The primitives became somewhat less dependent on hardware; software primitives became more common, although for raw speed hardware primitives still dominate.

One direction for the sophistication of graphics primitives has been in the geometric order of the primitive. Initially, primitives were discrete or first-order approximations of objects, that is, collections of points, lines, and planar polygons. This has been extended to higher-order primitives represented by polynomial or rational curves and surfaces in any dimension.

The other direction for the sophistication of primitives has been in attributes that are assigned to the geometry. Color, transparency, associated bitmaps and textures, surface normals, and labels are examples of attributes attached to a primitive and used in its display.

This summary of graphics primitives is in rough chronological order of development which basically corresponds to increasing complexity. It concentrates on common primitives. It is beyond the scope of this review to include anything but occasional allusions to the plentiful special-purpose developments.

36.2 Screen Specification

To locate the graphics primitive in the viewing window, a local coordinate system is defined. By convention the origin is at the bottom left corner of the window. The positive x -axis extends horizontally from it, while the positive y -axis extends vertically. For 3-D objects, the z -axis is imagined to extend into the screen away from the viewer. In the 3-D case, it is necessary to transform the object to the screen via a set of viewing transformations (see [Chapter 35](#)).

Unlike pen and paper, we cannot draw a straight line between two points. The screen is a discrete grid; individual pixels must be illuminated in some pattern to indicate the desired line segment or other graphics primitive. A screen has from 80 to 120 pixels per inch, with high-resolution screens exhibiting 300 per inch. Most screens are about 1024 pixels wide by 780 pixels high. The problem of rendering a graphics primitive on a raster screen is called *scan conversion* and is discussed in [Chapter 38](#). It is mentioned because it is closely related to the geometry of the object drawn and related drawing attributes. It is the scan conversion method that is embedded in hardware to accelerate the display of the graphics in a system. The expense and efficacy of graphics hardware depend on careful selection of the primitives for the facility desired.

36.3 Simple Primitives

36.3.1 Text

There are two standard ways to represent textual characters for graphics purposes. The first method is to save a representation of the letter as a bitmap, called a *font cache*. This method allows fast reproduction of the character on screen. Usually the font cache has more resolution than needed, and the character is downsampled to the display pixels. Even on high-resolution devices such as a quality laser printer, the discrete nature of the bitmap can be apparent, creating jagged edges. When transformations are applied to bitmaps such as rotations or shearing, aliasing problems can also be apparent. See the example in [Figure 36.1](#).

To improve the quality of transformed characters and to compress the amount of data needed to transfer text, a second method of representing characters was developed using polygons or curves. When the text is displayed, the curves or polygons are scan-converted; thus the quality is constant regardless of the transformation ([Figure 36.2](#)). The transformation is applied to the curve or polygon basis before scan conversion. Postscript™ is a well-known product for text transfer. In a “Postscript” printer, for instance, the definition of the fonts resides in the printer where it is scan-converted. Transfer across the network requires only a few parameters to describe font size, type, style, etc. Those printers which do not have resident Postscript databases and interpreters must transfer bitmaps with resulting loss of quality and time.

Postscript is based on parametrically defined curves called Bezier curves (see [Section 36.8](#)).

Fonts are designed in the bitmap case by simply scanning script from existing print, while special font design programs exist to design fonts with curves.

FIGURE 36.1 Bitmap characters. Note jagged edges and sampling artifacts. Compare to [Figure 36.2](#).

M(Q) M(Q)

FIGURE 36.2 Curved representation of characters scan-converted.

FIGURE 36.3 A polyline display of a turbine engine (Created on an Evans and Sutherland Multi-Picture System in 1986).

36.3.2 Lines and Polylines

The first and still one of the most prevalent of the graphics primitives is the *line* (actually a line segment), typically specified by “move to $(x1, y1)$ ” and then “draw to $(x2, y2)$ ” commands, where $(x1, y1)$ and $(x2, y2)$ are the end points of the line segments. The endpoints can also be given as 3-D points and then projected to the screen through viewing transforms (see [Chapter 35](#)).

The line can be easily extended to a *polyline* graphics primitive, that is to a piecewise polygonal path. It is usually stored as an array of 2-D or 3-D points. The first element of the array tells how many points are in the polyline. The following array elements are then the arguments of the line drawing commands. The first entry invokes the “move to” command; successive array entries use the “draw to” command as an operator.

Attributes for lines and polylines are used to modify their appearance without changing position. Popular attributes include *thickness*, *color*, and *style* (i.e., continuous, dotted, dashed, and variable dash lengths). In more advanced systems each vertex of a polyline is associated to a color and the line segment is drawn by linearly blending the one color to the other along the segment. This is called *color blending*.

Attributes are set either by extending the array to include attribute fields (polylines), or they are set *modally* (lines and polylines); that is, there is an independent command that sets the mode of the line drawing until changed explicitly by another command. Default values control the attributes that are not explicitly set. “Continuous” is the default for style, for example.

Impressive pictures can be produced from these simple line-based primitives. Figure 36.3 shows a turbine engine done with polylines.

Because of the discrete, pixel-based nature of the raster display screen, lines are prone to alias (see [Chapter 39](#)); that is, they may break apart or merge with one another to form distracting moire patterns.

They are also susceptible to jagged edges, a signature of older graphics displays. Serious line-drawing systems found it therefore important to add hardware that would “antialias” their lines while drawing them. See [Chapter 39](#) for more details. [Figure 36.3](#) used hardware antialiasing.

A *marker* is another primitive; it is either a point or a small square, triangle, or circle, often placed at the vertices of a polyline to indicate specific details such as distinguishing between lines of a chart. Markers are themselves usually made by predetermined lines or polylines. This unifies the display technology for the hardware, making them faster to draw. Even the point is often a very short line. A single command is then used to center the marker. Style attributes don’t usually apply to markers, but color and thickness attributes can be used to advantage.

36.3.3 Elliptical Arcs

Elliptical arcs in 2-D may be specified in many equivalent ways. One way is to give the center position, major and minor axes, and start and end angles. Both angles are given counterclockwise from the major axis. Elliptical arcs may have all the attributes given to lines.

Such an arc may be a closed figure if the angles are properly chosen. In this case, it makes sense to have the ability to *fill* the ellipse with a given pattern or color using a scan conversion algorithm. Even in the case of partial arcs, the object is closed by a line between the end points of the arc so that it may be filled, if wished.

In 3-D the plane of the elliptical arc must also be specified by the unit normal of the plane. While 2-D arcs are common, 3-D arcs are limited to high-end systems that can justify the cost of the hardware. Viewing transforms must compute the arc that is the image on the screen and then scan-convert that arc (usually elliptical, since perspective takes conics to conics).

It should be mentioned that arcs can also be represented by a polyline with enough segments; thus a software primitive for the arc which induces the properly segmented and positioned polyline may be a cost-effective *macro* for elliptical arcs. This macro should consider the effects of zoom and perspective to avoid revealing the underlying polygonality of the arc. It is surprising how small a number of line segments, properly chosen, can give the impression of a smooth arc.

One of the most commonly used elliptical arcs is, of course, the circular arc and its closure, the circle.

36.4 Wireframes

Given hardware or software macro arc primitives in a system, complex curves can be generated by piecing the arcs and lines end to end. Several computer aided design (CAD) systems exist that can generate a rich set of line-based models in both 2-D and 3-D. They are called **wireframe** models. [Figure 36.3](#) is a wireframe model of a turbine engine.

Wireframe models are popular in engineering applications, for instance, because of their visual precision. Drafting is also a natural application. They have other advantages in 3-D because of the ability to see through them to parts of the object that are behind.

Too many lines can be confusing, however; to improve wireframe models a hidden-line routine may be employed (see [Chapter 38](#)). This requires derivation of a surface implied by the line. Yet line models can be ambiguous. [Figure 36.4](#) shows a classical example of an object for which the implied surface can be legitimately interpreted in many ways.

Finally, wireframe objects do not support realism. Most objects have a surface that is colored and reflects light according to physical laws of irradiance. This leads us to the next type of primitive.

36.5 Polygons

Closing a polyline by matching start and end points creates a **polygon**. It is probably the most commonly employed primitive in graphics, because it is easy to define an associated surface. Not all polygons have surfaces (they may be a primitive used in wireframe modeling), but most systems that admit polygons will

FIGURE 36.4 An ambiguous wireframe model. Where do the surfaces belong?

support both *filled* and *empty* polygons. Filling a polygon is an important example of scan conversion. There are many ways to do this (see [Chapter 38](#)). The different ways to fill become attributes of the polygon. The filled polygon is the basis for the numerous hidden-surface algorithms (see [Chapter 38](#)). Because of their usefulness for defining surfaces, polygons almost always appear as 3-D primitives which subsume the 2-D case.

The most sophisticated polygon primitive allows nonconvex polygons that contain other polygons, called *holes* or *islands* depending on whether they are filled or not. The scan conversion routine selectively fills the appropriate portions of the polygon depending on whether they are holes or islands. This complex polygon is probably made as a macro out of simple polygon primitives. Triangulation routines exist, for example, that reduce such polygons to simple triangular facets.

36.6 The Triangular Facet

If the polygon is the most popular primitive, then the simple triangle is certainly the most popular polygon. [Figure 36.5](#) shows an object simple object composed of triangular facets.

As mentioned, the triangular facet often supports more complex polygons. It is fast to draw and supports many diverse and powerful methods (see [Chapter 38](#)). Another major advantage is that they are always flat; they do not leave the plane due to numerical problems, data errors, or nonplane-preserving transformations. At this writing, graphics workstations exist that can render 10 million triangular facets per second with hidden surfaces removed and smooth shaded display between neighboring triangles implemented. It is certain that this number will continue to increase. With such capacity several dozens of the objects in [Figure 36.5](#) could be smoothly animated.

In order to increase the speed of polygon rendering and decrease the size of the database, triangular and quadrilateral facets can be stored and processed as meshes; i.e., collections of facets that share edges and vertices. The triangular mesh, for instance, is given by defining three vertices for the “lead” triangle, and then giving a new vertex for each successive triangle ([Figure 36.6](#)). The succeeding triangles use the last two vertices in the list with the newly given one to form the next triangle. Such a mesh contains about one-third the data and uses the shared edges to increase processing speed. Most graphics objects have large contiguous areas that can take advantage of meshing. The quadrilateral mesh requires two additional vertices be used, with the last two given, and therefore has less savings.

Because of its benefits and ubiquity, many other primitives are defined in software as configurations of the triangular facet. One example is the faceted sphere. With enough facets the sphere will look smooth. It is very commonly encountered in engineering applications and molecular modeling.

Most of the attributes associated with polygons, and triangular facets in particular, deal with the rendering of the facet (see [Chapter 38](#)), e.g., color blending between vertices, pointers into a bitmap for texturing, normal vectors (from an underlying surface), reflectance parameters, transparency, and color.

FIGURE 36.5 (See Plate 36.5 in color insert following page 29-22.) A model composed of simple triangular facets (polygon model).

FIGURE 36.6 A mesh of triangular facets.

36.7 Implicit Modeling

36.7.1 Implicit Primitives

The need to model mechanical parts drove the definition of implicitly defined primitives. These modeling primitives naturally became graphics primitives to serve the design industry. They have since been used in other fields such as animation.

An implicit function f maps a point \mathbf{x} in \mathbf{R}^n to a real number, i.e., $f(\mathbf{x}) = r$. Usually $n = 3$. By absorbing r into the function we can view the implicit function as mapping to zero, i.e., $g(\mathbf{x}) = f(\mathbf{x}) - r = 0$. The importance of implicit functions in modeling is that the function divides space into three parts: $f(\mathbf{x}) < 0$, $f(\mathbf{x}) > 0$, and $f(\mathbf{x}) = 0$. The last case defines the surface of an **implicit object**. The other two cases define respectively the *inside* and *outside* of the implicit object. Hence implicit objects are useful in *solid modeling* where it is necessary to distinguish the inside and outside of an object. Modeling objects by polygons does not, for instance, distinguish between the inside and outside of the object. It is, in fact, quite possible to describe an object in which inside and outside are ambiguous. This facility to determine inside and outside

is further enhanced by using Boolean operations on the implicit objects to define more complex objects (see the subsection on CSG objects below).

Another advantage of implicit objects is that the surface normal of an implicitly defined surface is given simply as the gradient of the function: $N(\mathbf{x}) = \nabla f(\mathbf{x})$. Furthermore, many common engineering surfaces are easily given as implicit surfaces; thus the *plane* (not the polygon) is defined by $\mathbf{n} \cdot \mathbf{x} + \mathbf{d} = 0$, where \mathbf{n} is the surface normal and \mathbf{d} is the perpendicular displacement of the plane to the origin. The *ellipsoid* is defined by $(x/a)^2 + (y/b)^2 + (z/c)^2 - r^2 = 0$, where $\mathbf{x} = (x, y, z)$. General *quadrics*, which include ellipsoids, paraboloids, and hyperboloids, are defined by $\mathbf{x}^T M \mathbf{x} + \mathbf{b} \cdot \mathbf{x} + \mathbf{d} = 0$, where M is a 3-by-3 matrix and \mathbf{b} and \mathbf{d} vectors in \mathbf{R}^3 . The quadrics include such important forms as the cylinder, cone, sphere, paraboloids, and hyperboloids of one and two sheets. Other implicit forms used are the *torus*, *blends* (transition surfaces between other surfaces), and *superellipsoids* defined by $(x/a)^k + (y/b)^k + (z/c)^k - R = 0$ for any integer k .

36.7.2 CSG Objects

An important extension to implicit modeling arises from applying set operations such as union, intersection, and difference to the sets defined by implicit objects. The intersection of six half spaces defines a cube, for example. This method of modeling is called *constructive solid geometry* (CSG) [Foley 1990]. All set operations can be reduced to some combination of just union, intersection, and complementation. Because these create an algebra on the sets that is isomorphic to Boolean algebra, corresponding to multiply, add, and negate, respectively, the operations are often referred to as *Booleans*.

A convenient form for visualizing and storing a CSG object is to use a tree in which the nodes are implicit objects and the branches indicate the operation. Traversal of the tree indicates the order of the binary operations and to which sets they pertain. Figure 36.7 shows a CSG tree for a simple model.

Figure 36.8 demonstrates an object made exclusively from Boolean parts of plane quadrics, a part torus, and blended transition surfaces. For any point in space it is straightforward to determine whether it is

FIGURE 36.7 A CSG model and its tree.

FIGURE 36.8 A solid model of a drill.

inside, outside, or on the surface of the object. This is important in determining volume, center of mass, and moments and for performing Boolean operations needed by CSG models.

Unfortunately, implicit forms tend to be difficult to render, except for ray tracing. Algorithms for polygonizing implicits and CSG models tend to be quite complex [Bloomenthal 1988]. The implicit object gives information about a point relative to the surface in space, but no information is given as to where on the surface a point is located; there is no local coordinate system. This makes it difficult to tessellate into rendering elements such as triangular facets. In the case of ray tracing, however, the parametric form of a ray $\mathbf{x}(t) = (x(t), y(t), z(t))$ composed with implicit function $f(\mathbf{x}(t)) = 0$ leads to a root-finding solution of the intersection points on the surface which are critical points in the ray-tracing algorithm. Determining whether points are part of a CSG model is simply exclusion testing on the CSG tree.

36.8 Parametric Curves

An important class of geometric primitives are formed by **parametrically defined curves and surfaces**. These constitute a flexible set of modeling primitives that are locally parametrized; thus in space the curve is given by $\mathbf{x}(t) = (x(t), y(t), z(t))$ and the surface by $\mathbf{s}(u, v) = (x(u, v), y(u, v), z(u, v))$. In this section and the next one, we will give examples of only the most popular types of parametric curves and surfaces. There are many variations on the parametric forms (see Farin [1992]).

36.8.1 Bezier Curves

The general form of a Bezier curve of degree n is

$$\mathbf{f}(t) = \sum_{i=0}^n \mathbf{b}_i B_i^n(t) \quad (36.1)$$

where \mathbf{b}_i are vector coefficients, the *control points*, and

$$B_i^n(t) = \binom{n}{i} t^i (1 - t)^{n-i}$$

where $\binom{n}{i}$ is the binomial coefficient. The $B_i^n(t)$ are called *Bernstein functions*. They form a basis for the set of polynomials of degree n . Bezier curves have a number of characteristics which are derived from the Bernstein functions and which define their behavior.

End-point interpolation: The Bezier curve interpolates the first and last control points, \mathbf{b}_0 and \mathbf{b}_n . In terms of the interpolation parameter t , $\mathbf{f}(0) = \mathbf{b}_0$ and $\mathbf{f}(1) = \mathbf{b}_n$.

Tangent conditions: The Bezier curve is cotangent to the first and last segments of the *control polygon* (defined by connecting the control points) at the first and last control points; specifically

$$\mathbf{f}'(0) = (\mathbf{b}_1 - \mathbf{b}_0)n \quad \text{and} \quad \mathbf{f}'(1) = (\mathbf{b}_n - \mathbf{b}_{n-1})n$$

Convex hull: The Bezier curve is contained in the convex hull of its control points for $0 \leq t \leq 1$.

Affine invariance: The Bezier curve is affinely invariant with respect to its control points. This means that any linear transformation or translation of the control points defines a new curve which is just the transformation or translation of the original curve.

Variation diminishing: The Bezier curve does not undulate any more than its control polygon; it may undulate less.

Linear precision: The Bezier curve has linear precision: If all the control points form a straight line, the curve also forms a line.

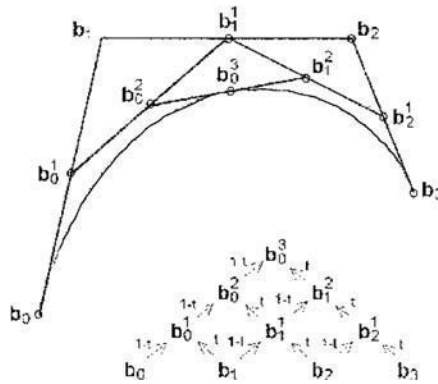

FIGURE 36.9 Bezier curve, control polygon, and de Casteljau algorithm.

Figure 36.9 shows a Bezier curve with its control polygon. Notice how it follows the general shape. This together with the other properties makes it desirable for shape design.

Evaluation of the Bezier curve function at a given value t produces a point $\mathbf{f}(t)$. As t varies from 0 to 1, the point $\mathbf{f}(t)$ traces out the curve segment. One way to evaluate Equation 36.1 is by direct substitution. This is probably the worst way. There are several better methods available for evaluating the Bezier curve. One method is the *de Casteljau algorithm*. This method not only provides a general, relatively fast and robust algorithm, but it gives insight into the behavior of Bezier curves and leads to several important operations on the curves.

To formalize de Casteljau's algorithm we need to use a recursive scheme. The control points are the input. Thereafter each point is superscripted by its level of recursion. Finally, for any point,

$$\mathbf{b}_i^j(t) = (1-t)\mathbf{b}_i^{j-1} + t\mathbf{b}_{i+1}^{j-1} \quad \text{for } i = 0, \dots, n, \quad j = 0, \dots, n-i$$

Note that $\mathbf{b}_0^n(t) = \mathbf{f}(t)$; it is a point on the curve.

One of the most important devices for evaluating curves is the systolic array. It is a triangular arrangement of vectors in which each row reflects the levels of recursion of the de Casteljau algorithm. The first row consists of the Bezier control points. Each successive row corresponds to the points produced by iterating with de Casteljau's algorithm.

The point \mathbf{b}_0^3 is the point on the curve for some value of the parameter t . Any point in the systolic array may be computed by linearly interpolating the two points in the preceding row with the parameter t ; thus for example:

$$\mathbf{b}_1^2 = \mathbf{b}_1^1(1-t) + \mathbf{b}_2^1t$$

One of the most important operations on a curve is that of subdividing it. The de Casteljau algorithm not only evaluates a point on the curve, it also subdivides a curve into two parts as a bonus. The control points of the two new curves are given as the legs of the systolic array. In Figure 36.10 is a cubic Bezier curve after three iterations of the de Casteljau algorithm, with the parameter $t = 0.5$. By using the left and right legs of the systolic array as control points, we obtain two separate Bezier curves which together replicate the original. We have subdivided the curve at $t = 0.5$.

Subdivision permits existing designs to be refined and modified; for example, by incorporating additional curves into an object. One method of intersecting a Bezier curve with a line is to recursively subdivide the curve, testing for intersections of the curve's control polygons with the line. This process is continued until a sufficiently fine intersection is attained.

FIGURE 36.10 Subdividing the curve.

FIGURE 36.11 Defining basis functions by convolution.

36.8.2 B-Spline Curves

A single *B-spline* curve segment is defined much like a Bezier curve. It looks like

$$\mathbf{d}(t) = \sum_{i=0}^n \mathbf{d}_i N_i(t)$$

where \mathbf{d}_i are control points, called *de Boor points*. The $N_i(t)$ are the basis functions of the B-spline curve. The degree of the curve is n .

Note that the basis functions used here are different from the Bernstein basis polynomials. Schoenberg first introduced the B-spline in 1949. He defined the basis functions using integral convolution (the “B” in B-spline stands for “basis”). Higher-degree basis functions are given by convolving multiple basis functions of one degree lower. Linear basis functions are just “tents” as shown in Figure 36.11. When convolved together they make piecewise parabolic “bell” curves.

The tent basis function (which has a degree of one) is non-zero over two intervals, the parabola is nonzero over three intervals, and so forth. This gives the region of influence for different degree B-spline control points. Notice also that each convolution results in higher-order continuity between segments of the basis function. When the control points (de Boor points) are weighted by these basis functions, the B-spline curve results.

FIGURE 36.12 B-spline curve with two segments.

The major advantage of the B-spline form is in piecing curves together to form a *spline*. If two B-spline curve segments share $n - 1$ control points, they will fit together at the junction point with C^{n-1} continuity. The picture in Figure 36.12 shows the case for a cubic B-spline with two segments:

- The first curve has control points \mathbf{d}_0 , \mathbf{d}_1 , \mathbf{d}_2 , and \mathbf{d}_3 .
- The second curve has control points \mathbf{d}_1 , \mathbf{d}_2 , \mathbf{d}_3 , and \mathbf{d}_4 .

Instead of integrating to evaluate the basis functions, a recursive formula has been derived:

$$N_i^n(u) = \frac{u - u_{i-1}}{u_{i+n-1} - u_{i-1}} N_i^{n-1}(u) + \frac{u_{i+n} - u}{u_{i+n} - u_i} N_{i+1}^{n-1}(u)$$

where

$$N_i^0(u) = \begin{cases} 1 & \text{if } u_{i-1} \leq u \leq u_i \\ 0 & \text{otherwise} \end{cases}$$

The terms in u represent a *knot sequence*, the spans over which the de Boor points influence the B-spline.

More control points can be added to make a longer and more elaborate spline curve. As seen in Figure 36.12 neighboring curve segments share n control points.

It can be seen that for any parameter value u only four basis functions are nonzero; thus only four control points affect the curve at u . If a control point is moved it influences only a limited portion of the curve. This *local support* property is important for modeling.

If the first n and last n control points are made to correspond, then the curve's end points will match; it will form a closed curve. This is called a *periodic B-spline*.

Any point on the curve is a convex combination of the control points, i.e., it must be in the convex hull of the control points associated with the nonzero basis functions.

Like the Bezier curve, the B-spline curve also satisfies a variation-diminishing property, and is affinely invariant. Linear precision follows, as in the Bezier-curve case, from the convex-hull property.

The recursive form for evaluating B-splines via basis functions is seldom used in practice. The best way to evaluate a B-spline curve is to use the de Boor algorithm.

Formally, the de Boor algorithm is written as

$$\mathbf{d}_i^k(u) = \frac{u_{i+n-k} - u}{u_{i+n-k} - u_{i-1}} \mathbf{d}_{i-1}^{k-1}(u) + \frac{u - u_{i-1}}{u_{i+n-k} - u_{i-1}} \mathbf{d}_i^{k-1}(u)$$

We see that the de Boor points form a systolic array; each point is defined in terms of preceding points. Thus we may write an iterative procedure to evaluate a point on a B-spline curve in much the same way as de Casteljau's algorithm above evaluates a point on a Bezier curve. Only the weighting factors differ. The last point produced in the method is the point on the curve.

36.9 Parametric Surfaces

36.9.1 Bezier Surfaces

Imagine moving the control points of the Bezier curve in three dimensions. As they move in space, new curves are generated. If they are moved smoothly, then the curves formed create a surface, which may be thought of as a bundle of curves. If each of the control points is moved along a Bezier curve of its own, then a Bezier surface patch is created; if a B-spline curve is extruded, then a B-spline surface results (Figure 36.13).

In the Bezier case this can be written by changing the control points in the Bezier formula into Bezier curves; thus a surface is defined by

$$\mathbf{s}(u, v) = \sum_{i=0}^n \mathbf{b}_i(u) B_i(v) \quad (36.2)$$

Notice that we have one parameter for the control curves and one for the “swept” curve. It is convenient to write the control curves as Bezier curves of the same degree. If we let the i th control curve have control points \mathbf{b}_{ij} , then the surface given in Equation 36.2 above can be written as

$$\mathbf{s}(u, v) = \sum_{i=0}^n \left(\sum_{j=0}^m \mathbf{b}_{ij} B_j(u) \right) B_i(v) \quad (36.3)$$

where m is the degree of the control curves.

A surface can always be thought of as nesting one set of curves inside another. From this simple characteristic we derive many properties and operations for surfaces. Simple algebra changes Equation 36.3 above into

$$\mathbf{s}(u, v) = \sum_{i=0}^n \left(\sum_{j=0}^m \mathbf{b}_{ij} B_j(u) \right) B_i(v) = \sum_{i=0}^n \sum_{j=0}^m \mathbf{b}_{ij} B_i(v) B_j(u) \quad (36.4)$$

That is, even though we started with one curve and swept it along the other, there is no preferred direction.

The surface patch could have been written as:

$$\mathbf{s}(u, v) = \sum_{i=0}^n \mathbf{b}_j(v) B_j(u), \quad \text{where } \mathbf{b}_j(v) = \sum_{i=0}^n \mathbf{b}_{ij} B_i(v)$$

The curve is simply swept in the other direction.

The set of control points forms a rectangular control mesh. A 3-by-3 (bicubic) control mesh is shown in Figure 36.14 with the surface. There are 16 control points in the bicubic control mesh. In general there

FIGURE 36.13 Sweeping a curve to make the surface.

FIGURE 36.14 Bicubic surface with control mesh.

will be $(n + 1) \times (m + 1)$ control points. By convention we associate the i -index with the u -parameter, and the j -index with the v -parameter. Hence if we take:

$$\mathbf{b}_{i0}, \quad i = 1, \dots, n$$

we get the Bezier curve

$$\mathbf{b}(u, 0) = \sum_{i=0}^n \mathbf{b}_{i0} B_i^n(u)$$

Each marginal set of control points defines a Bezier curve (the four border curves), and each of these curves is a boundary of the Bezier surface patch. Such a surface is shown in white in Figure 36.14.

Many of the properties of the Bezier surface are derived directly from those of the Bezier curve, especially those curves that form the boundaries of the patch:

End-point interpolation: The Bezier surface patch passes through all four corner control points.

Tangent conditions: The four border curves of the Bezier surface patch are cotangent to the first and last segments of each border control polygon, at the first and last control points. The normal to the surface patch at each vertex may be found from the cross product of the tangents.

Convex hull: The Bezier surface patch is contained in the convex hull of its control mesh for $0 < u < 1$ and $0 < v < 1$.

Affine invariance: The Bezier surface patch is affinely invariant with respect to its control mesh. This means that any linear transformation or translation of the control mesh defines a new patch which is just the transformation or translation of the original patch.

36.9.1.1 Evaluation of the Bezier Surface Patch

As with the properties described above, the evaluation of a Bezier surface patch can also be derived from the Bezier curve. If we want to evaluate a point on the patch at parameter value (u, v) , we apply the de Casteljau algorithm in a nested fashion to Equation 36.3. That is, we first evaluate the control curves in the u direction, which reduce to control points in the v direction. These points are again evaluated with de Casteljau's algorithm.

36.9.1.2 Subdivision of the Bezier Surface Patch

Again, as with the Bezier curve, we can apply the de Casteljau algorithm in nested fashion to subdivide a Bezier surface patch. When a surface patch is subdivided, it yields four subpatches that share a corner at the (u, v) subdivision point. Recall that when a curve was subdivided, the new curve's control points appeared as the legs of a systolic array. In the surface case we subdivide each row of the control mesh, producing points of the systolic array for each. Each point on each leg of every row's systolic array now becomes a control point for a columnar set. A biquadratic case is shown in Figure 36.15. Here we see that three points in each row produce five after subdivision. Now we consider the points in columns, subdividing the

FIGURE 36.15 First-level subdivision.

FIGURE 36.16 Control points: progression for subdivision.

FIGURE 36.17 The subdivided patch.

columns with de Casteljau's algorithm. The points in the legs of their systolic arrays become the control points of the new subpatches. In our example rows with three control points produce five "leg" points, i.e., five columns of three points. Each column then produces five control points, so a 3-by-3 grid generates a 5-by-5 grid after subdivision. The control meshes of the four new patches are produced as shown in Figure 36.16. The central row and column of control points are shared by each 3-by-3 subpatch as shown in Figure 36.17. Note that the order of the scheme does not matter. Columns might have been taken first, and then rows.

Subdivision is a basic operation on surfaces. Many "divide and conquer" algorithms are based on it. To clip a surface to a viewing window we can use the convex-hull property and subdivision, for example. The convex-hull test can determine if a patch is entirely contained in the window. If not, it is subdivided, and the subpatches are then tested. Recursion is applied until the pixel level.

36.9.2 B-Spline Surfaces

As with the Bezier surface, the B-spline surface is defined as a nested bundle of curves, thus yielding

$$s(u, v) = \sum_{i=0}^{L+n-1} \sum_{j=0}^{M+m-1} \mathbf{d}_{ij} N_i(u) N_j(v)$$

FIGURE 36.18 (See Plate 36.18 in color insert following page 29-22.) Turbine engine modeled by B-spline surfaces.

where

n, m are the degrees of the B-splines,

L, M are the number of segments, so there are $L \times M$ patches.

All operations used for B-spline curves carry over to the surface via the nesting scheme implied by its definition. We recall that B-spline curves are especially convenient for obtaining continuity between polynomial segments. This convenience is even stronger in the case of B-spline surfaces; the patches meet with higher-order continuity depending on the degree of the respective basis functions. B-splines define quilts of patches with “local support” design flexibility. Finally, since B-spline curves are more compact to store than Bezier curves, the advantage is “squared” in the case of surfaces.

These advantages are tempered by the fact that operations are typically more efficient on Bezier curves. Conventional wisdom says that it is best to design and represent surfaces as B-splines, and then convert to Bezier form for operations. Figure 36.18 shows an object made of many surface patches.

36.10 Standards

Several movements have occurred to standardize primitives. Some of the standards grew out of the mechanical CAD/CAM industry, because of the obvious connection between it and graphics. IGES is a popular one. Although it cannot be said that IGES has become commonplace in the graphics world, it is quite often important to translate between graphics models and these standards when dealing with CAD/CAM applications. GKS [ANSI 1985], PHIGS, and PHIGS+ [ANSI 1988] are standards developed by a broad consortium of academics and industrial users. In spite of major efforts and backing, they have not been as directly successful as the standards evolved in the industry. They have, however, been an intellectual force that has influenced many of the industrial efforts.

In industry each company has developed and pushed for its particular set of graphics standards. Perhaps the most successful at this time is GL (for Graphics Library), which was developed by Silicon Graphics,

Inc., a company which based its computer workstation product on high-powered graphics. It has been licensed by IBM and many other companies. It has evolved into Open GL, which is supported by many manufacturers and threatens to become the standard.

36.11 Research Issues and Summary

There have been efforts to cast higher-order primitives like parametric surfaces into graphics hardware, but the best approach seems to be to convert these into polygons and then render [Rockwood et al. 1990]. There may be hardware support for this process, but the polygon processing remains at the heart of graphics primitives. This trend is likely to continue into the future if for no other reason than its own inertia. Special needs will continue to drive the development of specialized primitives.

One new trend that may affect development is that of volume rendering (see [Chapter 41](#)). Although it is currently quite expensive to render, hardware improvements and cheaper memory costs should make it increasingly more viable. As a technique it subsumes many of the current methods, usually with better quality, as well as enabling the visualization of volume-based objects. Volume-based primitives, i.e., tetrahedra, cuboids, and curvilinear volume cubes, will receive more attention and research.

Defining Terms

Implicit objects: Defined by implicit functions, they define solid objects of which outside and inside can be distinguished. Common engineering forms such as the plane, cylinder, sphere, torus, etc. are defined simply by implicit functions.

Parametrically defined curves and surfaces: Higher-order surface primitives used widely in industrial design and graphics. Parametric surfaces such as B-spline and Bezier surfaces have flexible shape attributes and convenient mathematical representations.

Polygon: A closed object consisting of vertices, lines, and usually an interior. When pieced together it gives a piecewise (planar) approximation of objects with a surface. Triangular facets are the most common form and form the basis of most graphics primitives.

Wireframe: Simplest and earliest form of graphics model, consisting of line segments and possibly elliptical arcs that suggest the shape of an object. It is fast to display and has advantages in precision and “see through” features.

37.1 Introduction

Geometric modeling techniques in computer graphics have evolved significantly as the field matured and attempted to portray the complexities of nature. Earlier geometric models, such as polygonal models, patches, points, and lines, are insufficient to represent the complexities of natural objects and intricate man-made objects in a manageable and controllable fashion. Higher-level modeling techniques have been developed to provide an *abstraction* of the model, encode classes of objects, and allow high-level control and specification of the models. Most of these advanced modeling techniques can be considered *procedural* modeling techniques: code segments or algorithms are used to abstract and encode the details of the model, instead of explicitly storing vast numbers of low-level primitives. The use of algorithms unburdens the modeler/ animator from low-level control, provides great flexibility, and allows amplification of their efforts through parametric control: a few parameters to the model yield large amounts of geometric detail (Smith [1984] referred to this as *database amplification*). This amplification allows a savings in storage of data and user specification time. The modeler has the flexibility to capture the *essence* of the object or phenomena being modeled without being constrained by the laws of physics and nature. He can include as much physical accuracy, and also as much artistic expression, as he wishes in the model.

This survey examines several types of procedural advanced geometric modeling techniques, including **fractals**, **grammar-based models**, **volumetric procedural models**, **implicit surfaces**, and **particle systems**. Most of these techniques are used to model natural objects and phenomena because the inherent complexity of nature renders traditional modeling techniques impractical. These techniques can also be classified into **surface-based modeling** techniques and **volumetric modeling** techniques. Fractals, grammar-based models, and implicit surfaces* are surface-based modeling techniques. Volumetric procedural models and particle systems are volumetric modeling techniques.

*Implicit surfaces are rendered as surfaces, although the actual model is volumetric.

37.2 Fractals

Fractals and chaos theory have rapidly grown in popularity since the early 1960s [Peitgen et al. 1992]. Mathematicians in the late 19th century and early 20th century, including Cantor, Sierpiński, and von Koch, “discovered” fractal mathematics, but considered these formulas to be “mathematical monsters” that defied normal mathematical principles. Benoit Mandelbrot, who coined the term *fractal*, was the first person to realize that these mathematical formulas were a geometry for describing nature.

Fractals [Peitgen et al. 1992] have a precise mathematical definition, but in computer graphics their definition has been extended to generally refer to models with a large degree of *self-similarity*: subpieces of the object appear to be scaled down, possibly translated and rotated versions of the original object.* Along these lines, Musgrave [Ebert et al. 2002] defines a fractal as “a geometrically complex object, the complexity of which arises through the repetition of form over some range of scale.” Many natural objects exhibit this characteristic, including mountains, coastlines, trees, plants (e.g., cauliflower), water, and clouds. In describing fractals, the amount of “roughness,” “detail,” or amount of space filled by the fractal can be mathematically characterized by its *fractal dimension* (self-similarity dimension), D . The fractal dimension is related to the common integer dimensionality of geometric objects: a line is 1-D, a plane is 2-D, a sphere is 3-D. Fractal objects have noninteger dimensionality. An easy way to explain fractal dimension is to define it in terms of the recursive subdivision technique usually used to create simple fractals. If the original object is subdivided into a pieces using a reduction factor of s , the dimension D is related by the power law [Peitgen et al. 1992]

$$a = \frac{1}{s^D}$$

which yields

$$D = \frac{\log a}{\log(1/s)}$$

Normal geometric objects produce fractal (self-similarity) dimensions that are integers. Fractals produce noninteger, fractional, fractal dimensions. The following examples will illustrate this. If a cube is subdivided into 27 equal pieces, each one is scaled down by a factor of one third, yielding

$$D = \frac{\log 27}{\log(1/\frac{1}{3})} = \frac{\log 27}{\log 3} = 3$$

Conversely, a fractal object such as the *von Koch snowflake*** has a noninteger fractal dimension. The von Koch snowflake can be constructed by taking each side of an equilateral triangle, recursively dividing it into three equal pieces, and replacing the middle piece with two equal length pieces rotated to form two sides of an equilateral triangle as illustrated in [Figure 37.1](#). Analyzing the self-similarity dimension of this object yields a noninteger value:

$$D = \frac{\log 4}{\log(1/\frac{1}{3})} = \frac{\log 4}{\log 3} \approx 1.2618595$$

The von Koch curve has a fractal dimension between one and two, indicating that it is more space-filling than a line, but not as much as a two-dimensional object. This property is characteristic of fractal curves. By definition, a fractal has a noninteger self-similarity dimension.

Fractals can generally be classified as deterministic and nondeterministic (also called random fractals), depending on whether they contain randomness. In computer graphics, deterministic fractals are closely

*Mathematically speaking, the self-similarity must be infinite for the set to be a true fractal.

**Named for the mathematician Helga von Koch, who “discovered” it in 1904.

FIGURE 37.1 The von Koch snowflake after 0, 1, 2, 3, 4, and 5 iterations.

FIGURE 37.2 (See Plate 37.2 in the color insert following page 29-22.) A fractal terrain model by Ken Musgrave. (*Slickrock* © 1992 F. Kenton Musgrave.)

related to the grammar-based L-systems described in the following section. Random fractals have been used extensively in computer graphics to model self-similar, complex, natural objects, including terrain, mountains, clouds, water, and even entire planets [Ebert et al. 2002]. Indeed, fractals are the most common technique used in graphics for modeling mountains. Most fractal terrain generation algorithms work through recursive subdivision and pseudorandom perturbation. An original surface is defined and divided equally into subparts. New vertices are added and pseudorandomly displaced from the original surface, with a displacement magnitude that decreases at each iteration. Therefore, the first iteration gives the large peaks on the surface, and later subdivisions add smaller-scale detail. A common algorithm for mountains by Fournier, Fussell, and Carpenter uses this technique by starting with a triangle, adding new vertices at the midpoint of each edge with a random height displacement, generating new triangles from these points, and repeating this subdivision with decreased height displacements at each iteration. Typically, only parameters for controlling the random number generator, the level of subdivision, and the “roughness” of the surface are needed to define extremely complex mountains and terrain. Others have used simulations of fractional Brownian motion (fBm) and statistical simulations of noise to produce the height displacements for the mountains. Musgrave [Ebert et al. 2002] uses a nonrecursive algorithm to displace the vertices of a regular grid with values iteratively calculated based on fBm and noise functions (at each iteration, the frequency is increased and the magnitude decreased) to create realistic terrain models. Recent work on fractal terrain generation has included eroding the fractal terrain to simulate natural erosion processes and the use of *multifractal* models. Multifractal terrain models allow the fractal dimension of the terrain to vary across the surface. This variation allows rougher areas and smoother areas, providing more realistic natural terrain. An example of the realistic landscapes that can be produced by these techniques can be seen in Figure 37.2.

Recent work in fractals has included the simulation of diffusion-limited aggregation (DLA) models, the previously mentioned use of multifractals, and the use of fractal models to add complex details into models. DLA is a process based on random walks (fBm motion) of particles. Several initial sticky particles are placed in space. A large number of additional particles are moved on random walks; if they touch one of the sticky particles, they stick and may become sticky also. This process continues until all the additional particles attach to or move far enough away from the original particles. DLA models are being used to model a wide range of random processes from the formation of dendrite clusters to the formation of galaxies.

There are two common applications where geometric details are added with fractals. One is the addition of realistic, detailed, fractal terrain to coarse digital elevation data to provide realistic, higher-resolution terrain models. Another is the use of fractals to add small levels of geometric detail to standard geometric models. This allows less geometry in the model, with the procedural fractal functions being applied at rendering time to add an appropriate level of detail [Hart 1995].

There are many open areas of research in fractal modeling. Better erosion models that take into account different rock hardnesses, better rain distribution models, deposition of material in addition to erosion, wind erosion, and the use of nonheight fields to allow rock overhangs will improve the realism of fractal terrains. Multifractals, diffusion-limited aggregation, and fractal detail addition are active areas of research that show great potential for geometric modeling.

37.3 Grammar-Based Models

Grammar-based models also allow natural complexity to be specified with a few parameters. Smith [1984] introduced grammar-based models to graphics, calling them *graftals*. The most commonly used grammar-based model, an L-system (named for Aristid Lindenmayer), was originally developed as a mathematical theory of plant development [Prusinkiewicz and Lindenmayer 1990]. An L-system is a formal language, a parallel graph grammar, where all the rules are applied in parallel to provide a final “word” describing the object. This parallel application of the production rules distinguishes L-systems from Chomsky grammars. Like Chomsky grammars, there are context-free L-systems (0L) and context-sensitive L-systems (1L and 2L).

Grammar-based models have been used by many authors, including Fowler, Lindenmayer, Prusinkiewicz, and Smith, to produce remarkably realistic models and images of trees, plants, and seashells. These models describe natural structures algorithmically and are closely related to deterministic fractals in their self-similarity, but fail to meet the precise mathematical definition of a fractal. Many deterministic fractals can be defined with L-systems, but not all L-systems meet the definition of a fractal.

As with most formal languages, an L-system can be described by an alphabet for the grammar, the grammar production rules, and an initial axiom. In plant modeling, alphabet symbols represent botanical structures (usually letters) and branching commands (usually “[]” denotes the beginning and end of a branch). We can add denotation for angular movement by introducing a “+” for clockwise rotations and “-” for counterclockwise rotations. The following simple L-system can produce a basic tree:

Alphabet: $a, [,], +, -$
Production Rule: $a \rightarrow a[+a]a[-a - a]a$
Initial Axiom: a

In the L-system, each terminal symbol represents a part of the object (e.g., a branch element, internode, apex) or a directional command (e.g., turn left 30 deg) to be interpreted by a three-dimensional drawing mechanism (turtle graphics). A “word” for a tree would contain subwords describing each branch, its length, size, and branching angle, when it develops, and its connection in the tree. For example, if we interpret each “[+a]” as defining a right branch at 30 deg, each “[−a]” as defining a left branch at 30 deg,

FIGURE 37.3 Trees produced after 1, 2, and 3 derivations with the PGF software by Prusinkiewicz.

and each “*a*” as a tree segment (internode or apex), the above grammar can be interpreted graphically as the trees in Figure 37.3 after 1, 2, and 3 derivations and symbolically as the following:

Derivation	Word
0	<i>a</i>
1	<i>a</i> [+ <i>a</i>] <i>a</i> [− <i>a</i> − <i>a</i>] <i>a</i>
2	<i>a</i> [+ <i>a</i>] <i>a</i> [− <i>a</i> − <i>a</i>] <i>a</i> [+ <i>a</i>][+ <i>a</i>] <i>a</i> [− <i>a</i> − <i>a</i>] <i>a</i> [+ <i>a</i>] <i>a</i> [− <i>a</i> − <i>a</i>] <i>a</i> [− <i>a</i>][+ <i>a</i>] <i>a</i> [− <i>a</i> − <i>a</i>] <i>a</i> − <i>a</i> [+ <i>a</i>] <i>a</i> [− <i>a</i> − <i>a</i>] <i>a</i> [+ <i>a</i>] <i>a</i> [− <i>a</i> − <i>a</i>] <i>a</i>

To allow more complex plant and plant growth models, L-systems have been extended to include context sensitivity, word age information, and stochastic rule evaluation. Context sensitivity allows the relationships between parts of plants to be incorporated into the model. 1L-systems have one-sided contexts: either a right or a left context, yielding production rules of the form

$$a_l < a \rightarrow F$$

and

$$a > a_r \rightarrow F$$

The production rule is applied if and only if either its right context, aa_r , is satisfied or its left context, $a_l a$, is satisfied (either if *a* is preceded by a_l or if *a* is followed by a_r). 2L-systems have both a left context and a right context, yielding production rules of the form

$$a_l < a > a_r \rightarrow F$$

Stochastic L-systems assign a probability to the application of a rule. This allows randomness into the creation of the plant, so that each plant is slightly different. Deterministic L-systems produce identical plants each time they are evaluated and would, therefore, create an unrealistic field of identical flowers. Stochastic rule evaluation is added into the grammar by associating a probability, *p*, with each production rule as follows:

$$a \xrightarrow{p} F$$

Parametric L-systems allow word age information and conditional expressions based on parameter values to be included into the model, permitting developmental growth models for plants. A parametric L-system has rules of the form

$$F(t) : t > 2 \rightarrow F(t - 1)H(t + 7)$$

where *H* is another parametric production rule. Parametric L-systems can be combined with stochastic L-systems and context-sensitive L-systems to achieve a powerful, flexible grammar.

Recent work in L-systems allows better developmental models, more advanced biologically based growth models, incorporation of more growth parameters, and environmental effects. Extensions of L-systems allow the death of the buds, dropping of leaves, and cutting of branches with the inclusion of erasing and

FIGURE 37.4 (See Plate 37.4 in the color insert following page 29-22.) Horse chestnut tree created with a modified L-system that takes into account branch competition for light. (© 1995 R. Měch and P. Prusinkiewicz.)

cutting operators. Botanically based flowering structures (inflorescences), branching structures (sympodial and monopodial), and arrangement of lateral plant organs (phyllotaxis) [Fowler et al. 1992] have been incorporated into L-systems to more accurately model plants. **Tropism** effects (gravity, wind, growth toward light), pruning, amount of light, and availability of nutrients have also been incorporated into these grammars. These natural effects and growth processes not only affect the structure (topology) of the tree, but also affect the branching angles, petal and seed location and shape, and thickness of each branch segment. When generating the geometric plant model from the L-system grammar, these effects need to be included in determining the geometry and size of each structure in the plant. Figure 37.4 shows a realistic image of a horse chestnut tree generated by a modified L-system that takes into account the competition of branches for light.

Ongoing L-systems research includes environmentally-sensitive L-systems [Prusinkiewicz et al. 1995], the modeling of entire ecosystems [Deussen et al. 1998], modeling feathers [Chen et al. 2002], procedural modeling of cities [Parish and Miller 2001], and the use of L-systems for modeling other growth processes and artificial life. Additionally, better developmental models can be simulated and more accurate modeling of natural growth factors can be included.

37.4 Procedural Volumetric Models

Another procedural modeling technique, procedural volumetric modeling (also called hypertextures, volume density functions, and fuzzy blobbies), uses algorithms to define and animate three-dimensional volumetric objects and natural phenomena [Ebert et al. 2002]. These techniques have been used to model natural phenomena such as fire (Stam and Inakage), gases such as smoke, clouds, and fog (Ebert, Perlin, Sakas, Stam), and water (Ebert, Perlin). The volumetric procedures take as input a point location in space, time (if animating), and parameters that describe the object being modeled, and return the density and color of the object for that location in space. Complex volumetric phenomena can therefore be described with a few parameters.

An extremely simple procedural volumetric model for a spherical volume object is given below. This function, **spherical_pvm**, defines a sphere of radius **outer_radius**, with a solid center of radius **inner_radius**. The region between **inner_radius** and **outer_radius** is a semi-solid area that increases in density as the inner radius is approached. The following function, suggested by Perlin to create a *soft sphere* [Ebert et al. 2002], returns a density value when a point in space and the sphere definition are given as input:

```
typedef struct rgb_td { float r,g,b} rgb_td;
typedef struct xyz_td { float x,y,z} xyz_td;
typedef struct vol_td
{
    float density;
    rgb_td color;
} vol_td;

vol_td spherical_pvm(xyz_td pnt,xyz_td center,float inner_radius,
                    float outer_radius, float density_factor)
{
    float outer_radius_2, inner_radius_2, distance_2;
    vol_td vol;

    distance_2 = (pnt.x - center.x)*(pnt.x - center.x)
                + (pnt.y - center.y)* (pnt.y - center.y)
                + (pnt.z - center.z)*(pnt.z - center.z);

    /* compute outer and inner radius squared values */
    outer_radius_2 = outer_radius * outer_radius;
    inner_radius_2 = inner_radius * inner_radius;

    if (distance_2 < inner_radius_2)
    { /* inside inner radius */
        vol.density =1.0*density_factor;
        vol.color.r = 1.0; vol.color.g = 0.0; vol.color.b = 0.0;
    }
    else if (distance_2 > outer_radius_2)
    { /* outside of the sphere */
        vol.density = 0.0;
        vol.color.r = 0.0; vol.color.g = 0.0; vol.color.b = 0.0;
    }
    else
    { /* in the soft area of the sphere */
        vol.density = density_factor*(distance-inner_radius_2)/
                    (outer_radius_2-inner_radius_2);
        vol.color.r=vol.color.g = 1.0*vol.density;vol.color.b=0;
    }
    return(vol);
}
```

Many authors have used these techniques to describe a wide range of natural objects. Perlin has successfully created realistic rock arches, woven fabric, smoke, and fur [Ebert et al. 2002], basing his procedures on a statistical simulation of turbulence and random noise to give natural-looking complexity to the objects. Perlin's turbulence function has been used as a building block for volumetric procedural objects,

solid textures, and many other applications in computer graphics. This turbulence function defines a three-dimensional turbulence space by summing octaves of random noise, increasing the frequency and decreasing the amplitude at each step. The C function below is one implementation of Perlin's turbulence function:

```
float turbulence(xyz_td pnt, float pixel_size)
{
    float t, scale;
    t=0;
    for(scale=1.0; scale >pixel_size; scale/=2.0)
    {
        pnt.x = pnt.x/scale; pnt.y = pnt.y/scale;
        pnt.z = pnt.z/scale;
        t+=calc_noise(pnt)* scale;
    }
    return(t);
}
```

This function takes as input a three-dimensional point location in space, **pnt**, and an indication of the number of octaves of noise to sum, **pixel.size**,* and returns the turbulence value for that location in space. This function has a fractal characteristic in that it is self-similar and sums the octaves of random noise, doubling the frequency while halving the amplitude at each step. The heart of the **turbulence** function is the **calc_noise** function used to simulate uncorrelated random noise. Many authors have used various implementations of the noise function (see [Ebert et al. 2002] for several possible implementations). One implementation is the **calc_noise** function given below, which uses linear interpolation of a $64 \times 64 \times 64$ grid of random numbers**:

```
#define SIZE          64
#define SIZE_1       65
double drand48();
float calc_noise();
float noise[SIZE+1][SIZE+1][SIZE+1];

/*
*****
*
*                               Calc_noise
*****
* This is basically how the trilinear interpolation works:
* interpolate down left front edge of the cube first, then the
* right front edge of the cube(p_l, p_r). Next, interpolate down
* the left and right back edges (p_l2, p_r2). Interpolate across
* the front face between p_l and p_r (p_face1) and across the
* back face between p_l2 and p_r2 (p_face2). Finally, interpolate
* along line between p_face1 and p_face2.
*****
*/
```

*This variable name is used in reference to the projected area of the pixel in the three-dimensional turbulence space for antialiasing.

**The actual implementation uses a 65^3 table with the 64th entry equal to the 0th entry for quicker interpolation.

```

float
calc_noise(xyz_td pnt)
{
    float t1;
    float p_l,p_l2, /* value lerped down left side of face1 &
                    * face 2 */
           p_r,p_r2, /* value lerped down right side of face1 &
                    * face 2 */
           p_face1, /* value lerped across face 1 (x-y plane ceil
                    * of z) */
           p_face2, /* value lerped across face 2 (x-y plane floor
                    * of z) */
           p_final; /* value lerped through cube (in z) */

    extern float noise[SIZE-1][SIZE-1][SIZE-1];
    float      tnoise;
    register int x, y, z,px,py,pz;
    int        i,j,k, ii,jj,kk;
    static int  firsttime =1;

    /* During first execution, create the random number table of
     * values between 0 and 1, using the Unix random number
     * generator drand48(). Other random number generators may be
     * substituted. These noise values can also be stored to a
     * file to save time.
     */
    if (firsttime)
    { for (i=0; i<SIZE; i++)
      for (j=0; j<SIZE; j++)
        for (k=0; k<SIZE; k++)
          {
              noise[i][j][k] = (float)drand48();
              /* A crude way to make element[64]=element[0] for
               * easier linear interpolation */
              if(i==0) noise[SIZE][j][k] = noise[i][j][k];
              if(j==0) noise[i][SIZE][k] = noise[i][j][k];
              if(k==0) noise[i][j][SIZE] = noise[i][j][k];
          }
        firsttime=0;
    }

    px = (int)pnt.x;
    py = (int)pnt.y;
    pz = (int)pnt.z;
    x = px &(SIZE-1); /* make sure the values are in the table */
    y = py &(SIZE-1); /* Effectively, replicates the table
                    * throughout space */
    z = pz &(SIZE-1);

    t1 = pnt.y - py;
    p_l = noise[x][y][z+1] +t1*(noise[x][y+1][z+1]
        - noise[x][y][z+1]);

```

```

p_r = noise[x+1][y][z+1] +t1*(noise[x+1][y+1][z+1]
    - noise[x+1][y][z+1]);
p_l2 = noise[x][y][z] +t1*(noise[x][y+1][z] - noise[x][y][z]);
p_r2 = noise[x+1][y][z] +t1*(noise[x+1][y+1][z]
    - noise[x+1][y][z]);
t1 = pnt.x - px;
p_face1 = p_l + t1 * (p_r - p_l);
p_face2 = p_l2 + t1 * (p_r2 -p_l2);
t1 = pnt.z - pz;
p_final = p_face2 + t1*(p_face1 -p_face2);
return(p_final);
}

```

Ebert et al. [2002] have used similar functions to model and animate steam, fog, smoke, clouds, and solid marble. The turbulence function and random noise functions allow a simple simulation of turbulent flow processes. To simulate steam rising from a teacup, a volume of gas is placed over the teacup. The basic gas is defined by the following function:

```

float basic_gas(xyz_td pnt, float density, float density_scalar,
    float exponent)
{
    float turb, density;
    turb =turbulence(pnt);
    density = pow(turb*density_scalar, exponent);
    return(density);
}

```

This function creates a three-dimensional gas space controlled by the values **density_scalar** and **exponent**. **density_scalar** controls the denseness of the gas, while **exponent** controls the sharpness and sparseness of the gas (from continuously varying to sharp individual plumes). This function is then shaped to create steam over the center of the teacup by spherically attenuating the density toward the edge of the cup and linearly attenuating the density as the distance from the top of the cup increases, simulating the gas dissipation as it rises. The following procedure will produce an image of steam rising from a teacup, as in Figure 37.5.

FIGURE 37.5 Steam rising from a teacup. (See Plate 37.5 in the color insert following page 29-22.) (© 1991 David S. Ebert.)

```

float steam(xyz_td pnt, xyz_td pnt_world, float exponent,
           float density_scalar,xyz_td tea_center,float radius)
{
    float    turb, dist, dist_sq, density_max, fall_off, offset;
    xyz_td   diff;

    turb = turbulence(pnt);
    density = pow(turb*density_scalar, exponent);

    /* determine distance from center of the teacup squared. */
    XYZ_SUB(diff,tea_center, pnt_world);
    dist_sq = DOT_XYZ(diff,diff);
    /* calculate relative distance from center with some
     * randomness */
    density_max = dist_sq/(radius*radius);
    density_max += .2*noise(pnt);

    /* Use a cosine function to spherically attenuate the
     * density */
    if(density_max >= .25) /* ramp off if > 25% from center */
        { /* get table index 0:RAMP_SIZE-1 */
            density_max = MAX((density_max -.25)*4/3, 1.0);
            fall_off = (cos(density_max*M-PI)+1.0)/2.0;
            density *=fall_off;
        }
    /* Use exponential attenuation to decrease density as steam
     * rises */
    dist = pnt_world.y - tea_center.y;
    if(dist > 0.0)
        { dist = (dist +noise(pnt)*.1)/radius.y;
          if(dist > .05)
              { offset = (dist -.05)*1.111111;
                offset = 1 - (exp(offset)-1.0)/1.718282;
                density = density*offset;
              }
          }
    return(density);
}

```

These procedural techniques can be easily animated by adding time as a parameter to the algorithm [Ebert et al. 2002]. They allow the use of simple simulations of natural complexity (noise, turbulence) to speed computation, but also allow the incorporation of physically based parameters where appropriate and feasible. This flexibility is one of the many advantages of procedural techniques.

Procedural volumetric models require volume rendering techniques to create images of these objects. Traditionally, most authors have used a modification of volume ray tracing. Several authors have incorporated physically based models for shadowing and illumination into rendering algorithms for these models [Ebert and Parent 1990, Stam and Fiume 1995]. However, with the advent of programmable graphics hardware that allow user-defined programs to be executed for each polygonal pixel-sized fragment, these function can potentially be evaluated at interactive rates by the graphics hardware. Ebert et al. [2002] describe methods to adapt procedural volumetric modeling techniques to modern graphics hardware.

Procedural volumetric modeling is still an active area of research and has many research problems to address. Efficient rendering of these models is still an important issue, as is the development of a

FIGURE 37.6 A close-up of a fly through of a procedural volumetric cloud incorporating volumetric implicit models into the procedural volumetric model. (©2002 David S. Ebert.)

larger toolbox of useful primitive functions. The incorporation of more physically based models will increase the accuracy and realism of the water, gas, and fire simulations. Finally, the development of an interactive procedural volumetric modeling system will speed the development of procedural volumetric modeling techniques. The procedural interfaces in the latest commercial modeling, rendering, and animation packages are now allowing the specification of procedural models, but the user control is still lacking.

Combining traditional volumetric procedural models with implicit functions, described below, creates a model that has the advantages of both techniques. Implicit functions have been used for many years as a modeling tool for creating solid objects and smoothly blended surfaces [Bloomenthal et al. 1997]. However, only a few researchers have explored their potential for modeling volumetric density distributions of semi-transparent volumes (e.g., [Nishita et al. 1996, Stam and Fiume 1991, Stam and Fiume 1993, Stam and Fiume 1995, Ebert 1997]). Ebert's early work on using volume rendered implicit spheres to produce a fly-through of a volumetric cloud was described in [Ebert et al. 1997]. This work has been developed further to use implicits to provide a natural way of specifying and animating the global structure of the cloud, while using more traditional procedural techniques to model the detailed structure. More details on the implementation of these techniques can be found in [Ebert et al. 2002]. An example of a procedural volumetric cloud modeled using the above turbulence-based techniques combined with volumetrically evaluated implicit spheres, can be seen in Figure 37.6.

37.5 Implicit Surfaces

While previously discussed techniques have been used primarily for modeling the complexities of nature, implicit surfaces [Bloomenthal et al. 1997] (also called blobby molecules [Blinn 1982], metaballs [Nishimura et al. 1985], and soft objects [Wyvill et al. 1986]) are used in modeling organic shapes, complex man-made shapes, and “soft” objects that are difficult to animate and describe using more traditional techniques. Implicit surfaces are surfaces of constant value, **isosurfaces**, created from blending primitives (functions or skeletal elements) represented by implicit equations of the form $F(x, y, z) = 0$, and were first introduced into computer graphics by Blinn [1982] to produce images of electron density clouds. A simple example of an implicit surface is the sphere defined by the equation

$$F(x, y, z) : x^2 + y^2 + z^2 - r^2 = 0$$

Implicit surfaces are a more concise representation than parametric surfaces and provide greater flexibility in modeling and animating soft objects.

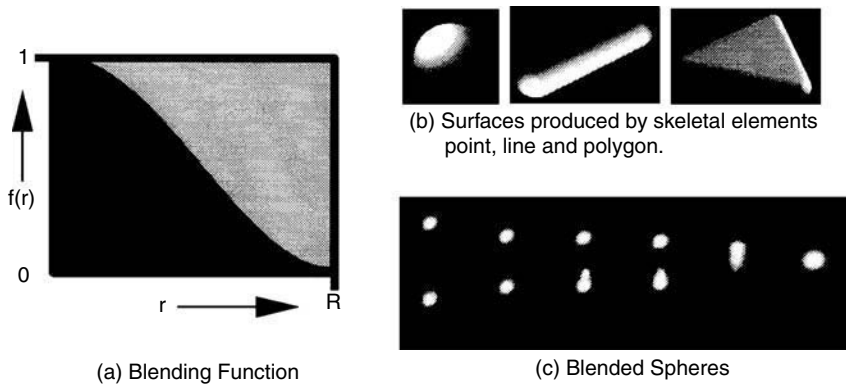

FIGURE 37.7 (a) Blending function, (b) surfaces produced by skeletal elements point, line and polygon, and (c) blended spheres. (© 1995 Brian Wyvill.)

For modeling complex shapes, several basic implicit surface primitives are smoothly blended to produce the final shape. For the blending function, Blinn used an exponential decay of the field values, whereas Wyvill [Wyvill et al. 1986, 1993] uses the cubic function

$$F_{\text{cub}}(r) = -\frac{4}{9} \frac{r^6}{R^6} + \frac{17}{9} \frac{r^4}{R^4} - \frac{22}{9} \frac{r^2}{R^2} + 1$$

This cubic blending function, whose values range from 1 when $r = 0$ to 0 at $r = R$, has several advantages for complex shape modeling. First, its value drops off quickly to zero (at the distance R), reducing the number of primitives that must be considered in creating the final surface. Second, it has zero derivatives at $r = 0$ and $r = R$ and is symmetrical about the contour value 0.5, providing for smooth blends between primitives. Finally, it can provide volume-preserving primitive blending. Figure 37.7(a) shows a graph of this blending function, and Figure 37.7(c) shows the blending of two spheres using this function. A good comparison of blending functions can be found in [Bloomenthal et al. 1997].

For implicit surface primitives, Wyvill uses procedures that return a functional (field) value for the field defined by the primitive. Field primitives, such as lines, points, polygons, circles, splines, spheres, and ellipsoids, are combined to form a basic skeleton for the object being modeled. The surfaces resulting from these skeletal elements can be seen in Figure 37.7(b). The object is then defined as an offset (isosurface) from this series of blended skeletal elements. Skeletons are an intuitive representation and are easily displayed and animated.

Modeling and animation of implicit surfaces is achieved by controlling the skeletal elements and blending functions, providing complex models and animations from a few parameters (another example of data amplification). Deformation, path following, warping, squash and stretch, gravity, and metamorphosis effects can all be easily achieved with implicit surfaces. Very high-level animation control is achieved by animating the basic skeleton, with the surface defining the character following naturally. The animator does not have to be concerned with specifying the volume-preserving deformations of the character as it moves.

There are two common approaches to rendering implicit surfaces. One approach is to directly ray-trace the implicit surfaces, requiring the modification of a standard ray tracer. The second approach is to polygonalize the implicit surfaces [Ning and Bloomenthal 1993, Wyvill et al. 1993] and then use traditional polygonal rendering algorithms on the result. Uniform-voxel space polygonization can create large numbers of unnecessary polygons to accurately represent surface details. More complicated tessellation and shrinkwrap algorithms have been developed which create appropriately sized polygons [Wyvill et al. 1993].

Recent work in implicit surfaces [Wyvill and Gascuel 1995, Wyvill et al. 1999] has extended their use to character modeling and animation, human figure modeling, and representation of rigid objects through

FIGURE 37.8 (See Plate 37.8 in the color insert following page 29-22.) Ten years in implicit surface modeling. The locomotive labeled 1985 shows a more traditional soft object created by implicit surface techniques. The locomotive labeled 1995 shows the results achievable by incorporating constructive solid geometry techniques with implicit surface models. (© 1995 Brian Wyvill.)

the addition of constructive solid geometry (CSG) operators. Implicit surface modeling techniques have advanced significantly in the past 10 years, as can be seen by comparing the locomotives in Figure 37.8. The development of better blending algorithms, which solve the problems of unwanted primitive blending and surface bulging, is an active area of research [Bloomenthal 1995]. Advanced animation techniques for implicit surfaces, including higher-level animation control, surface collision detection, and shape metamorphosis animation, are also active research areas. Finally, the development of interactive design systems for implicit surfaces will greatly expand the use of this modeling technique. The use of implicit functions have also expanded to compact representations of surface objects [Turk and O'Brien 2002].

37.6 Particle Systems

Particle systems are different from the previous four techniques in that their abstraction is in control of the animation and specification of the object. A particle-system object is represented by a large collection (cloud) of very simple geometric particles that change stochastically over time. Therefore, particle systems do use a large database of geometric primitives to represent natural objects (“fuzzy objects”), but the animation, location, birth, and death of the particles representing the object are controlled algorithmically. As with the other procedural modeling techniques, particle systems have the advantage of database amplification, allowing the modeler/animater to specify and control this extremely large cloud of geometric particles with only a few parameters.

Particle systems were first used in computer graphics by Reeves [1983] to model a wall of fire for the movie *Star Trek II: The Wrath of Khan* (see Figure 37.9). Because particle systems are a volumetric modeling technique, they are most commonly used to represent volumetric natural phenomena such as fire, water, clouds, snow, and rain [Reeves 1983]. An extension of particle systems, *structured particle systems*, has also been used to model grass and trees [Reeves and Balu 1985].

A particle system is defined by both a collection of geometric particles and the algorithms that govern their creation, movement, and death. Each geometric particle has several attributes, including its initial position, velocity, size, color, transparency, shape, and lifetime.

To create an animation of a particle system object, the following steps are performed at each time step [Reeves 1983]:

1. New particles are generated and assigned their attributes.
2. Particles that have existed in the system past their lifetime are removed.

FIGURE 37.9 (See Plate 37.9 in the color insert following page 29-22.) An image from *Star Trek II: The Wrath of Khan* showing a wall of fire created with a particle system. (© 1987 Pixar.)

3. Each remaining particle is moved and transformed by the particle-system algorithms as prescribed by their individual attributes.
4. These particles are rendered, using special-purpose rendering algorithms, to produce an image of the particle system.

The creation, death, and movement of particles are controlled by stochastic procedures, allowing complex, realistic motion to be created with a few parameters. The creation procedure for particles is controlled by parameters defining either the mean number of particles created at each time step and its variance, or the mean number of particles created per unit of screen area at each time step and its variance.* The actual number of particles created is stochastically determined to be within $mean + variance$ and $mean - variance$. The initial color, velocity, size, and transparency are also stochastically determined by mean and variance values. The initial shape of the particle system is defined by an origin, a region about this origin in which new generated particles are placed, angles defining the orientation of the particle system, and the initial direction of movement for the particles.

The movement of particles is also controlled by stochastic procedures (stochastically determined velocity vectors). These procedures move the particles by adding their velocity vector to their position vector. Random variations can be added to the velocity vector at each frame, and acceleration procedures can be incorporated to simulate effects such as gravity, vorticity, and conservation of momentum and energy. The simulation of physically based forces allows realistic motion and complex dynamics to be displayed by the particle system, while being controlled by only a few parameters. In addition to the movement of particles, their color and transparency can also change dynamically to give more complex effects. The death of particles is controlled very simply by removing particles from the system whose lifetimes have expired or that have strayed more than a given distance from the origin of the particle system.

An example of the effects achievable by such a particle system can be seen in Figure 37.9, an image from the Genesis Demo sequence from *Star Trek II: The Wrath of Khan*. In this image, a two-level particle system was used to create the wall of fire. The first-level particle system generated concentric, expanding rings of particle systems on the planet's surface. The second-level particle system generated particles at each of these locations, simulating explosions. During the Genesis Demo sequence, the number of particles in the system ranged from several thousand initially to over 750,000 near the end.

Reeves extended the use of particle systems to model fields of grass and forests of trees, calling this new technique structured particle systems [Reeves and Blau 1985]. In structured particle systems, the particles are no longer an independent collection of particles, but rather form a connected, cohesive three-dimensional object and have many complex relationships among themselves. Each particle represents an

*These values can be varied over time as well.

element of a tree (e.g., branch, leaf) or part of a blade of grass. These particle systems are therefore similar to L-systems and graftals, specifically probabilistic, context-sensitive L-systems. Each particle is similar to a letter in an L-system alphabet, and the procedures governing the generation, movement, and death of particles are similar to the production rules. However, they differ from L-systems in several ways. First, the goal of structured particle systems is to model the visual appearance of whole collections of trees and grass, and not to correctly model the detailed geometry of each plant. Second, they are not concerned with biological correctness or modeling growth of plants. Structured particle systems construct trees by recursively generating subbranches, with stochastic variations of parameters such as branching angle, thickness, and placement within a value range for each type of tree. Additional stochastic procedures are used for placement of the trees on the terrain, random warping of branches, and bending of branches to simulate tropism. A forest of such trees can therefore be specified with a few parameters for distribution of tree species and several parameters defining the mean values and variances for tree height, width, first branch height, length, angle, and thickness of each species.

Both regular particle systems and structured particle systems pose special rendering problems because of the large number of primitives. Regular particle systems have been rendered simply as point light sources (or linear light sources for antialiased moving particles) for fire effects, accumulating the contribution of each particle into the frame buffer and compositing the particle system image with the surface rendered image (as in [Figure 37.9](#)). No occlusion or interparticle illumination is considered. Structured particle systems are much more difficult to render, and specialized probabilistic rendering algorithms have been developed to render them [Reeves and Blau 1985]. Illumination, shadowing, and hidden-surface calculations need to be performed for the particles. Because stochastically varying objects are being modeled, approximately correct rendering will provide sufficient realism. Probabilistic and approximate techniques are used to determine the shadowing and illumination of each tree element. The particle's distance into the tree from the light source determines its amount of **diffuse shading** and probability of having **specular highlights**. Self-shadowing is simulated by exponentially decreasing the **ambient illumination** as the particle's distance within the tree increases. External shadowing is also probabilistically calculated to simulate the shadowing of one tree by another tree. For hidden-surface calculations, an initial depth sort of all trees and a **painter's algorithm** is used. Within each tree, again, a painter's algorithm is used, along with a back-to-front bucket sort of all the particles. This will not correctly solve the hidden-surface problem in all cases, but will give realistic, approximately correct images.

Efficient rendering of particle systems is still an open research problem (e.g., [Etzmuss et al. 2002]). Although particle systems allow complex scenes to be specified with only a few parameters, they sometimes require rather slow, specialized rendering algorithms. Simulation of fluids [Miller and Pearce 1989], cloth [Breen et al. 1994, Baraff and Witkin 1998, Plath 2000], and surface modeling with oriented particle systems [Szeliski and Tonnesen 1992] are recent, promising extensions of particle systems. Sims [1990] demonstrated the suitability of highly parallel computing architectures to particle-system simulation. Particle systems, with their ease of specification and good dynamical control, have great potential when combined with other modeling techniques such as implicit surfaces [Witkin and Heckbert 1994] and volumetric procedural modeling.

Particle systems provide a very nice, powerful animation system for high-level control of complex dynamics and can be combined with many of the procedural techniques described in this chapter. For example, turbulence functions are often combined with particle systems, such as Ebert's use of particle systems for animating cloud dynamics [Ebert et al. 2002].

37.7 Research Issues and Summary

Advanced modeling techniques will continue to play an important role in computer graphics. As computers become more powerful, the complexity that can be rendered will increase; however, the capability of humans to specify more geometric complexity (millions of primitives) will not. Therefore, procedural techniques, with their capability to amplify the user's input, are the only viable alternative. These techniques will evolve in their capability to specify and control incredibly realistic and detailed models with a small number of

user-specified parameters. More work will be done in allowing high-level control and specification of models in user-understandable terms, while more complex algorithms and improved physically based simulations will be incorporated into these procedures. Finally, the automatic generation of procedural models through artificial evolution techniques, similar to those of Sims [1994], will greatly enhance the capabilities and uses of these advanced modeling techniques.

Defining Terms

Ambient illumination: An approximation of the global illumination on the object, usually modeled as a constant amount of illumination per object.

Diffuse shading: The illumination of an object where light is reflected equally in all directions, with the intensity varying based on surface orientation with respect to the light source. This is also called Lambertian reflection because it is based on Lambert's law of diffuse reflection.

Fractal: Generally refers to a complex geometric object with a large degree of self-similarity and a non-integer fractal dimension that is not equal to the object's topological dimension.

Grammar-based modeling: A class of modeling techniques based on formal languages and formal grammars where an alphabet, a series of production rules, and initial axioms are used to generate the model.

Implicit surfaces: Isovalued surfaces created from blending primitives that are modeled with implicit equations.

Isosurface: A surface defined by all the points where the field value is the same.

L-system: A parallel graph grammar in which all the production rules are applied simultaneously.

Painter's algorithm: A hidden-surface algorithm that sorts primitives in back-to-front order, then "paints" them into the frame buffer in this order, overwriting previously "painted" primitives.

Particle system: A modeling technique that uses a large collection (thousands) of particles to model complex natural phenomena, such as snow, rain, water, and fire.

Phyllotaxis: The regular arrangement of plant organs, including petals, seeds, leaves, and scales.

Procedural volumetric models: Use algorithms to define the three-dimensional volumetric representation of an object.

Specular highlights: The bright spots or highlights on objects caused by angular-dependent illumination. Specular illumination depends on the surface orientation, the observer location, and the light source location.

Surface-based modeling: Refers to techniques for modeling the three-dimensional surfaces of objects.

Tropism: An external directional influence on the branching patterns of trees.

Volumetric modeling: Refers to techniques that model objects as three-dimensional volumes of material, instead of being defined by surfaces.

Further Information

There are many sources of further information on advanced modeling techniques. Two of the best resources are the proceedings and course notes of the annual ACM SIGGRAPH conference. The SIGGRAPH conference proceedings usually feature a section on the latest, and often best, results in modeling techniques. The course notes are a very good source for detailed, instructional information on a topic. Several courses at SIGGRAPH '92, '93, '94, and '95 contained notes on procedural modeling, fractals, particle systems, implicit surfaces, L-systems, artificial evolution, and artificial life.

Standard graphics texts, such as *Computer Graphics: Principles and Practice* by Foley, van Dam, Feiner, and Hughes [Foley et al. 1990] and *Advanced Animation and Rendering Techniques* by Watt and Watt [1992], contain introductory explanations to these topics. The reference list contains references to excellent books and, in most cases, the most comprehensive sources of information on the subject. Additionally, the book entitled *The Fractal Geometry of Nature*, by Mandelbrot [1983], is a classic reference for fractals. For implicit surfaces, the book by Bloomenthal, Wyvill, et al. [1997] is a great reference.

Another good source of reference material is specialized conference and workshop proceedings on modeling techniques. For example, the proceedings of the Eurographics '95 Workshop on Implicit Surfaces contains state-of-the-art implicit surfaces techniques.

38.1 Introduction

Rendering is the name given to the process in three-dimensional graphics whereby a geometric description of an object is converted into a two-dimensional image-plane representation that looks real.

Three methods of rendering are now firmly established. The first and most common method is to use a simulation of light-object interaction in conjunction with **polygon mesh** objects; we have called this approach *rendering polygon mesh objects*. Although the light-object simulation is independent of the object representation, the combination of empirical light-object interaction and polygon mesh representation has emerged as the most popular rendering technique in computer graphics. Because of its ubiquity and importance, we shall devote most of this chapter to this approach.

This approach to rendering suffers from a significant disadvantage. The reality of light-object interaction is simulated as a crude approximation — albeit an effective and cheap simulation. In particular, objects are considered to exist in isolation with respect to a light source or sources, and no account is taken of light interaction between objects themselves. In practice, this means that although we simulate the reflection of light incident on an object from a light source, we resolutely ignore the effects that the reflected light has on the scene when it travels onward from its first reflection to encounter, perhaps, other objects, and so on. Thus, common phenomena that depend on light reflecting from one object onto another, like shadows and objects reflecting in each other, cannot be produced by such a model. Such defects in straightforward polygon mesh rendering have led to the development of many and varied enhancements that attempt to address its shortcomings. Principal among these are mapping techniques (texture mapping, environment mapping, etc.) and various shadow algorithms.

Such models are called **local reflection models** to distinguish them from **global reflection models**, which attempt to follow the adventures of light emanating from a source as it hits objects, is reflected, hits other objects, and so on. The reason local reflection models work — in the sense that they produce visually acceptable, or even impressive, results — is that in reality the reflected light in a scene that emanates from first-hit incident light predominates. However, the subtle object–object interactions that one normally encounters in an environment are important. This motivation led to the development of the two global reflection models: **ray tracing** and **radiosity**.

Ray tracing simulates global interaction by explicitly tracking infinitely thin beams, or rays, of light as they travel through the scene from object to object. *Radiosity*, on the other hand, considers light reflecting in all directions from the surface of an object and calculates how light radiates from one surface to another as a function of the geometric relationship between surfaces — their proximity, relative orientation, etc. Ray tracing operates on points in the scene, radiosity on finite areas called patches.

Ray tracing and radiosity formed popular research topics in the 1980s. Both methods are much more expensive than polygon mesh rendering, and a common research motivation was efficiency, particularly in the case of ray tracing.

For reasons that will become clear later, ray tracing and radiosity each can simulate only one aspect of global interaction. Ray tracing deals with specular interaction and is fine for scenes consisting of shiny, mutually reflective objects. On the other hand, radiosity deals with diffuse or dull surfaces and is used mostly to simulate interiors of rooms. In effect, the two methods are mutually exclusive: ray tracing cannot simulate diffuse interaction, and radiosity cannot cope with specular interaction. This fact led to another major research effort, which was to incorporate specular interaction in the radiosity method.

Whether radiosity and ray tracing should be categorized as mainstream is perhaps debatable. Certainly the biggest demand for three-dimensional computer graphics is real-time rendering for computer games. Ray tracing and radiosity cannot be performed in real time on consumer equipment and, unless used in precalculation mode, are excluded from this application. However, radiosity in particular is used in professional applications, such as computer-aided architectural design.

38.2 Rendering Polygon Mesh Objects

38.2.1 Introduction

The overall process of rendering polygon mesh objects can be broken down into a sequence of geometric transformations and pixel processes that have been established for at least two decades as a *de facto* standard. Although they are not the only way to produce a shaded image of a three-dimensional object, the particular processes we shall describe represent a combination of popularity and ease of implementation. There is no established name for this group of processes, which has emerged for rendering objects represented by a polygon mesh — by far the most popular form of representation. The generic term *rendering pipeline* applies to any set of processes used to render objects in three-dimensional graphics.

Ignoring any transformations that are involved in positioning many objects to make up a scene — modeling transformations — we can summarize these processes as follows:

Viewing transformation — A process that is invoked to generate a representation of the object or scene as seen from the viewpoint of an observer positioned somewhere in the scene and looking toward some aspect of it. This involves a simple transformation that changes the object from its database representation to one that is represented in a coordinate system related to the viewer's position and viewing direction. It establishes the size of the object, according to its distance from the viewer, and the parts of it seen from the viewing direction.

Clipping — The need for clipping is easily exemplified by considering a viewpoint that is embedded among objects in the scene. Objects and parts of objects, for example, behind the viewer must be eliminated from consideration. Clipping is nontrivial because, in general, it involves removing parts of polygons and creating new ones. It means “cutting chunks” off the objects.

Projective transformation — This transformation generates a two-dimensional image on the image or viewing plane from the three-dimensional view-space representation of the object.

Shading algorithm — The orientation of the polygonal facets that represent the object are compared with the position of a light source (or sources), and a reflected light intensity is calculated for each point on the surface of the object. In practice, “each point on the surface” means those pixels onto which the polygonal facet projects. Thus, it is convenient to calculate the set of pixels onto which a polygon projects and to drive this process from pixel space — a process that is usually called *rasterization*. Shading algorithms use a local reflection model and an *interpolative method* to distribute the appropriate light intensity among pixels inside a polygon. The computational efficiency and visual efficacy of the shading algorithm have supported the popularity of the polygon mesh representation. (The polygon mesh representation has many drawbacks — its major advantage is simplicity.)

Hidden-surface removal — Those surfaces that cannot be seen from the viewpoint need to be removed from consideration. In the 1970s, much research was carried out on the best way to remove hidden surfaces, but the Z-buffer algorithm, with its easy implementation, is the *de facto* algorithm, with others being used only in specialized contexts. However, it does suffer from inefficiency and produces aliasing artifacts in the final image.

The preceding processes are not carried out in a sequence but are merged together in a way that depends on the overall rendering strategy. The use of the Z-buffer algorithm, as we shall see, conveniently allows polygons to be fetched from the database in any order. This means that the units on which the whole rendering process operates are single polygons that are passed through the processes one at a time. The entire process can be seen as a black box, with a polygon input as a set of vertices in three-dimensional world space. The output is a shaded polygon in two-dimensional screen space as a set of pixels onto which the polygon has been projected.

Although, as we have implied, the processes themselves have become a kind of standard, rendering systems vary widely in detail, particularly in differences among subprocesses such as rasterization and the kind of viewing system used.

The marriage of interpolative shading with the polygon mesh representation of objects has served, and continues to serve, the graphics community well. It does suffer from a significant disadvantage, which is that **antialiasing** measures are not easily incorporated in it (except by the inefficient device of calculating a virtual image at a resolution much higher than the final screen resolution). Antialiasing measures are described elsewhere in this text.

The first two processes, viewing transformation and clipping, are geometric processes that operate on the vertex list of a polygon, producing a new vertex list. At this stage, polygons are still represented by a list of vertices where each vertex is a coordinate in a three-dimensional space with an implicit link between vertices in the list. The projective transformation is also a geometric process, but it is embedded in the pixel-level processes. The shading algorithm and hidden-surface removal algorithm are pixel-level processes operating in screen space (which, as we shall see, is considered for some purposes to possess a third dimension). For these processes, the polygon becomes a set of pixels in two-dimensional space. However, some aspects of the shading algorithm require us to return to three-dimensional space. In particular, calculating light intensity is a three-dimensional calculation. This functioning of the shading algorithm in both screen space and a three-dimensional object space is the source of certain visual artifacts. These arise because the projective transformation is nonlinear. Such subtleties will not be considered here, but see [Watt and Watt, 1992] for more information on this point.

38.2.2 Viewing and Clipping

When viewing transformations are considered in computer graphics, an analogy is often made with a camera, and the term **virtual camera** is employed. There are certainly direct analogies to be made between a camera, which records a two-dimensional projection of a real scene on a film, and a computer graphics system. However, keep in mind that these concern external attributes, such as the position of the camera and the direction in which it is pointing. There are implementations in a computer graphics system (notably

FIGURE 38.1 The three basic attributes required in a viewing system.

FIGURE 38.2 View frustum formed by near and far planes.

the near and far clip planes) that are not available in a camera and facilities in a camera that are not usually imitated in a computer graphics system (notably depth of field and lens distortion effects). The analogy is a general one, and its utility disappears when details are considered.

The facilities incorporated into a viewing system can vary widely. In this section, we will look at a system that will suffice for most general-purpose rendering systems. The ways in which the attributes of the viewing system are represented, which have ramifications for the design of a user interface for a viewing system, also vary widely.

We can discuss our requirements by considering just three attributes (see Figure 38.1). First, we establish a viewpoint and a viewing direction. A *viewpoint*, which we can also use as a center of projection, is a single point in world space, and a *viewing direction* is a vector in this space.

Second, we position a view plane somewhere in this space. It is convenient to constrain the view plane normal to be the viewing direction and its position to be such that a line from the viewpoint, in the viewing direction, passes through the center of the view plane. The distance of the viewpoint from the object being viewed and the distance of the view plane from the viewpoint determine the size of the projection of the object on the view plane. Also, these two distances determine the degree of perspective effect in the object projection, since we will be using a perspective projection. This arrangement defines a new three-dimensional space, known as *view space*. Normally, we would take the origin of this space to be the viewpoint, and the coordinate axes are oriented by the viewing direction.

Usually, we assume that the view plane is of finite extent and rectangular, far clip planes (Figure 38.2)

to constrain further those elements of the scene that are projected onto the view plane — a caprice of computer graphics not available in a camera.

Such a setup, as can be seen in Figure 38.2, defines a so-called *view volume*, and consideration of this gives the motivation for clipping. Clipping means that the part of the scene that lies outside the view frustum should be discarded from the rendering process. We perform this operation in three-dimensional view space, clipping polygons to the view volume. This is a nontrivial operation, but it is vital in scenes of any complexity where only a small proportion of the scene will finally appear on the screen. In simple single-object applications, where the viewpoint will not be inside the bounds of the scene and we do not implement a near and a far clip plane, we can project all the scene onto the view plane and perform the clipping operation in two-dimensional space.

Now we are in a position to define **viewing** and **clipping** as those operations that transform the scene from world space into view space, at the same time discarding that part of the scene or object that lies outside the view frustum.

We will deal separately with the transformation into the view space and clipping. First, we consider the viewing transformation. A useful practical facility that we should consider is the addition of another vector to specify the rotation of the view plane about its axis (the view-direction vector). Returning to our camera analogy, this is equivalent to allowing the user to rotate the camera about the direction in which it is pointing. A user of such a system must specify the following:

1. A viewpoint or camera position **C**, which forms the origin of view space. This point is also the center of projection (see Section 38.2.4).
2. A viewing direction vector **N** (the positive z-axis in view space) — this is a vector normal to the view plane.
3. An “up” vector **V** that orients the camera about the view direction.
4. An optional vector **U**, to denote the direction of increasing *x* in the eye coordinate system. This establishes a right- or left-handed coordinate system (**UVN**). This system is represented in Figure 38.3.

The transformation required to take an object from world space into view space, T_{view} , can be split into a translation T and a change of basis B :

$$T_{\text{view}} = TB$$

where

$$T = \begin{bmatrix} 1 & 0 & 0 & -C_x \\ 0 & 1 & 0 & -C_y \\ 0 & 0 & 1 & -C_z \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

FIGURE 38.3 UVN coordinate system embedded in the view plane.

It can be shown [Fiume, 1989] that B is given by

$$B = \begin{bmatrix} U_x & U_y & U_z & 0 \\ V_x & V_y & V_z & 0 \\ N_x & N_y & N_z & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

The only problem now is specifying a user interface for the system and mapping whatever parameters are used by the interface into U , V , and N . A user needs to specify C , N , and V . C is easy enough. N , the viewing direction or view plane normal, can be entered, say, by using two angles in a spherical coordinate system. V is more problematic. For example, a user may require “up” to have the same sense as “up” in the world coordinate system. However, this cannot be achieved by setting

$$V = (0, 0, 1)$$

because V must be perpendicular to N . A useful strategy is to allow the user to specify, through a suitable interface, an approximate value for V , having the program alter this to a correct value.

38.2.3 Clipping and Culling

Clipping and culling mean discarding, at an early stage in the rendering process, polygons or parts of polygons that will not appear on the screen. Polygons that must be discarded fall into three categories:

1. Complete objects that lie outside the view volume should be removed entirely without invoking any tests at the level of individual polygons. This can be done by comparing a bounding volume, such as a sphere, with the view-volume extents and removing (or not) the entire set of polygons that represent an object.
2. Complete polygons that face away from a viewer need not invoke the expense of a clipping procedure. These are called *back-facing polygons*, and in any (convex) object they account, on average, for 50% of the object polygons. These can be eliminated by a simple geometric test, which is termed **culling** or *back-face removal*.
3. Polygons that straddle a view-volume plane must be clipped against the view frustum and the resulting fragment, which comprises a new polygon, passed on to the remainder of the process.

Clipping is carried out in the three-dimensional domain of view space; culling is performed in this space, also. Culling is a pure geometric operation that discards polygons on the basis of the direction of their surface normal compared to the viewing direction. Clipping is an algorithmic operation, because some process must be invoked that produces a new polygon from the polygon that is clipped by one of the view-volume planes.

We deal with the simple operation of culling first. If we are considering a single convex object, then culling performs complete hidden-surface removal. If we are dealing with objects that are partially concave, or if there is more than one object in the scene, then a general hidden-surface removal algorithm is required. In these cases, the event of one polygon partially obscuring another arises — a situation impossible with a single convex object.

Determining whether a single polygon is visible from a viewpoint involves a simple geometric test (see [Figure 38.4](#)). We compare the angle between the (true) normal of each polygon and a line-of-sight vector. If this is greater than 90° , then the polygon cannot be seen. This condition can be written as

$$\text{visibility} := \mathbf{N}_p \cdot \mathbf{L}_{os} > 0$$

where \mathbf{N}_p is the polygon normal and \mathbf{L}_{os} is a vector representing a line from one vertex of the polygon to the viewpoint. A polygon normal can be calculated from any three (noncollinear) vertices by taking a cross product of vectors parallel to the two edges defined by the vertices.

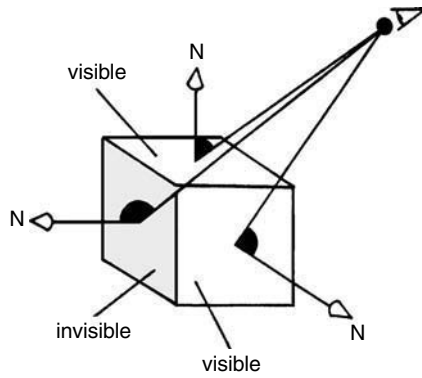

FIGURE 38.4 Back-face removal or culling.

FIGURE 38.5 Sutherland-Hodgman clipper clips each polygon against each edge of each rectangle.

The most popular clipping algorithm, like most of the algorithms used in rendering, goes back over 25 years and is the Sutherland-Hodgman reentrant polygon clipper [Sutherland and Hodgman, 1974]. We will describe, for simplicity, its operation in two-dimensional space, but it is easily extended to three dimensions. A polygon is tested against a clip boundary by testing each polygon edge against a single infinite clip boundary. This structure is shown in Figure 38.5.

We consider the innermost loop of the algorithm, where a single edge is being tested against a single clip boundary. In this step, the process outputs zero, one, or two vertices to add to the list of vertices defining the clipped polygon. Figure 38.6 shows the four possible cases. An edge is defined by vertices **S** and **F**. In the first case, the edge is inside the clip boundary and the existing vertex **F** is added to the output list. In the second case, the edge crosses the clip boundary and a new vertex **I** is calculated and output. The third case shows an edge that is completely outside the clip boundary. This produces no output. (The intersection for the edge that caused the excursion outside is calculated in the previous iteration, and the intersection for the edge that causes the incursion inside is calculated in the next iteration.) The final case again produces a new vertex, which is added to the output list.

To calculate whether a point or vertex is inside, outside, or on the clip boundary, we use a dot-product test. Figure 38.7 shows clip boundary **C** with an outward normal N_c and a line with end points **S** and **F**. We represent the line parametrically as

$$\mathbf{P}(t) = \mathbf{S} + (\mathbf{F} - \mathbf{S})t \quad (38.1)$$

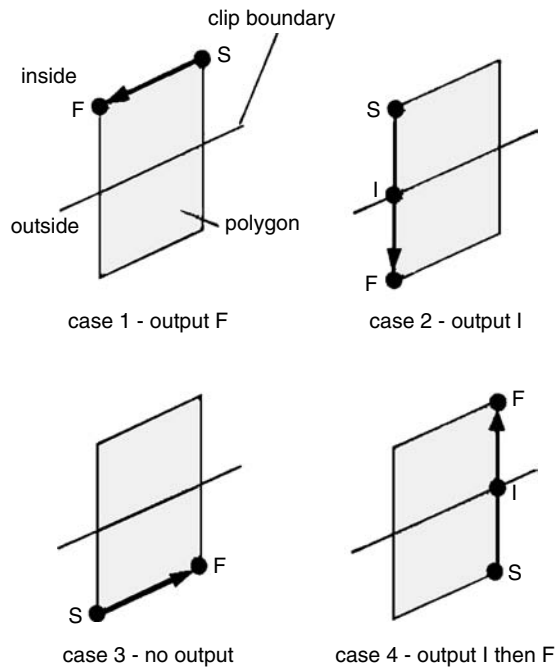

FIGURE 38.6 Sutherland–Hodgman clipper: within the polygon loop, each edge of a polygon is tested against each clip boundary.

FIGURE 38.7 Dot-product test determines whether a line is inside or outside a clip boundary.

where

$$0 \leq t \leq 1$$

We define an arbitrary point on the clip boundary as X and consider a vector from X to any point on the line. The dot product of this vector and the normal allows us to distinguish whether a point on the line is

outside, inside, or on the clip boundary. In the case shown in [Figure 38.7](#),

$$\mathbf{N}_c \cdot (\mathbf{S} - \mathbf{X}) > 0 \Rightarrow \mathbf{S} \text{ is outside the clip region}$$

$$\mathbf{N}_c \cdot (\mathbf{F} - \mathbf{X}) < 0 \Rightarrow \mathbf{F} \text{ is inside the clip region}$$

and

$$\mathbf{N}_c \cdot (\mathbf{P}(t) - \mathbf{X}) = 0$$

defines the point of intersection of the line and the clip boundary. Solving Equation 38.1 for t enables the intersecting vertex to be calculated and added to the output list.

In practice, the algorithm is written recursively. As soon as a vertex is output, the procedure calls itself with that vertex, and no intermediate storage is required for the partially clipped polygon. This structure makes the algorithm eminently suitable for hardware implementation.

A projective transformation takes the object representation in view space and produces a projection on the view plane. This is a fairly simple procedure, somewhat complicated by the fact that we must retain a depth value for each point for eventual use in the hidden-surface removal algorithm. Sometimes, therefore, the space of this transformation is referred to as *three-dimensional screen space*.

38.2.4 Projective Transformation and Three-Dimensional Screen Space

A perspective projection is the more popular or common choice in computer graphics because it incorporates foreshortening. In a perspective projection, relative dimensions are not preserved, and a distant line is displayed smaller than a nearer line of the same length. This familiar effect enables human beings to perceive depth in a two-dimensional photograph or a stylization of three-dimensional reality. A perspective projection is characterized by a point known as the *center of projection*, the same point as the viewpoint in our discussion. The projection of three-dimensional points onto the view plane is the intersection of the lines from each point to the center of projection. This familiar idea is shown in [Figure 38.8](#).

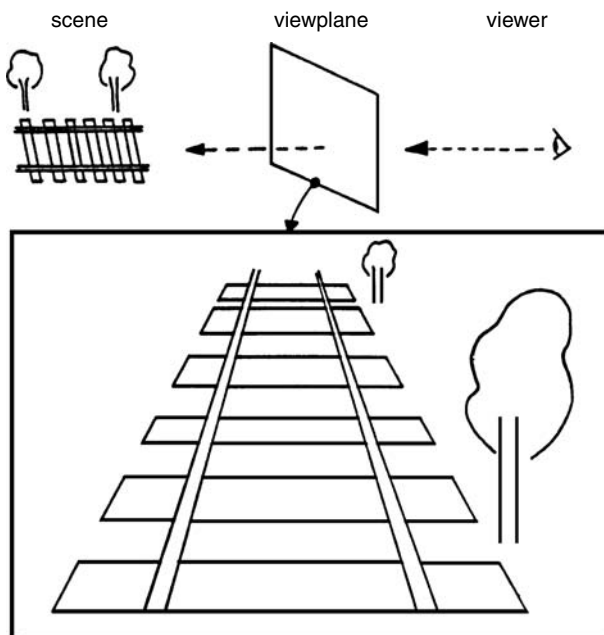

FIGURE 38.8 The perspective effect.

FIGURE 38.9 Perspective projection.

Figure 38.9 shows how a perspective projection is derived. Point $P(x_e, y_e, z_e)$ is a three-dimensional point in the view coordinate system. This point is to be projected onto a view plane normal to the z_e -axis and positioned at distance D from the origin of this system. Point P' is the projection of this point in the view plane. It has two-dimensional coordinates (x_s, y_s) in a view-plane coordinate system, with the origin at the intersection of the z_e -axis and the view plane. In this system, we consider the view plane to be the view surface or screen.

Similar triangles give

$$x_s = D(x_e/z_e)$$

$$y_s = D(y_e/z_e)$$

Screen space is defined to act within a closed volume — the viewing frustum that delineates the volume of space to be rendered. For the purposes of this chapter, we will consider a simplified view volume that constrains some of the dimensions that would normally be found in a more general viewing system. A simple view volume can be specified as follows: suppose we have a square window — that area of the view plane that is mapped onto the view surface or screen — of size $2h$, arranged symmetrically about the viewing direction. The four planes defined by

$$x_e = \pm h(z_e/D)$$

$$y_e = \pm h(z_e/D)$$

together with the two additional planes, called the near and far clipping planes, respectively (perpendicular to the viewing direction), which are defined by

$$z_e = D$$

$$z_e = F$$

make up the definition of the viewing frustum, as shown in Figure 38.10. Additionally, we invoke the constraint that the view plane and the near clip plane are to be coincident. This simple system is based on a treatment given in an early, classic textbook on computer graphics [Newman and Sproull, 1973].

This deals with transforming the x and y coordinates of points in view space. We shall now discuss the transformation of the third component of screen space, namely z_e . In order to perform hidden-surface calculations (in the Z-buffer algorithm), depth information must be generated on arbitrary points, in practice pixels, within the polygon by interpolation. This is possible in screen space only if, in moving

FIGURE 38.10 The six planes that define the view frustum.

from view space to screen space, lines transform into lines and planes transform into planes. It can be shown [Newman and Sproull, 1973] that these conditions are satisfied, provided the transformation of z takes the form

$$z_s = A + (B/z_e)$$

where A and B are constants. These constants are determined from the following constraints:

1. Choosing $B < 0$ so that as z_e increases, so does z_s . This preserves depth. If one point is behind another, then it will have a larger z_e -value; if $B < 0$, it will also have a larger z_s -value.
2. Normalizing the range of z_s -values so that the range z_e in $[D, F]$ maps into the range z_s in $[0, 1]$. This is important to preserve accuracy, because a pixel depth will be represented by a fixed number of bits in the Z-buffer.

The full perspective transformation is then given by

$$\begin{aligned} x_s &= D(x_e/(hz_e)) \\ y_s &= D(y_e/(hz_e)) \\ z_s &= F(1 - D/z_e)/(F - D) \end{aligned}$$

where the additional constant h appearing in the transformation for x_s and y_s ensures that these values fall in the range $[-1, 1]$ over the square screen.

It is instructive to consider the relationship between z_e and z_s a little more closely; although, as we have seen, they both provide a measure of the depth of a point, interpolating along a line in eye space is not the same as interpolating along this line in screen space. As z_e approaches the far clipping plane, z_s approaches 1 more rapidly. Objects in screen space thus get pushed and distorted toward the back of the viewing frustum. This difference can lead to errors when interpolating quantities, other than position, in screen space.

38.2.5 Shading Algorithm

This part of the process calculates a light intensity for each pixel onto which a polygon projects. The input information to this process is the vertex list of the polygon, transformed into eye or view space, and the process splits into two subprocesses:

1. First we find the set of pixels that make up our polygon. We change the polygon from a vertex list into a set of pixels in screen space — through *rasterization*.

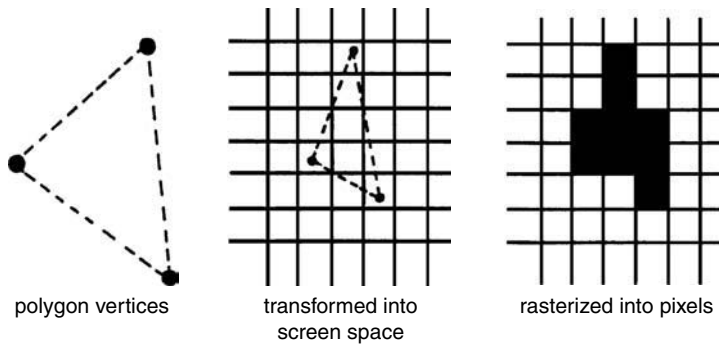

FIGURE 38.11 Different representations of a polygon in the rendering process.

2. Second we find a light intensity associated with each pixel. This is done by associating a local reflection model with each vertex of the polygon and calculating an intensity for the vertex. These vertex intensities are then used in a *bilinear interpolation* scheme to find the intensity of each pixel. By this process, we are finding the intensity of that part of the object surface that corresponds to the pixel area in screen space. The particular way in which this is done leads to the (efficiency–quality) hierarchy of **flat shading**, **Gouraud shading**, and **Phong shading**.

38.2.5.1 Rasterization

Rasterization, or finding the set of polygons onto which the polygon projects, must be done carefully because adjacent polygons must fit together accurately after they have been mapped into pixel sets. If it is not done accurately, holes can result in the image — probably the most common defect seen in rendering software.

As shown in Figure 38.11, the precise geometry of the polygon will map into a set of fully and partially covered pixels. We must decide which of the partially covered pixels are to be considered part of the polygon. Deciding on the basis of the area of coverage is extremely expensive and would wipe out the efficiency advantage of the bilinear interpolation scheme that is used to find a pixel intensity. It is better to map the vertices in some way to the nearest pixel coordinate and set up a consistent rule for deciding the fate of partially covered pixels. This is the crux of the matter. If the rules are not consistent and carefully formulated, then the rounding process will produce holes or unfilled pixels between polygons that share the same scan line. Note that the process will cause a shape change in the polygon, which we ignore because the polygon is already an approximation, and to some extent an arbitrary representation of the “real” surface of the object.

Sometimes called *scan-line conversion*, rasterization proceeds by moving a horizontal line through the polygon in steps of a pixel height. For a current scan line, interpolation (see Section 38.2.5.2) between the appropriate pairs of polygon vertices will yield x_{start} and x_{end} , the start and end points of the portions of the scan line crossing the polygons (using real arithmetic). The following scheme is a simple set of rules that converts these values into a run of pixels:

1. Round x_{start} up.
2. Round x_{end} down.
3. If the fractional part of x_{end} is 0, then subtract 1 from it.

Applying the rasterization process to a complete polygon implies embedding this operation in a structure that keeps track of the edges that are to be used in the current scan-line interpolation. This is normally implemented using a linked-list approach.

FIGURE 38.12 Notation used in property interpolation within a polygon.

38.2.5.2 Bilinear Interpolation

As we have already mentioned, light intensity values are assigned to the set of pixels that we have now calculated, not by individual calculation but by interpolating from values calculated only at the polygon vertices. At the same time, we interpolate depth values for each pixel to be used in the hidden-surface determination. So in this section, we consider the interpolation of a pixel property from vertex values independent of the nature of the property. Referring to Figure 38.12, the interpolation proceeds by moving a scan line down through the pixel set and obtaining start and end values for a scan line by interpolating between the appropriate pair of vertex properties. Interpolation along a scan line then yields a value for the property at each pixel. The interpolation equations are

$$\begin{aligned}
 p_a &= \frac{1}{y_1 - y_2} [p_1(y_s - y_2) + p_2(y_1 - y_s)] \\
 p_b &= \frac{1}{y_1 - y_4} [p_1(y_s - y_4) + p_4(y_1 - y_s)] \\
 p_s &= \frac{1}{x_b - x_a} [p_a(x_b - x_s) + p_b(x_s - x_a)]
 \end{aligned} \tag{38.2}$$

These would normally be implemented using an incremental form, the final equation, for example, becoming

$$p_s := p_s + \Delta p$$

with the constant value Δp calculated once per scan line.

38.2.5.3 Local Reflection Models

Given that we find pixel intensities by an interpolation process, the next thing to discuss is how to find the reflected light intensity at the vertices of a polygon, those values from which the pixel intensity values are derived. This is done by using a simple local reflection model — the one most commonly used is the Phong reflection model [Phong, 1975]. (This reflection model is not to be confused with Phong shading, which is a vector interpolation scheme.)

FIGURE 38.13 Components of the Phong local reflection model.

A local reflection model calculates a value for the reflected light intensity at a point on the surface of an object — in this case, that point is a polygon vertex — due to incident light from a source, which for reasons we will shortly examine is usually a point light source. The model is a linear combination of three components: **diffuse**, **specular**, and **ambient**. We assume that the behavior of reflected light at a point on a surface can be simulated by assuming that the surface is some combination of a perfect diffuse surface together with an (imperfect) specular or mirrorlike surface. The light scattered from a perfect diffuse surface is the same in all directions, and the reflected light intensity from such a surface is given by Lambert's cosine law, which is, in computer graphics notation

$$I_d = I_i k_d \mathbf{L} \cdot \mathbf{N}$$

where \mathbf{L} is the light direction vector and both \mathbf{L} and \mathbf{N} are unit vectors, as shown in Figure 38.13a; k_d is a diffuse reflection coefficient; and I_i is the intensity of a (point) light source. The specular contribution is a function of the angle between the viewing direction \mathbf{V} and the mirror direction \mathbf{R}

$$I_s = I_i k_s (\mathbf{R} \cdot \mathbf{V})^n$$

where n is an index that simulates surface roughness and k_s is a specular reflection coefficient.

For a perfect mirror, n would be infinity and reflected light would be constrained to the mirror direction. For small integer values of n , a reflection lobe is generated, where the thickness of the lobe is a function of the surface roughness (see Figure 38.13b). The effect of the specular reflection term in the model is to produce a so-called highlight on the rendered object. This is basically a reflection of the light source spread over an area of the surface to an extent that depends on the value of n . The color of the specularly reflected light is different from that of the diffuse reflected light — hence the term *highlight*. In simple models of specular reflection, the specular component is assumed to be the color of the light source. If, say, a green surface were illuminated with white light, then the diffuse reflection component would be green, but the highlight would be white.

Adding the specular and diffuse components gives a very approximate imitation to the behavior of reflected light from a point on the surface of an object. Consider Figure 38.13c. This is a cross section of the overall reflectivity response as a function of the orientation of the view vector \mathbf{V} . The cross section is in a plane that contains the vector \mathbf{L} and the point \mathbf{P} ; thus, it slices through the specular bump. The magnitude of the reflected intensity, the sum of the diffuse and specular terms, is the distance from \mathbf{P} along the direction \mathbf{V} to where \mathbf{V} intersects the profile.

An ambient component is usually added to the diffuse and specular terms. Such a component illuminates surfaces that, because we generally use a point light source, would otherwise be rendered black. These are surfaces that are visible from the viewpoint but not from the light source. Essentially, the ambient term is a constant that attempts to simulate the global interreflection of light between surfaces.

Adding the diffuse, specular, and ambient components (Equation 38.3), we have

$$I = k_a + I_i (k_d \mathbf{L} \cdot \mathbf{N} + k_s (\mathbf{R} \cdot \mathbf{V})^n) \quad (38.3)$$

where k_a is the constant ambient term. The expense of Equation 38.3 can be considerably reduced by making some geometric assumptions and approximations. First, if the light source and the viewpoint

FIGURE 38.14 \mathbf{H} is the unit normal to a hypothetical surface oriented in a direction that bisects the angle between \mathbf{L} and \mathbf{V} .

are considered to be at infinity, then \mathbf{L} and \mathbf{V} are constant over the domain of the scene. The vector \mathbf{R} is expensive to calculate; although Phong gives an efficient method for calculating \mathbf{R} , it is better to use a vector \mathbf{H} . This appears to have been first introduced by Blinn [1977]. The specular term then becomes a function of $\mathbf{N} \cdot \mathbf{H}$ rather than $\mathbf{R} \cdot \mathbf{V}$. \mathbf{H} is the unit normal to a hypothetical surface that is oriented in a direction halfway between the light direction vector \mathbf{L} and the viewing vector \mathbf{V} (see Figure 38.14).

$$\mathbf{H} = (\mathbf{L} + \mathbf{V})/2$$

Together with a shading algorithm, this simple model is responsible for the look of most shaded computer graphics images, and it has been in use constantly since 1975. Its main disadvantages are that objects look as if they were made from some kind of plastic material, which is either shiny or dull. Also, in reality the magnitude of the specular component is not independent, as Equation 38.3 implies, of the direction of the incoming light. Consider, for example, the glare from a (nonshiny) road surface when you are driving in the direction of the setting sun: this does not occur when the sun is overhead.

We should now return to the term *local*. The reflection model is called a local model because it considers that the point on the surface under consideration is illuminated directly by the light source in the scene. No other (indirect) source of illumination is taken into account. Light reflected from nearby objects is ignored, so we see no reflections of neighboring objects in the object under consideration. It also means that shadows, which are areas that cannot “see” the light source and which receive their illumination indirectly from another object, cannot be modeled. In a scene using this model, objects are illuminated as if they were floating in a dark space illuminated only by the light source.

When shadows are added into rendering systems that use local reflection models, these are purely geometric. That is, the area that the shadow occupies on the surface of an object, due to the intervention of another object between it and the light source, is calculated. The reflected light intensity within this area is then arbitrarily reduced. When using local reflection models, there is no way to calculate how much indirect light illuminates the shadowed area. The visual consequences of this should be considered when including shadows in an add-on manner. These may detract from the real appearance of the final rendered image rather than add to it. First, because shadows are important to us in reality, we easily spot shadows in computer graphics that have the wrong intensity. This is compounded by the hard-edged shadow boundaries calculated by geometric algorithms. In reality, shadows normally have soft, subtle edges.

Finally, we briefly consider the role of color. For colored objects, the easiest approach is to model the specular highlights as white (for a white light source) and to control the color of the objects by appropriate setting of the diffuse reflection coefficients. We use three intensity equations to drive the monitor’s red,

green, and blue inputs:

$$I_r = k_a + I_i(k_{dr}\mathbf{L} \cdot \mathbf{N} + k_s(\mathbf{N} \cdot \mathbf{H})^n)$$

$$I_g = k_a + I_i(k_{dg}\mathbf{L} \cdot \mathbf{N} + k_s(\mathbf{N} \cdot \mathbf{H})^n)$$

$$I_b = k_a + I_i(k_{db}\mathbf{L} \cdot \mathbf{N} + k_s(\mathbf{N} \cdot \mathbf{H})^n)$$

where the specular coefficient k_s is common to all three equations, but the diffuse component varies according to the object's surface color.

This three-sample approach to color is a crude approximation. Accurate treatment of color requires far more than three samples. This means that to model the behavior of reflected light accurately, we would have to evaluate many more than three equations. We would have to sample the spectral energy distribution of the light source as a function of wavelength and the reflectivity of the object as a function of wavelength and apply Equation 38.3 at each wavelength sample. The solution then obtained would have to be converted back into three intensities to drive the monitor. The colors that we would get from such an approach would certainly be different from the three-sample implementation. Except in very specialized applications, this problem is completely ignored.

We now discuss shading options. These options differ in where the reflection model is applied and how calculated intensities are distributed among pixels. There are three options: flat shading, Gouraud shading, and Phong shading, in order of increasing expense and increasing image quality.

38.2.5.4 Flat Shading

Flat shading is the option in which we invoke no interpolation within a polygon and shade each pixel within the polygon with the same intensity. The reflection model is used once only per polygon. The (true) normal for the polygon (in eye or view space) is inserted into Equation 38.3, and the calculated intensity is applied to the polygon. The efficiency advantages are obvious — the entire interpolation procedure is avoided, and shading reduces to rasterization plus a once-only intensity calculation per polygon. The (visual) disadvantage is that the polygon edges remain glaringly visible, and we render not the surface that the polygon mesh represents but the polygon mesh itself. As far as image quality is concerned, this is more disadvantageous than the fact that there is no variation in light intensity among the polygon pixels. Flat shading is used as a fast preview facility.

38.2.5.5 Gouraud Shading

Both Gouraud and Phong shadings exhibit two strong advantages — in fact, these advantages are their *raison d'être*. Both use the interpolation scheme already described and so are efficient, and they diminish or eliminate the visibility of the polygon edges. In a Gouraud- or Phong-shaded object, these are now visible only along silhouette edges. This elegant device meant their enduring success; the idea originated by Gouraud [1971] and cleverly elaborated by Phong [1975] was one of the major breakthroughs in three-dimensional computer graphics.

In Gouraud shading, intensities are calculated at each vertex and inserted into the interpolation scheme. The trick is in the normals used at a polygon vertex. Using the true polygon normal would not work, because all the vertex normals would be parallel and the reflection model would evaluate the same intensity at each. What we must do is calculate a normal at each vertex that somehow relates back to the original surface. Gouraud vertex normals are calculated by considering the average of the true polygon normals of those polygons that contribute to the vertex (see [Figure 38.15](#)). This calculation is normally regarded as part of the setting up of the object, and these vectors are stored as part of the object database (although there is a problem when polygons are clipped: new vertex normals then must be calculated as part of the rendering process). Because polygons now share vertex normals, the interpolation process ensures that there is no change in intensity across the edge between two polygons; in this way, the polygonal structure of the object representation is rendered invisible. (However, an optical illusion, known as *Mach banding*, persists along the edges with Gouraud shading.)

FIGURE 38.15 The concept of a vertex normal.

Gouraud shading is used extensively and gives excellent results for the diffuse component. However, calculating reflected light intensity only at the vertices leads to problems with the specular component. The easiest case to consider is that of a highlight which, if it were visible, would be within the polygon boundaries — meaning it does not extend to the vertices. In this case, the Gouraud scheme would simply miss the highlight completely.

38.2.5.6 Phong Shading

Phong shading [Phong, 1975] was developed to overcome the problems of Gouraud shading and specular highlights. In this scheme, the property to be interpolated is the vertex normals themselves, with each vector component now inserted into three versions of Equation 38.3. It is a strange hybrid, with an interpolation procedure running in pixel or screen space controlling vector interpolation in three-dimensional view space (or world space). But it works very well.

We estimate the normal to the surface at a point that corresponds to the pixel under consideration in screen space, or at least estimate it to within the limitations and approximations that have been imposed by the polygonal representation and the interpolation scheme. We can then apply the reflection model at each pixel, and a unique reflected light intensity is now calculated for each pixel. We may end up with a result that is different from what would be obtained if we had access to the true surface normal at the point on the real surface that corresponded to the pixel, but it does not matter, because the quality of Phong shading is so good that we cannot perceive any erroneous effects on the monitor.

Phong shading is much slower than Gouraud shading because the interpolation scheme is three times as lengthy, and also the reflection model (Equation 38.3) is now applied at each pixel. A good rule of thumb is that Phong shading has five times the cost of Gouraud shading.

38.2.6 Hidden-Surface Removal

As already mentioned, we shall describe the Z-buffer as the *de facto* hidden-surface removal algorithm. That it has attained this status is due to its ease of implementation — it is virtually a single *if* statement — and its ease of incorporation into a polygon-based renderer. Screen space algorithms (the Z-buffer falls into this category) operate by associating a depth value with each pixel. In our polygon renderer, the

depth values are available only at a vertex, and the depth values for a pixel are obtained by using the same interpolation scheme as for intensity in Gouraud shading.

Hidden-surface removal eventually comes down to a point-by-point depth comparison. Certain algorithms operate on area units, scan-line segments, or even complete polygons, but they must contain a provision for the worst case, which is a depth comparison between two pixels. The Z-buffer algorithm performs this comparison in three-dimensional screen space. We have already defined this space and we repeat, for convenience, the equation for Z_s :

$$z_s = F(1 - D/z_e)/(F - D)$$

The Z-buffer algorithm is equivalent, for each pixel (x_s, y_s) , to a search through the associated z -values of every polygon point that projects onto that pixel to find that point with the minimum z -value — the point nearest the viewer. This search is conveniently implemented by using a Z-buffer, which holds for each pixel the smallest z -value so far encountered. During the processing of a polygon, we either write the intensity of a pixel into the frame buffer or not, depending on whether the depth of the current pixel is less than the depth so far encountered as recorded in the Z-buffer.

Apart from its simplicity, another advantage of the Z-buffer is that it is independent of object representation. Although we see it used most often in the context of polygon mesh rendering, it can be used with any representation: all that is required is the ability to calculate a z -value for each point on the surface of an object. If the z -values are stored with pixel values, separately rendered objects can be merged into a multiple-object scene using Z-buffer information on each object.

The main disadvantage of the Z-buffer is the amount of memory it requires. The size of the Z-buffer depends on the accuracy to which the depth value of each point (x, y) is to be stored, which is a function of scene complexity. Usually, 20 to 32 bits is deemed sufficient for most applications. Recall our previous discussion of the compression of z_s -values. This means that a pair of distinct points with different z_e -values can map into identical z_s -values. Note that for frame buffers with less than 24 bits per pixel, say, the Z-buffer will in fact be *larger* than the frame buffer. In the past, Z-buffers have tended to be part of the main memory of the host processor, but now graphics cards are available with dedicated Z-buffers. This represents the best solution.

38.3 Rendering Using Ray Tracing

Ray tracing is a simple and elegant algorithm whose appearance in computer graphics is usually attributed to Whitted [1980]. It combines in a single algorithm

- Hidden-surface removal

- Reflection due to direct illumination (the same factor we calculated in the previous method using a local model)

- Reflection due to indirect illumination (i.e., reflection due to light striking) — the object which itself has been reflected from another object

- Transmission of light through transparent or partially transparent objects

- Shading due to object-object interaction (global illumination)

- The computation of (hard-edged) shadows

It does this by tracing rays — infinitesimally thin beams of light — in the reverse direction of light propagation; that is, it traces light rays from the eye into the scene and from object to object. In this way, it “discovers” the way in which light interacts between objects and can produce visualizations such as objects reflecting in other objects and the distortion of an object viewed through another (transparent or glass) object due to refraction. Rays are traced from the eye or viewpoint, because we are interested only in those rays that pass through the view plane. If we traced rays from the light source, then theoretically we would have to trace an infinity of rays.

Ray-tracing algorithms exhibit a strong visual signature because a basic ray tracer can simulate only one aspect of the global interaction of light in an environment: specular reflection and specular transmission. Thus ray-traced scenes always look ray-traced, because they tend to consist of objects that exhibit mirrorlike reflection, in which you can see the perfect reflections of other objects. Simulating nonperfect specular reflection is computationally impossible with the normal ray-tracing approach, because this means that at a hit point a single incoming ray will produce a multiplicity of reflected rays instead of just one. The same argument applies to transparent objects. A single incident ray can produce only a single transmitted or refracted ray. Such behavior would happen only in a perfect material that did not scatter light passing through it. With transparent objects, the refractive effect can be simulated, but the material looks like perfect glass. Thus, perfect surfaces and perfect glass, behavior that does not occur in practice, betray the underlying rendering algorithm.

A famous development, called *distributed ray tracing* [Cook et al., 1984], addressed exactly this problem, using a Monte Carlo approach to simulate the specular reflection and specular transmission spread without invoking a combinatorial explosion. The algorithm produces shiny objects that look real (i.e., their surfaces look rough or imperfect), blurred transmission through glass, and blurred shadows. The modest cost of this method involved initiating 16 rays per pixel instead of one. This is still a considerable increase in an already expensive algorithm, and most ray tracers still utilize the perfect specular interaction model.

The algorithm is conceptually easy to understand and is also easy to implement using a recursive procedure. A pictorial representation is given in Figure 38.16. The algorithm operates in three-dimensional

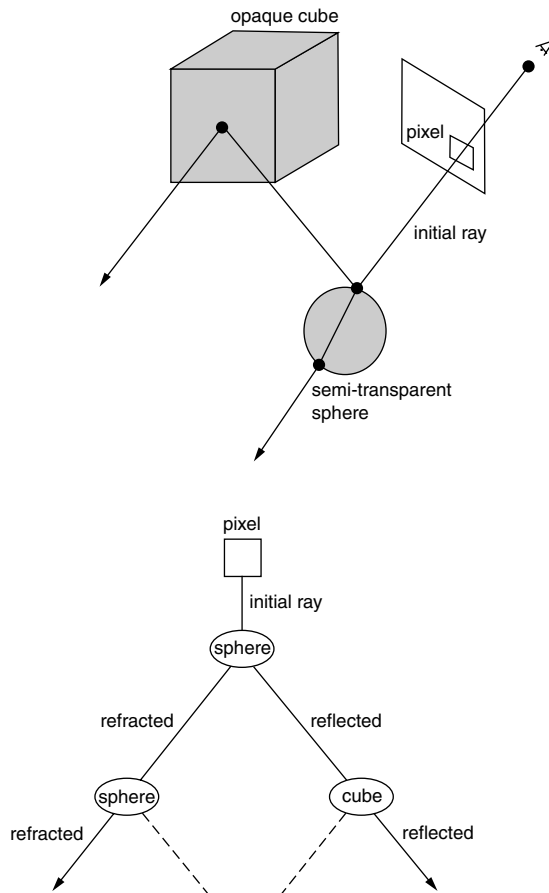

FIGURE 38.16 A representation of a ray-tracing algorithm.

world space, and for each pixel in screen space we calculate an initial ray from the viewpoint through the center of the pixel. The ray is injected into the scene and will either hit an object or not. (In the case of a closed environment, some object will always be encountered by an initial ray, even if it is just the background, such as a wall.) When the ray hits an object, it spawns two more rays: a reflected ray and a transmitted ray, which refracts into the object if the object is partially transparent. These rays travel onward and themselves spawn other rays at their next hits. The process is sometimes represented as a binary tree, with a light–surface hit at each node in the tree.

This process can be implemented as a recursive procedure, which for each ray invokes an intersection test that spawns a transmitted and a reflected ray by calling itself twice with parameters representing the reflected and the transmitted or refracted directions of the new rays. At the heart of the recursive control procedure is an intersection test. This procedure is supplied with a ray, compares the ray geometry with all objects in the scene, and returns the nearest surface that the ray intersects. If the ray is an initial ray, then this effectively implements hidden-surface removal. Intersection tests account for most of the computational overheads in ray tracing, and much research effort has gone into how to reduce this cost.

Grafted onto this basic recursive process, which follows specular interaction through the scene, are the computation of direct reflection and shadow computation. At each node or surface hit, we calculate these two contributions. Direct reflection is calculated by applying, for each light source, a Phong reflection model (or some other local model) at the node under consideration. The direct reflection contribution is diminished if the point is in shadow with respect to a light source. Thus, at any hit point or node, there are three contributions to the light intensity passed back up through the recursion:

- A reflected-ray contribution

- A transmitted-ray contribution

- A local contribution unaltered or modified by the shadow computation

Shadow computation is easily implemented by injecting the light direction vector, used in the local contribution calculation, into the intersection test to see if it is interrupted by any intervening objects. This ray is called a *shadow feeler*. If L is so interrupted, then the current surface point lies in shadow. If a wholly opaque object lies in the path of the shadow feeler, then the local contribution is reduced to the ambient value. An attenuation in the local contribution is calculated if the intersecting object is partially transparent. Note that it is no longer appropriate to consider L a constant vector (light source at infinity) and the so-called shadow feelers are rays whose direction is calculated at each hit point. Because light sources are normally point sources, this procedure produces, like add-on shadow algorithms, hard-edged shadows. (Strictly speaking, a shadow feeler intersecting partially transparent objects should be refracted. It is not possible to do this, however, in the simple scheme described. The shadow feeler is initially calculated as the straight line between the surface intersection and the light source. This is an easy calculation, and it would be difficult to trace a ray from this point to the light source and include refractive effects.)

Finally note that, as the number of light sources increases from one, the computational overheads for shadow testing rapidly predominate. This is because the main rays are traced only to an average depth of between one and two. However, each ray-surface intersection spawns n shadow feelers (where n is the number of light sources), and the object intersection cost for a shadow feeler is exactly the same as for a main ray.

38.3.1 Intersection Testing

We have mentioned that intersection testing forms the heart of a ray tracer and accounts for most of the cost of the algorithm. In the 1980s, much research was devoted to this aspect of ray tracing. There is a large body of literature on the subject that dwarfs the work devoted to improvements in the ray-traced image such as, for example, distributed ray tracing.

Intersection testing means finding whether a ray intersects an object and, if so, the point of intersection. Expressing the problem in this way hints at the usual approach, which is to try to cut down the overall cost by using some scheme, like a bounding volume, that prevents the intersection test from searching through all the polygons in an object if the ray cannot hit the object.

The cost of ray tracing and the different possible approaches depend much on the way in which objects are represented. For example, if a voxel representation is used and the entire space is labeled with object occupancy, then discretizing the ray into voxels and stepping along it from the start point will reveal the first object that the ray hits. Contrast this with a brute-force intersection test, which must test a ray against every object in the scene to find the hit nearest to the ray start point.

38.4 Rendering Using the Radiosity Method

The *radiosity method* arrived in computer graphics in the mid-1980s, a few years after ray tracing. Most of the early development work was carried out at Cornell University under the guidance of D. Greenberg, a major figure in the development of the technique. The emergence of the **hemicycle** algorithm and, later, the progressive refinement algorithm, established the method and enabled it to leave research laboratories and become a practical rendering tool. Nowadays, many commercial systems are available, and most are implementations of these early algorithms.

The radiosity method provides a solution to diffuse interaction, which, as we have discussed, cannot easily be incorporated in ray tracing, but at the expense of dividing the scene into large patches (over which the radiosity is constant). This approach cannot cope with sharp specular reflections. Essentially, we have two global methods: ray tracing, which simulates global specular reflection, and transmission and radiosity, which simulate global diffuse interaction.

In terms of the global phenomena that they simulate, the methods are mutually exclusive. Predictably, a major research bias has involved the unification of the two methods into a single global solution. Research is still actively pursued into many aspects of the method — particularly form-factor determination and scene decomposition into elements or patches.

38.4.1 Basic Theory

The radiosity method works by dividing the environment into largish elements called *patches*. For every pair of patches in the scene, a parameter F_{ij} is evaluated. This parameter, called a *form factor*, depends on the geometric relationship between patches i and j . This factor is used to determine the strength of diffuse light interaction between pairs of patches, and a large system of equations is set up which, on solution, yields the radiosity for each patch in the scene.

The radiosity method is an object-space algorithm, solving for a single intensity for each surface patch within an environment and not for pixels in an image-plane projection. The solution is thus independent of viewer position. This complete solution is then injected into a renderer that computes a particular view by removing hidden surfaces and forming a projection. This phase of the method does not require much computation (intensities are already calculated), and different views are easily obtained from the general solution. The method is based on the assumption that all surfaces are perfect diffusers or ideal Lambertian surfaces.

Radiosity, B , is defined as the energy per unit area leaving a surface patch per unit time and is the sum of the emitted and the reflected energy:

$$B_i dA_i = E_i dA_i + R_i \int_j B_j F_{ji} dA_j$$

Expressing this equation in words, we have for a single patch i

$$\text{radiosity} \times \text{area} = \text{emitted energy} + \text{reflected energy}$$

E_i is the energy emitted from a patch, and emitting patches are, of course, light sources. The reflected energy is given by multiplying the incident energy by R_i , the reflectivity of the patch. The incident energy is the energy that arrives at patch i from all other patches in the environment; that is, we integrate over the environment, for all j ($j \neq i$), the term $B_j F_{ji} dA_j$. This is the energy leaving each patch j that arrives at patch i .

For a discrete environment, the integral is replaced by a summation and constant radiosity is assumed over small discrete patches. It can be shown that

$$B_i = E_i + R_i \sum_{j=1}^n B_j F_{ij}$$

Such an equation exists for each surface patch in the enclosure, and the complete environment produces a set of n simultaneous equations of the form.

$$\begin{bmatrix} 1 - R_1 F_{11} & -R_1 F_{12} & \dots & -R_1 F_{1n} \\ -R_2 F_{21} & 1 - R_2 F_{22} & \dots & -R_2 F_{2n} \\ \dots & \dots & \dots & \dots \\ \dots & \dots & \dots & \dots \\ \dots & \dots & \dots & \dots \\ -R_n F_{n1} & -R_n F_{n2} & \dots & 1 - R_n F_{nn} \end{bmatrix} \begin{bmatrix} B_1 \\ B_2 \\ \dots \\ \dots \\ \dots \\ B_n \end{bmatrix} = \begin{bmatrix} E_1 \\ E_2 \\ \dots \\ \dots \\ \dots \\ E_n \end{bmatrix}$$

The E_i s are nonzero only at those surfaces that provide illumination, and these terms represent the input illumination to the system. The R_i s are known, and the F_{ij} s are a function of the geometry of the environment. The reflectivities are wavelength-dependent terms, and the previous equation should be regarded as a monochromatic solution, a complete solution being obtained by solving for however many color bands are being considered. We can note at this stage that $F_{ii} = 0$ for a plane or convex surface — none of the radiation leaving the surface will strike itself. Also, from the definition of the form factor, the sum of any row of form factors is unity.

Since the form factors are a function only of the geometry of the system, they are computed once only. Solving this set of equations produces a single value for each patch. This information is then input to a modified Gouraud renderer to give an interpolated solution across all patches.

38.4.2 Form-Factor Determination

A significant early development was a practical method to evaluate form factors. The algorithm is both an approximation and an efficient method of achieving a numerical estimation of the result. The form factor between patches i and j is defined as

$$F_{ij} = \frac{\text{radiative energy leaving surface } A_i \text{ that strikes } A_j \text{ directly}}{\text{radiative energy leaving } A_i \text{ in all directions in the hemispherical space surrounding } A_i}$$

This is given by

$$F_{ij} = \frac{1}{A_i} \int_{A_i} \int_{A_j} \frac{\cos \phi_i \cos \phi_j}{\pi r^2} dA_j dA_i$$

where the geometric conventions are illustrated in [Figure 38.17](#). Now, it can be shown that this patch-to-patch form factor can be approximated by the differential-area-to-finite-area form factor

$$F_{dA_i A_j} = \int_{A_j} \frac{\cos \phi_i \cos \phi_j}{\pi r^2} dA_j$$

where we are now considering the form factor between the elemental area da_i and the finite area A_j . This approximation is calculated by the hemicube algorithm [Cohen and Greenberg, 1985]. The factors that enable the approximation to a single integral and its veracity are quite subtle and are outside the scope of this treatment.

A good intuition of the workings of the algorithm can be gained from a pictorial visualization (see [Figure 38.18](#)). [Figure 38.18a](#) is a representation of the property known as the *Nusselt analog*. In the example, patches A , B , and C all have the same form factor with respect to patch i . Patch B is the projection of A onto a hemicube, centered on patch i , and C is the projection of A onto a hemisphere. This property is the

FIGURE 38.17 Parameters used in the definition of a form factor.

foundation of the hemicube algorithm, which places a hemicube on each patch i — (Figure 38.18b). The hemicube is subdivided into elements; associated with each element is a precalculated *delta form factor*. The hemicube is placed on patch i , and then patch j is projected onto it. In practice, this involves a clipping operation, because in general a patch can project onto three faces of the hemicube. Evaluating F_{ij} involves simply summing the values of the delta form factors onto which patch j projects (Figure 38.18c).

Another aspect of form-factor determination solved by the hemicube algorithm is the intervening-patch problem. Normally, we cannot evaluate the form-factor relationship between a pair of patches independently of one or more patches that happen to be situated between them. The hemicube algorithm solves this by making the hemicube a kind of Z-buffer in addition to its role as five projection planes. This is accomplished as follows. For the patch i under consideration, every other patch in the scene is projected onto the hemicube. For each projection, the distance from patch i to the patch being projected is compared with the smallest distance associated with previously projected patches, which is stored in hemicube elements. If a projection from a nearer patch occurs, then the identity of that patch and its distance from patch i are stored in the hemicube elements onto which it projects. When all patches are projected, the form factor F_{ij} is calculated by summing the delta form factors that have registered patch j as a nearest projection.

Finally, consider Figure 38.19, which gives an overall view of the algorithm. This emphasizes the fact that there are three entry points into the process for an interactive program. Changing the geometry of the scene means an entire recalculation, starting afresh with the new scene. However, if only the wavelength-dependent properties of the scene are altered (reflectivities of objects and colors of light sources), then the expensive part of the process — the form-factor calculations — is unchanged. Because the method is view-independent, changing the position of the viewpoint involves only the final process of interpolation and hidden-surface removal. This enables real-time, interactive walkthroughs using the precalculated solution, a popular application of the radiosity technique in computer-aided design (see Figure 38.20). The high-quality imagery gives designers a better feel for the final product than would be possible with simple rendering packages.

38.4.3 Problems with the Basic Method

Several problems occur if the method is implemented without elaboration. Here, we will restrict ourselves to identifying these and giving a pointer to the solutions that have emerged. The reader is referred to the appropriate literature for further details.

The first problem emerges from consideration of how to divide the environment into patches. Dividing the scene equally into large patches, as far as the geometry of the objects allows, will not suffice. The basic radiosity solution calculates a constant radiosity over the area of a patch. Larger patches mean fewer patches and a faster solution, but there will be areas in the scene that will exhibit a fast change in reflected

FIGURE 38.18 Visualization of the properties used in the hemicube algorithm for form-factor evaluation. (a) Nusselt analogue: patches A , B , and C have the same form factor with respect to patch i . (b) Delta form factors are precalculated for the hemicube. (c) The hemicube is positioned over patch i . Each patch j is projected onto the hemicube. F_{ij} is calculated by summing the delta form factors of the hemicube elements onto which j projects.

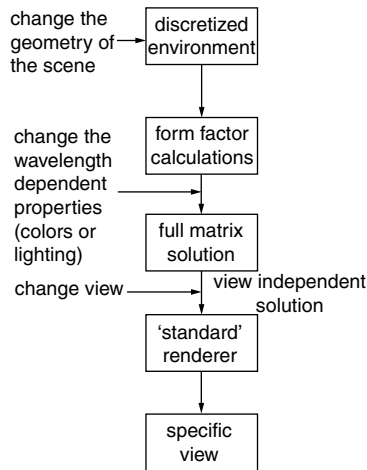

FIGURE 38.19 Processes and interactive entry points in a radiosity algorithm.

FIGURE 38.20 The interior of a car rendered using the radiosity method. (Image rendered using LightWorks, courtesy of LightWork Design.)

light per unit area. Shadow boundaries, for example, exhibit a shape that depends on the obscuring object, and small patches are required in the area of these, which will in general be curves. If the shadowed surface is not sufficiently subdivided, then the shadow boundary will exhibit steps in the shape of the (square or rectangular) patches. However, we do not know until the solution is computed where such areas are in the scene. A common approach to this problem is to incorporate a variable subdivision into the solution, subdividing as a solution emerges until the difference in radiosity between adjacent patches falls below a threshold [Cohen et al., 1986].

Another problem is the time taken by the algorithm — approximately one order of magnitude longer than ray tracing. An ingenious reordering of the method for solving the equation set, called the *progressive refinement algorithm* [Cohen et al., 1988], ameliorates this problem and provides a user with an early (approximate) image which is progressively refined, that is, it becomes more and more accurate. In a normal solution, each patch progresses toward a final value in turn. In the progressive refinement algorithm, each and every patch is updated for each iteration, and all patches proceed toward their final value simultaneously. The scene is at first dark and then gets lighter and lighter as the patches increase their radiosity. Early, approximate solutions are quickly computed by distributing an arbitrary ambient component among all patches. The early solutions are “fully” lit but incorrect. Progressive refinement means displaying more and more accurate radiosities on each patch and reducing the approximate ambient component at the same time. A user can thus see from the start some solution, which then proceeds to get more and more accurate. The process can then be interrupted at some stage if the image is not as required or has some visually obvious error.

38.5 The (Irresistible) Survival of Mainstream Rendering

Three-dimensional computer graphics have evolved significantly over the past three decades. We saw at first the development of expensive workstations, which were used in expensive applications, such as computer-aided architectural design, and which were unaffordable to home consumers. Recently, PC graphics hardware has undergone a rapid evolution, resulting in extremely powerful graphics cards being available to consumers at a cost of \$500 or less. This market has, of course, been spurred by the apparently never-ending popularity of computer games. This application of three-dimensional computer graphics has dwarfed all others and hastened the rapid development of games consoles.

The demand from the world of computer games is to render three-dimensional environments, at high quality, in real time. The shift of emphasis to real-time rendering has resulted in many novel rendering methods that address the speed-up problem [Akenine-Möller and Haines, 2002; Watt and Policarpo, 2001]. The demand for ever-increasing quality led to a number of significant stages in rendering methodology. First, there was the shift of the rendering load from the CPU onto graphics cards. This add-on hardware performed most of the rendering tasks, implementing the mainstream polygon rendering described previously. Much use was made of texture mapping hardware to precalculate light maps, which enabled rendering to be performed in advance for all static detail in the environment.

At the time of writing (2003), consumer hardware is now available which is powerful enough to enable all rendering in real time, obviating the need for precalculation. This makes for better game content, with dynamic and static objects having access to the same rendering facilities.

Although graphics cards were at first simply viewed as black boxes that received a massive list of polygons, recent developments have seen cards with functionality exposed to the programmer. Such functionality has enabled the per-pixel (or per-fragment) programming necessary for real increases in image quality. Thus, we have the polygon processing returned to the control of the programmer and the need for an expansion of graphics APIs (such as OpenGL) to enable programmers to exploit this new functionality. Companies such as NVIDIA and ATI have thrived on offering such functionality.

One of the enduring facts concerning the history of this evolution is the inertia of the mainstream rendering methodology. Polygon meshes have survived as the most popular representation, and the rendering of polygons using interpolative shading and a set of light sources seems as firmly embedded as ever.

38.6 An OpenGL Example

We complete this chapter with a simple example in OpenGL that renders a single object: a teapot (see Figure 38.21). Two points are worth noting. First, polygons become triangles. Although we have consistently used the word *polygon* in this text, most graphics hardware is optimized to deal with triangles. Second, there is no exposure to the programmer of processes such as rasterization. This pixel process is invisible, although we briefly discussed in [Section 38.5](#) that new graphics cards are facilitating access to pixel processing.

FIGURE 38.21 A teapot rendered using OpenGL.

                              // glut determines that the contents of
                              // the screen window need to be redisplayed,
                              // e.g., when a window is uncovered after being
                              // covered by another window.

    glutReshapeFunc(viewingSystem);
                              // If the window is resized, e.g., enlarged, the
                              // viewingSystem function is called.

    glutMainLoop();           // Last thing that is done. Now the window is
                              // shown on screen and event processing begins,
                              // i.e., continuous loop processing events such
                              // as resize window until program is
                              // terminated.

    return 0;
}

```

Defining Terms

Ambient: The constant term used in local reflection models to simulate global illumination. It illuminates parts of a surface which cannot be seen from the light source but which are visible from the viewpoint.

Antialiasing: The term given to measures designed to eliminate defects in computer graphics images, the most common being the effect produced when a curved edge in the image is displayed as jagged due to the finite extent of the pixels. The term is somewhat inappropriate, as *aliasing* is a specific signal-processing term and many computer graphics defects are not aliases in that sense.

Clipping: It is common to define a view frustum, a volume emanating from the viewpoint, against which objects are clipped. For example, objects behind the viewer must be eliminated from consideration.

Culling: A process to remove whole polygons that cannot be seen from the viewpoint and therefore do not need to be considered by the hidden-surface removal algorithm.

Diffuse: Local reflection models separately evaluate a diffuse, a specular, and an ambient component. The diffuse component is the light that is reflected from a point equally in all directions, simulating a matte or plastic-like surface.

Flat shading: A shading option in which all the pixels for a polygon are allocated the same shade — there is no variation within a polygon. This makes the underlying polygonal structure visible.

Global reflection models: Models that attempt to model indirect illumination. At a surface point, they consider both light coming directly from light sources and light that has been reflected from other objects.

Gouraud shading: An interpolative shading method for polygons in which the parameter that is interpolated is the reflected light intensity at the vertices.

Hemicube: An algorithmic device that enables an efficient calculation of the form-factor values in the radiosity method. A hemicube is an efficient approximation to a hemisphere.

Hidden-surface removal: The general algorithm that removes hidden surfaces and deals with such cases where one object partially obscures another. In general, a hidden-surface algorithm will eliminate those fragments of a polygon that are not visible because they are behind another object.

Local reflection models: Models that simulate the reflection of light incident directly on an object from a light source. Unlike global models, they take no account of indirect light reflected from another object.

Phong shading: An interpolative shading method in which the parameter that is interpolated is the vertex normal at the vertices. This produces an interpolated normal for every pixel onto which the polygon projects, and a reflection model is evaluated at each pixel in the image plane.

Polygon mesh: The most common form of object representation is to build a set of planar facets or polygons that (approximately, in general) represent the surface of an object.

Progressive refinement: An elaboration of the original radiosity method that enables a visualization of the solution to emerge as the equations are being solved. The solution, originally approximated with an ambient term, is gradually made more and more accurate.

Projective transformation: Usually the final geometric transformation, it produces the perspective foreshortening desired in most applications.

Radiosity: A global reflection model that divides the scene into large elements called patches, calculates a parameter that reflects the geometric relationship between all pairs of patches, and sets up a system of equations whose solution yields a constant radiosity for each patch. These radiosity values are input to a Gouraud-type interpolation to produce a rendered image. The geometric extent of the patches means that the basic method can deal only with diffuse interaction.

Ray tracing: A global reflection model that casts infinitesimally thin rays into the scene from each pixel and follows or traces these as they are reflected and transmitted by objects that they encounter. Such a ray tracer can find out only about specular interaction.

Shading algorithm: A general term that describes that part of the process that makes a geometric description look like a solid, three-dimensional object.

Specular: The specular component is the light reflected from a point in the mirror direction, as if the surface were a perfect mirror. In practice, this component is empirically spread to simulate a practical glossy surface.

Viewing transformation: Generates a representation of the object or scene as seen from the viewpoint of an observer positioned somewhere in the scene and looking toward some aspect of it.

Virtual camera: A common analogy used for the series of geometric transformations that form a two-dimensional image on the view surface. These transformations have the same effect as a (perfect) pinhole camera. The analogy is particularly useful in animation where the camera is to be choreographed.

Further Information

The References section comprises mostly the original sources of the algorithms that are commonly incorporated in rendering engines. A would-be implementer, however, would be best directed to a general textbook, such as [Watt and Watt, 1992], or the encyclopedic *Computer Graphics: Principles and Practice* by Foley et al.

Undoubtedly, the best source of rendering techniques and their development is the annual ACM SIGGRAPH conference (proceedings published by ACM Press). Browsing through past proceedings gives a feel for the fascinating development and history of image synthesis. Indeed, in 1998, ACM SIGGRAPH published the book *Seminal Graphics: Pioneering Efforts that Shaped the Field*, edited by Wolfe, which includes many of the pioneering rendering papers listed in the References section.

39.1 Introduction

This chapter reviews the principal ideas of sampling theory, reconstruction, and antialiasing. Sampling theory is central to the study of sampled-data systems, e.g., digital image transformations. It lays a firm mathematical foundation for the analysis of sampled signals, offering invaluable insight into the problems and solutions of sampling. It does so by providing an elegant mathematical formulation describing the relationship between a continuous signal and its samples. We use it to resolve the problems of image reconstruction and aliasing. Reconstruction is an interpolation procedure applied to the sampled data. It permits us to evaluate the discrete signal at any desired position, not just the integer lattice upon which the sampled signal is given. This is useful when implementing geometric transformations, or warps, on the image. Aliasing refers to the presence of unreproducibly high frequencies in the image and the resulting artifacts that arise upon undersampling.

Together with defining theoretical limits on the continuous reconstruction of discrete input, sampling theory yields the guidelines for numerically measuring the quality of various proposed filtering techniques.

FIGURE 39.1 Oblique checkerboard: (a) unfiltered, (b) filtered.

This proves most useful in formally describing reconstruction, aliasing, and the filtering necessary to combat the artifacts that may appear at the output.

In order to better motivate the importance of sampling theory and filtering, we demonstrate its role with the following examples. A checkerboard texture is shown projected onto an oblique planar surface in Figure 39.1. The image exhibits two forms of artifacts: jagged edges and moiré patterns. Jagged edges are prominent toward the bottom of the image, where the input checkerboard undergoes magnification. It reflects poor reconstruction of the underlying signal. The moiré patterns, on the other hand, are noticeable at the top, where minification (compression) forces many input pixels to occupy fewer output pixels. This artifact is due to aliasing, a symptom of undersampling.

Figure 39.1(a) was generated by projecting the center of each output pixel into the checkerboard and sampling (reading) the value of the nearest input pixel. This point sampling method performs poorly, as is evident by the objectionable results of Figure 39.1(a). This conclusion is reached by sampling theory as well. Its role here is to precisely quantify this phenomenon and to prescribe a solution. Figure 39.1(b) shows the same mapping with improved results. This time the necessary steps were taken to preclude artifacts. In particular, a superior reconstruction algorithm was used for interpolation to suppress the jagged edges, and antialiasing filtering was carried out to combat the symptoms of undersampling that gave rise to the moiré patterns.

39.2 Sampling Theory

Both reconstruction and antialiasing share the twofold problem addressed by sampling theory:

1. Given a continuous input signal $g(x)$ and its sampled counterpart $g_s(x)$, are the samples of $g_s(x)$ sufficient to exactly describe $g(x)$?
2. If so, how can $g(x)$ be reconstructed from $g_s(x)$?

The solution lies in the frequency domain, whereby spectral analysis is used to examine the spectrum of the sampled data.

The conclusions derived from examining the reconstruction problem will prove to be directly useful for resampling and indicative of the filtering necessary for antialiasing. Sampling theory thereby provides an elegant mathematical framework in which to assess the quality of reconstruction, establish theoretical limits, and predict when it is not possible.

FIGURE 39.2 Spectrum $G(f)$.

39.2.1 Sampling

Consider a 1-D signal $g(x)$ and its spectrum $G(f)$, as determined by the Fourier transform:

$$G(f) = \int_{-\infty}^{\infty} g(x)e^{-i2\pi fx} dx \quad (39.1)$$

Note that x represents spatial position and f denotes spatial frequency.

The magnitude spectrum of a signal is shown in Figure 39.2. It shows the frequency content of the signal, with a high concentration of energy in the low-frequency range, tapering off toward the higher frequencies. Since there are no frequency components beyond f_{\max} , the signal is said to be **bandlimited** to frequency f_{\max} .

The continuous output $g(x)$ is then digitized by an ideal impulse sampler, the comb function, to get the sampled signal $g_s(x)$. The ideal 1-D sampler is given as

$$s(x) = \sum_{n=-\infty}^{\infty} \delta(x - nT_s) \quad (39.2)$$

where δ is the familiar impulse function and T_s is the sampling period. The running index n is used with δ to define the impulse train of the comb function. We now have

$$g_s(x) = g(x)s(x) \quad (39.3)$$

Taking the Fourier transform of $g_s(x)$ yields

$$G_s(f) = G(f) * S(f) \quad (39.4)$$

$$= G(f) * \left[\sum_{n=-\infty}^{\infty} f_s \delta(f - nf_s) \right] \quad (39.5)$$

$$= f_s \sum_{n=-\infty}^{\infty} G(f - nf_s) \quad (39.6)$$

where f_s is the sampling frequency and $*$ denotes convolution. The above equations make use of the following well-known properties of Fourier transforms:

1. Multiplication in the spatial domain corresponds to convolution in the frequency domain. Therefore, Equation 39.3 gives rise to a convolution in Equation 39.4.
2. The Fourier transform of an impulse train is itself an impulse train, giving us Equation 39.5.
3. The spectrum of a signal sampled with frequency f_s ($T_s = 1/f_s$) yields the original spectrum replicated in the frequency domain with period f_s Equation 39.6.

FIGURE 39.3 Spectrum $G_s(f)$.

This last property has important consequences. It yields a spectrum $G_s(f)$, which, in response to a sampling period $T_s = 1/f_s$, is *periodic in frequency* with period f_s . This is depicted in Figure 39.3. Notice, then, that a small sampling period is equivalent to a high sampling frequency, yielding spectra replicated far apart from each other. In the limiting case when the sampling period approaches zero ($T_s \rightarrow 0$, $f_s \rightarrow \infty$), only a single spectrum appears — a result consistent with the continuous case.

39.3 Reconstruction

The above result reveals that the sampling operation has left the original input spectrum *intact*, merely replicating it periodically in the frequency domain with a spacing of f_s . This allows us to rewrite $G_s(f)$ as a sum of two terms, the low-frequency (baseband) and high-frequency components. The *baseband* spectrum is exactly $G(f)$, and the high-frequency components, $G_{\text{high}}(f)$, consist of the remaining replicated versions of $G(f)$ that constitute harmonic versions of the sampled image:

$$G_s(f) = G(f) + G_{\text{high}}(f) \tag{39.7}$$

Exact signal reconstruction from sampled data requires us to discard the replicated spectra $G_{\text{high}}(f)$, leaving only $G(f)$, the spectrum of the signal we seek to recover. This is a crucial observation in the study of sampled-data systems.

39.3.1 Reconstruction Conditions

The only provision for exact **reconstruction** is that $G(f)$ be undistorted due to overlap with $G_{\text{high}}(f)$. Two conditions must hold for this to be true:

1. The signal must be bandlimited. This avoids spectra with infinite extent that are impossible to replicate without overlap.
2. The sampling frequency f_s must be greater than twice the maximum frequency f_{max} present in the signal. This minimum sampling frequency, known as the **Nyquist rate**, is the minimum distance between the spectra copies, each with bandwidth f_{max} .

The first condition merely ensures that a sufficiently large sampling frequency exists that can be used to separate replicated spectra from each other. Since all imaging systems impose a bandlimiting filter in the form of a point spread function, this condition is always satisfied for images captured through an optical system. Note that this does not apply to synthetic images, e.g., computer-generated imagery.

The second condition proves to be the most revealing statement about reconstruction. It answers the problem regarding the sufficiency of the data samples to exactly reconstruct the continuous input signal. It states that exact reconstruction is possible only when $f_s > f_{\text{Nyquist}}$, where $f_{\text{Nyquist}} = 2f_{\text{max}}$. Collectively, these two conclusions about reconstruction form the central message of sampling theory, as pioneered by Claude Shannon in his landmark papers on the subject [Shannon 1948, 1949].

FIGURE 39.4 Ideal low-pass filter $H(f)$.

FIGURE 39.5 The sinc function.

39.3.2 Ideal Low-Pass Filter

We now turn to the second central problem: Given that it is theoretically possible to perform reconstruction, how may it be done? The answer lies with our earlier observation that sampling merely replicates the spectrum of the input signal, generating $G_{\text{high}}(f)$ in addition to $G(f)$. Therefore, the act of reconstruction requires us to completely suppress $G_{\text{high}}(f)$. This is done by multiplying $G_s(f)$ with $H(f)$, given as

$$H(f) = \begin{cases} 1, & |f| < f_{\text{max}} \\ 0, & |f| \geq f_{\text{max}} \end{cases} \quad (39.8)$$

$H(f)$ is known as an *ideal low-pass filter* and is depicted in Figure 39.4, where it is shown suppressing all frequency components above f_{max} . This serves to discard the replicated spectra $G_{\text{high}}(f)$. It is ideal in the sense that the f_{max} cutoff frequency is strictly enforced as the transition point between the transmission and complete suppression of frequency components.

39.3.3 Sinc Function

In the spatial domain, the ideal low-pass filter is derived by computing the inverse Fourier transform of $H(f)$. This yields the sinc function shown in Figure 39.5. It is defined as

$$\text{sinc}(x) = \frac{\sin(\pi x)}{\pi x} \quad (39.9)$$

The reader should note the reciprocal relationship between the height and width of the ideal low-pass filter in the spatial and frequency domains. Let A denote the amplitude of the sinc function, and let its zero crossings be positioned at integer multiples of $1/2W$. The spectrum of this sinc function is a rectangular pulse of height $A/2W$ and width $2W$, with frequencies ranging from $-W$ to W . In our example above, $A = 1$ and $W = f_{\text{max}} = 0.5$ cycles/pixel. This value for W is derived from the fact that digital images must not have more than one half cycle per pixel in order to conform to the Nyquist rate.

The sinc function is one instance of a large class of functions known as cardinal splines, which are interpolating functions defined to pass through zero at all but one data sample, where they have a value

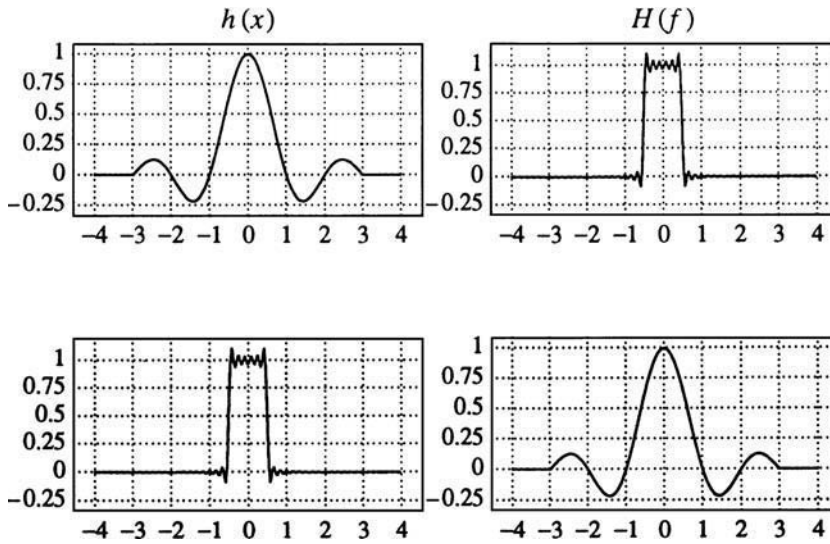

FIGURE 39.6 Truncation in one domain causes ringing in the other domain.

of one. This allows them to compute a continuous function that passes through the uniformly spaced data samples.

Since multiplication in the frequency domain is identical to convolution in the spatial domain, $\text{sinc}(x)$ represents the convolution kernel used to evaluate any point x on the continuous input curve g given only the sampled data g_s :

$$g(x) = \text{sinc}(x) * g_s(x) = \int_{-\infty}^{\infty} \text{sinc}(\lambda) g_s(x - \lambda) d\lambda \quad (39.10)$$

Equation 39.10 highlights an important impediment to the practical use of the ideal low-pass filter. The filter requires an infinite number of neighboring samples (i.e., an infinite filter support) in order to precisely compute the output points. This is, of course, impossible owing to the finite number of data samples available. However, truncating the sinc function allows for approximate solutions to be computed at the expense of undesirable “ringing,” i.e., ripple effects. These artifacts, known as the **Gibbs phenomenon**, are the overshoots and undershoots caused by reconstructing a signal with truncated frequency terms. The two rows in Figure 39.6 show that truncation in one domain leads to ringing in the other domain. This indicates that a truncated sinc function is actually a poor reconstruction filter because its spectrum has infinite extent and thereby fails to bandlimit the input.

In response to these difficulties, a number of approximating algorithms have been derived, offering a tradeoff between precision and computational expense. These methods permit local solutions that require the convolution kernel to extend only over a small neighborhood. The drawback, however, is that the frequency response of the filter has some undesirable properties. In particular, frequencies below f_{\max} are tampered, and high frequencies beyond f_{\max} are not fully suppressed. Thus, nonideal reconstruction does not permit us to exactly recover the continuous underlying signal without artifacts.

39.3.4 Nonideal Reconstruction

The process of nonideal reconstruction is depicted in Figure 39.7, which indicates that the input signal satisfies the two conditions necessary for exact reconstruction. First, the signal is bandlimited, since the replicated copies in the spectrum are each finite in extent. Second, the sampling frequency exceeds the Nyquist rate, since the copies do not overlap. However, this is where our ideal scenario ends. Instead of

FIGURE 39.7 Nonideal reconstruction.

using an ideal low-pass filter to retain only the baseband spectrum components, a nonideal reconstruction filter is shown in the figure.

The filter response $H_r(f)$ deviates from the ideal response $H(f)$ shown in Figure 39.4. In particular, $H_r(f)$ does not discard all frequencies beyond f_{\max} . Furthermore, that same filter is shown to attenuate some frequencies that should have remained intact. This brings us to the problem of assessing the quality of a filter.

The accuracy of a reconstruction filter can be evaluated by analyzing its frequency-domain characteristics. Of particular importance is the filter response in the passband and stopband. In this problem, the **passband** consists of all frequencies below f_{\max} . The **stopband** contains all higher frequencies arising from the sampling process.

An ideal reconstruction filter, as described earlier, will completely suppress the stopband while leaving the passband intact. Recall that the stopband contains the offending high frequencies that, if allowed to remain, would prevent us from performing exact reconstruction. As a result, the sinc filter was devised to meet these goals and serve as the ideal reconstruction filter. Its kernel in the frequency domain applies unity gain to transmit the passband and zero gain to suppress the stopband.

The breakdown of the frequency domain into passband and stopband isolates two problems that can arise due to nonideal reconstruction filters. The first problem deals with the effects of imperfect filtering on the passband. Failure to impose unity gain on *all* frequencies in the passband will result in some combination of image smoothing and image sharpening. Smoothing, or blurring, will result when the frequency gains near the cutoff frequency start falling off. Image sharpening results when the high-frequency gains are allowed to exceed unity. This follows from the direct correspondence of visual detail to spatial frequency. Furthermore, amplifying the high passband frequencies yields a sharper transition between the passband and stopband, a property shared by the sinc function.

The second problem addresses nonideal filtering on the stopband. If the stopband is allowed to persist, high frequencies will exist that will contribute to aliasing (described later). Failure to fully suppress the stopband is a condition known as **frequency leakage**. This allows the offending frequencies to fold over into the passband range. These distortions tend to be more serious, since they are visually perceived more readily.

In the spatial domain, nonideal reconstruction is achieved by centering a finite-width kernel at the position in the data at which the underlying function is to be evaluated, i.e., reconstructed. This is an interpolation problem which, for equally spaced data, can be expressed as

$$f(x) = \sum_{k=0}^{K-1} f(x_k)h(x - x_k) \quad (39.11)$$

where h is the reconstruction kernel that weighs K data samples at x_k . Equation 39.11 formulates interpolation as a convolution operation. In practice, h is nearly always a symmetric kernel, i.e., $h(-x) = h(x)$. We shall assume this to be true in the discussion that follows.

The computation of one interpolated point is illustrated in Figure 39.8. The kernel is centered at x , the location of the point to be interpolated. The value of that point is equal to the sum of the values of the

FIGURE 39.8 Interpolation of a single point.

FIGURE 39.9 Box filter: (a) kernel, (b) Fourier transform.

discrete input scaled by the corresponding values of the reconstruction kernel. This follows directly from the definition of convolution.

39.4 Reconstruction Kernels

The numerical accuracy and computational cost of reconstruction are directly tied to the convolution kernel used for low-pass filtering. As a result, filter kernels are the target of design and analysis in the creation and evaluation of reconstruction algorithms. They are subject to conditions influencing the tradeoff between accuracy and efficiency. This section reviews several common nonideal reconstruction filter kernels in the order of their complexity: box filter, triangle filter, cubic convolution, and windowed sinc functions.

39.4.1 Box Filter

The box filter kernel is defined as

$$h(x) = \begin{cases} 1, & -0.5 < x \leq 0.5 \\ 0, & \text{otherwise} \end{cases} \quad (39.12)$$

Various other names are used to denote this simple kernel, including the sample-and-hold function and Fourier window. The kernel and its Fourier transform are shown in Figure 39.9.

Convolution in the spatial domain with the rectangle function h is equivalent in the frequency domain to multiplication with a sinc function. Due to the prominent side lobes and infinite extent, a sinc function

FIGURE 39.10 Triangle filter: (a) kernel, (b) Fourier transform.

makes a poor low-pass filter. Consequently, this filter kernel has a poor frequency-domain response relative to that of the ideal low-pass filter. The ideal filter, drawn as a dashed rectangle, is characterized by unity gain in the passband and zero gain in the stopband. This permits all low frequencies (below the cutoff frequency) to pass and all higher frequencies to be suppressed.

39.4.2 Triangle Filter

The triangle filter kernel is defined as

$$h(x) = \begin{cases} 1 - |x|, & 0 \leq |x| < 1 \\ 0, & 1 \leq |x| \end{cases} \quad (39.13)$$

The kernel h is also referred to as a tent filter, roof function, Chateau function, or Bartlett window.

This kernel corresponds to a reasonably good low-pass filter in the frequency domain. As shown in Figure 39.10, its response is superior to that of the box filter. In particular, the side lobes are far less prominent, indicating improved performance in the stopband. Nevertheless, a significant amount of spurious high-frequency components continues to leak into the passband, contributing to some aliasing. In addition, the passband is moderately attenuated, resulting in image smoothing.

39.4.3 Cubic Convolution

The cubic convolution kernel is a third-degree approximation to the sinc function. It is symmetric, space-invariant, and composed of piecewise cubic polynomials:

$$h(x) = \begin{cases} (a + 2)|x|^3 - (a + 3)|x|^2 + 1, & 0 \leq |x| < 1 \\ a|x|^3 - 5a|x|^2 + 8a|x| - 4a, & 1 \leq |x| < 2 \\ 0, & 2 \leq |x| \end{cases} \quad (39.14)$$

where $-3 < a < 0$ is used to make h resemble the sinc function.

Of all the choices for a , the value -1 is preferable if visually enhanced results are desired. That is, the image is sharpened, making visual detail perceived more readily. However, the results are not mathematically precise, where precision is measured by the order of the Taylor series. To maximize this order, the value $a = -0.5$ is preferable. A cubic convolution kernel with $a = -0.5$ and its spectrum are shown in Figure 39.11.

39.4.4 Windowed Sinc Function

Sampling theory establishes that the sinc function is the ideal interpolation kernel. Although this interpolation filter is exact, it is not practical, since it is an infinite impulse response (IIR) filter defined by a slowly converging infinite sum. Nevertheless, it is perfectly reasonable to consider the effects of using a truncated, and therefore finite, sinc function as the interpolation kernel.

FIGURE 39.11 Cubic convolution: (a) kernel ($a = -0.5$), (b) Fourier transform.

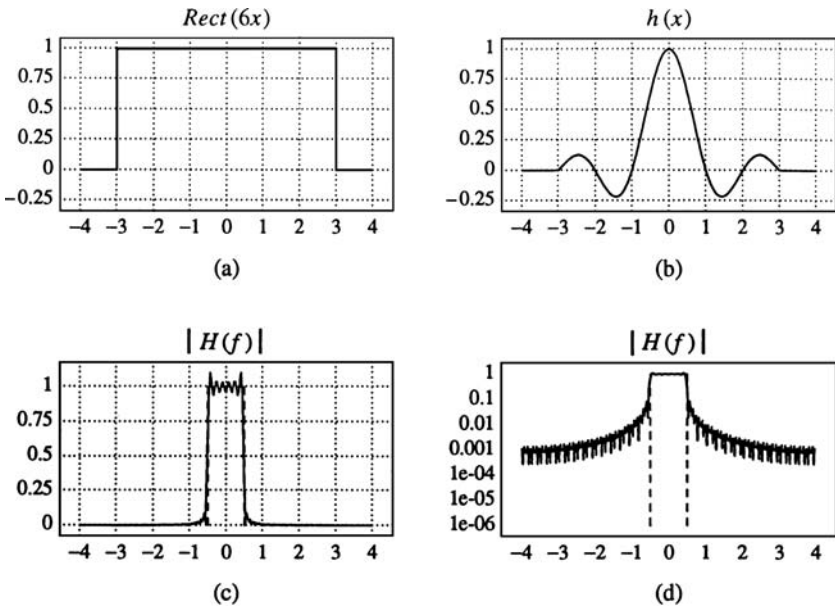

FIGURE 39.12 (a) Rectangular window; (b) windowed sinc; (c) spectrum; (d) log plot.

The results of this operation are predicted by sampling theory, which demonstrates that truncation in one domain leads to ringing in the other domain. This is due to the fact that truncating a signal is equivalent to multiplying it with a rectangle function $\text{Rect}(x)$, defined as the box filter of Equation 39.12. Since multiplication in one domain is convolution in the other, truncation amounts to convolving the signal's spectrum with a sinc function, the transform pair of $\text{Rect}(x)$. Since the stopband is no longer eliminated, but rather attenuated by a ringing filter (i.e., a sinc), the input is not bandlimited and aliasing artifacts are introduced. The most typical problems occur at step edges, where the Gibbs phenomena becomes noticeable in the form of undershoots, overshoots, and ringing in the vicinity of edges.

The Rect function above served as a window, or kernel, that weighs the input signal. In Figure 39.12(a), we see the Rect window extended over three pixels on each side of its center, i.e., $\text{Rect}(6x)$ is plotted. The corresponding windowed sinc function $h(x)$ is shown in Figure 39.12(b). This is simply the product of the sinc function with the window function, i.e., $\text{sinc}(x) \text{Rect}(6x)$. Its spectrum, shown in Figure 39.12(c), is nearly an ideal low-pass filter. Although it has a fairly sharp transition from the passband to the stopband, it is plagued by ringing. In order to more clearly see the values in the spectrum, we use a logarithmic scale for the vertical axis of the spectrum in Figure 39.12(d). The next few figures will use this same four-part format.

Ringings can be mitigated by using a different windowing function exhibiting smoother falloff than the rectangle. The resulting windowed sinc function can yield better results. However, since slow falloff requires larger windows, the computation remains costly.

Aside from the rectangular window mentioned above, the most frequently used window functions are Hann, Hamming, Blackman, and Kaiser. These filters identify a quantity known as the ripple ratio, defined as the ratio of the maximum side-lobe amplitude to the main-lobe amplitude. Good filters will have small ripple ratios to achieve effective attenuation in the stopband. A tradeoff exists, however, between ripple ratio and main-lobe width. Therefore, as the ripple ratio is decreased, the main-lobe width is increased. This is consistent with the reciprocal relationship between the spatial and frequency domains, i.e., narrow bandwidths correspond to wide spatial functions.

In general, though, each of these smooth window functions is defined over a small finite extent. This is tantamount to multiplying the smooth window with a rectangle function. While this is better than the Rect function alone, there will inevitably be some form of aliasing. Nevertheless, the window functions described below offer a good compromise between ringing and blurring.

39.4.5 Hann and Hamming Windows

The Hann and Hamming windows are defined as

$$\text{Hann/Hamming}(x) = \begin{cases} \alpha + (1 - \alpha) \cos \frac{2\pi x}{N-1}, & |x| < \frac{N-1}{2} \\ 0, & \text{otherwise} \end{cases} \quad (39.15)$$

where N is the number of samples in the windowing function. The two windowing functions differ in their choice of α . In the Hann window $\alpha = 0.5$, and in the Hamming window $\alpha = 0.54$. Since they both amount to a scaled and shifted cosine function, they are also known as the raised cosine window. The Hann window is illustrated in Figure 39.13. Notice that the passband is only slightly attenuated, but the stopband continues to retain high-frequency components in the stopband, albeit less than that of Rect(x).

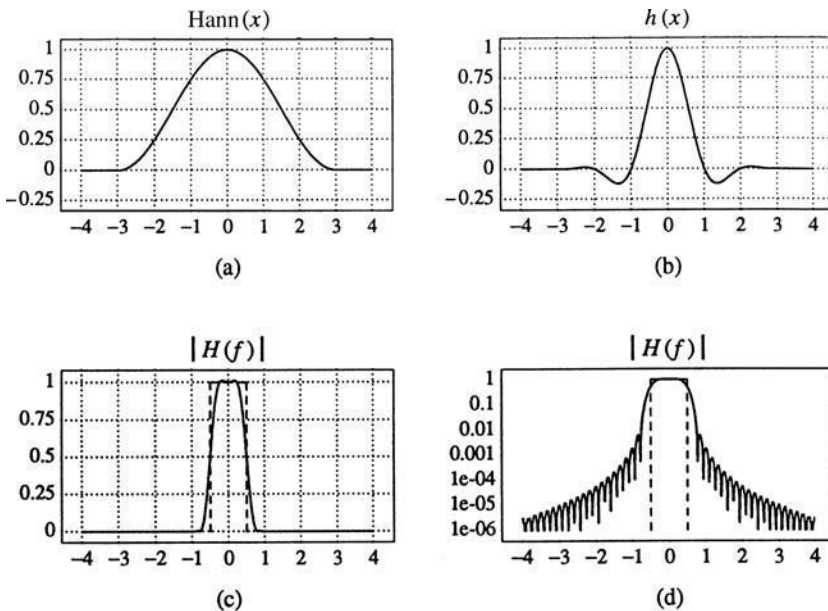

FIGURE 39.13 (a) Hann window; (b) windowed sinc; (c) spectrum; (d) log plot.

FIGURE 39.14 (a) Blackman window; (b) windowed sinc; (c) spectrum; (d) log plot.

39.4.6 Blackman Window

The Blackman window is similar to the Hann and Hamming windows. It is defined as

$$\text{Blackman}(x) = \begin{cases} 0.42 + 0.5 \cos \frac{2\pi x}{N-1} + 0.08 \cos \frac{4\pi x}{N-1}, & |x| < \frac{N-1}{2} \\ 0, & \text{otherwise} \end{cases} \quad (39.16)$$

The purpose of the additional cosine term is to further reduce the ripple ratio. This window function is shown in Figure 39.14.

39.4.7 Kaiser Window

The Kaiser window is defined as

$$\text{Kaiser}(x) = \begin{cases} \frac{I_0(\beta)}{I_0(\alpha)}, & |x| < \frac{N-1}{2} \\ 0, & \text{otherwise} \end{cases} \quad (39.17)$$

where I_0 is the zeroth-order Bessel function of the first kind, α is a free parameter, and

$$\beta = \alpha \left[1 - \left(\frac{2x}{N-1} \right)^2 \right]^{1/2} \quad (39.18)$$

The Kaiser window leaves the filter designer much flexibility in controlling the ripple ratio by adjusting the parameter α . As α is increased, the level of sophistication of the window function grows as well. Therefore, the rectangular window corresponds to a Kaiser window with $\alpha = 0$, while more sophisticated windows such as the Hamming window correspond to $\alpha = 5$.

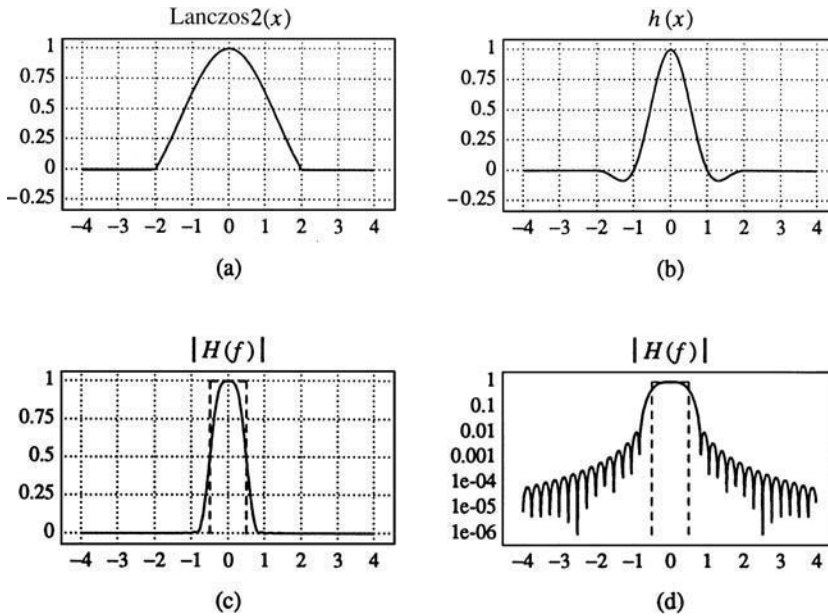

FIGURE 39.15 (a) Lanczos2 window; (b) windowed sinc; (c) spectrum; (d) log plot.

39.4.8 Lanczos Window

The Lanczos window is based on the sinc function rather than cosines as used in the previous methods. The two-lobed Lanczos window function is defined as

$$\text{Lanczos2}(x) = \begin{cases} \frac{\sin(\pi x/2)}{\pi x/2}, & 0 \leq |x| < 2 \\ 0, & 2 \leq |x| \end{cases} \quad (39.19)$$

The Lanczos2 window function, shown in Figure 39.15, is the central lobe of a sinc function. It is wide enough to extend over two lobes of the ideal low-pass filter, i.e., a second sinc function. This formulation can be generalized to an N -lobed window function by replacing the value 2 in Equation 39.19 with the value N . Larger N results in superior frequency response.

39.5 Aliasing

If the two reconstruction conditions outlined earlier are not met, sampling theory predicts that exact reconstruction is *not* possible. This phenomenon, known as **aliasing**, occurs when signals are not bandlimited or when they are undersampled, i.e., $f_s \leq f_{\text{Nyquist}}$. In either case there will be unavoidable overlapping of spectral components, as in Figure 39.16. Notice that the irreproducible high frequencies fold over into the low frequency range. As a result, frequencies originally beyond f_{max} will, upon reconstruction, appear in the form of much *lower* frequencies. In comparison with the spurious high frequencies retained by nonideal reconstruction filters, the spectral components passed due to undersampling are more serious, since they actually corrupt the components in the original signal.

Aliasing refers to the higher frequencies becoming aliased and indistinguishable from the lower-frequency components in the signal if the sampling rate falls below the Nyquist frequency. In other words, undersampling causes high-frequency components to appear as spurious low frequencies. This is depicted in Figure 39.17, where a high-frequency signal appears as a low-frequency signal after sampling it too sparsely. In digital images, the Nyquist rate is determined by the highest frequency that can be

FIGURE 39.16 Overlapping spectral components give rise to aliasing.

FIGURE 39.17 Aliasing artifacts due to undersampling.

displayed: one cycle every two pixels. Therefore, any attempt to display higher frequencies will produce similar artifacts.

There is sometimes a misconception in the computer graphics literature that jagged (staircased) edges are always a symptom of aliasing. This is only partially true. Technically, jagged edges arise from high frequencies introduced by inadequate reconstruction. Since these high frequencies are not corrupting the low-frequency components, no aliasing is actually taking place. The confusion lies in that the suggested remedy of increasing the sampling rate is also used to eliminate aliasing. Of course, the benefit of increasing the sampling rate is that the replicated spectra are now spaced farther apart from each other. This relaxes the accuracy constraints for reconstruction filters to perform ideally in the stopband, where they must suppress all components beyond some specified cutoff frequency. In this manner, the same nonideal filters will produce less objectionable output.

It is important to note that a signal may be densely sampled (far above the Nyquist rate) and continue to appear jagged if a zero-order reconstruction filter is used. Box filters used for pixel replication in real-time hardware zooms are a common example of poor reconstruction filters. In this case, the signal is clearly not aliased but rather poorly reconstructed. The distinction between reconstruction and aliasing artifacts becomes clear when we notice that the appearance of jagged edges is improved by blurring. For example, it is not uncommon to step back from an image exhibiting excessive blockiness in order to see it more clearly. This is a defocusing operation that attenuates the high frequencies admitted through nonideal reconstruction. On the other hand, once a signal is truly undersampled, there is no postprocessing possible to improve its condition. After all, applying an ideal low-pass (reconstruction) filter to a spectrum whose components are already overlapping will only blur the result, not rectify it.

39.6 Antialiasing

The filtering necessary to combat aliasing is known as **antialiasing**. In order to determine corrective action, we must directly address the two conditions necessary for exact signal reconstruction. The first solution calls for low-pass filtering *before* sampling. This method, known as **prefiltering**, bandlimits the signal to levels below f_{\max} , thereby eliminating the offending high frequencies. Notice that the frequency at which the signal is to be sampled imposes limits on the allowable bandwidth. This is often necessary when the output

sampling grid must be fixed to the resolution of an output device, e.g., screen resolution. Therefore, aliasing is often a problem that is confronted when a signal is forced to conform to an inadequate resolution due to physical constraints. As a result, it is necessary to bandlimit, or narrow, the input spectrum to conform to the allotted bandwidth as determined by the sampling frequency.

The second solution is to point-sample at a higher frequency. In doing so, the replicated spectra are spaced farther apart, thereby separating the overlapping spectra tails. This approach theoretically implies sampling at a resolution determined by the highest frequencies present in the signal. Since a surface viewed obliquely can give rise to arbitrarily high frequencies, this method may require extremely high resolution. Whereas the first solution adjusts the bandwidth to accommodate the fixed sampling rate f_s , the second solution adjusts f_s to accommodate the original bandwidth. Antialiasing by sampling at the highest frequency is clearly superior in terms of image quality. This is, of course, operating under different assumptions regarding the possibility of varying f_s . In practice, antialiasing is performed through a combination of these two approaches. That is, the sampling frequency is increased so as to reduce the amount of bandlimiting to a minimum.

39.6.1 Point Sampling

The naive approach for generating an output image is to perform **point sampling**, where each output pixel is a single sample of the input image taken independently of its neighbors (Figure 39.18). It is clear that information is lost between the samples and that aliasing artifacts may surface if the sampling density is not sufficiently high to characterize the input. This problem is rooted in the fact that intermediate intervals between samples, which should have some influence on the output, are skipped entirely.

The Star image is a convenient example that overwhelms most resampling filters due to the infinitely high frequencies found toward the center. Nevertheless, the extent of the artifacts is related to the quality of the filter and the actual spatial transformation. Figure 39.19 shows two examples of the moiré effects that can appear when a signal is undersampled using point sampling. In Figure 39.19(a), one out of every two pixels in the Star image was discarded to reduce its dimension. In Figure 39.19(b), the artifacts of undersampling are more pronounced, as only one out of every four pixels is retained. In order to see the small images more clearly, they are magnified using cubic spline reconstruction. Clearly, these examples show that point sampling behaves poorly in high-frequency regions.

Aliasing can be reduced by point sampling at a higher resolution. This raises the Nyquist limit, accounting for signals with higher bandwidths. Generally, though, the display resolution places a limit on the highest frequency that can be displayed, and thus limits the Nyquist rate to one cycle every two pixels. Any attempt to display higher frequencies will produce aliasing artifacts such as moiré patterns and jagged edges. Consequently, antialiasing algorithms have been derived to bandlimit the input *before* resampling onto the output grid.

FIGURE 39.18 Point sampling.

FIGURE 39.19 Aliasing due to point sampling: (a) 1/2 and (b) 1/4 scale.

FIGURE 39.20 Area sampling.

39.6.2 Area Sampling

The basic flaw in point sampling is that a discrete pixel actually represents an area, not a point. In this manner, each output pixel should be considered a window looking onto the input image. Rather than sampling a point, we must instead apply a low-pass filter (LPF) upon the projected area in order to properly reflect the information content being mapped onto the output pixel. This approach, depicted in Figure 39.20, is called **area sampling**, and the projected area is known as the **preimage**. The low-pass filter comprises the prefiltering stage. It serves to defeat aliasing by bandlimiting the input image prior to resampling it onto the output grid. In the general case, prefiltering is defined by the convolution integral

$$g(x, y) = \iint f(u, v)h(x - u, y - v) du dv \quad (39.20)$$

where f is the input image, g is the output image, h is the filter kernel, and the integration is applied to all $[u, v]$ points in the preimage.

Images produced by area sampling are demonstrably superior to those produced by point sampling. Figure 39.21 shows the Star image subjected to the same downsampling transformation as that in Figure 39.19. Area sampling was implemented by applying a box filter (i.e., unweighted averaging) to the Star image before point sampling. Notice that antialiasing through area sampling has traded moiré patterns for some blurring. Although there is no substitute for high-resolution imagery, filtering can make lower resolution less objectionable by attenuating aliasing artifacts.

FIGURE 39.21 Aliasing due to area sampling: (a) 1/2 and (b) 1/4 scale.

FIGURE 39.22 Supersampling.

39.6.3 Supersampling

The process of using more than one regularly spaced sample per pixel is known as **supersampling**. Each output pixel value is evaluated by computing a weighted average of the samples taken from their respective preimages. For example, if the supersampling grid is three times denser than the output grid (i.e., there are nine grid points per pixel area), each output pixel will be an average of the nine samples taken from its projection in the input image. If, say, three samples hit a green object and the remaining six samples hit a blue object, the composite color in the output pixel will be one-third green and two-thirds blue, assuming a box filter is used.

Supersampling reduces aliasing by bandlimiting the input signal. The purpose of the high-resolution supersampling grid is to refine the estimate of the preimages seen by the output pixels. The samples then enter the prefiltering stage, consisting of a low-pass filter. This permits the input to be resampled onto the (relatively) low-resolution output grid without any offending high frequencies introducing aliasing artifacts. In Figure 39.22 we see an output pixel subdivided into nine subpixel samples which each undergo inverse mapping, sampling the input at nine positions. Those nine values then pass through a low-pass filter to be averaged into a single output value.

Supersampling was used to achieve antialiasing in Figure 39.1 for pixels near the horizon. There are two problems, however, associated with straightforward supersampling. The first problem is that the newly designated high frequency of the prefiltered image continues to be fixed. Therefore, there will always be sufficiently higher frequencies that will alias. The second problem is cost. In our example, supersampling will take nine times longer than point sampling. Although there is a clear need for the additional computation, the dense placement of samples can be optimized. Adaptive supersampling is introduced to address these drawbacks.

39.6.4 Adaptive Supersampling

In **adaptive supersampling**, the samples are distributed more densely in areas of high intensity variance. In this manner, supersamples are collected only in regions that warrant their use. Early work in adaptive supersampling for computer graphics is described in Whitted [1980]. The strategy is to subdivide areas between previous samples when an edge, or some other high-frequency pattern, is present. Two approaches to adaptive supersampling have been described in the literature. The first approach allows sampling density to vary as a function of local image variance [Lee et al. 1985, Kajiya 1986]. A second approach introduces two levels of sampling densities: a regular pattern for most areas and a higher-density pattern for regions demonstrating high frequencies. The regular pattern simply consists of one sample per output pixel. The high density pattern involves local supersampling at a rate of 4 to 16 samples per pixel. Typically, these rates are adequate for suppressing aliasing artifacts.

A strategy is required to determine where supersampling is necessary. In Mitchell [1987], the author describes a method in which the image is divided into small square supersampling cells, each containing eight or nine of the low-density samples. The entire cell is supersampled if its samples exhibit excessive variation. In Lee et al. [1985], the variance of the samples is used to indicate high frequency. It is well known, however, that variance is a poor measure of visual perception of local variation. Another alternative is to use contrast, which more closely models the nonlinear response of the human eye to rapid fluctuations in light intensities [Caelli 1981]. Contrast is given as

$$C = \frac{I_{\max} - I_{\min}}{I_{\max} + I_{\min}} \quad (39.21)$$

Adaptive sampling reduces the number of samples required for a given image quality. The problem with this technique, however, is that the variance measurement is itself based on point samples, and so this method can fail as well. This is particularly true for subpixel objects that do not cross pixel boundaries. Nevertheless, adaptive sampling presents a far more reliable and cost-effective alternative to supersampling.

39.7 Prefiltering

Area sampling can be accelerated if constraints on the filter shape are imposed. Pyramids and preintegrated tables are introduced to approximate the convolution integral with a constant number of accesses. This compares favorably against direct convolution, which requires a large number of samples that grow proportionately to preimage area. As we shall see, though, the filter area will be limited to squares or rectangles, and the kernel will consist of a box filter. Subsequent advances have extended their use to more general cases with only marginal increases in cost.

39.7.1 Pyramids

Pyramids are multiresolution data structures commonly used in image processing and computer vision. They are generated by successively bandlimiting and subsampling the original image to form a hierarchy of images at ever decreasing resolutions. The original image serves as the base of the pyramid, and its coarsest version resides at the apex. Thus, in a lower-resolution version of the input, each pixel represents the average of some number of pixels in the higher-resolution version.

The resolution of successive levels typically differs by a power of two. This means that successively coarser versions each have one-quarter of the total number of pixels as their adjacent predecessors. The memory cost of this organization is modest: $1 + 1/4 + 1/16 + \dots = 4/3$ times that needed for the original input. This requires only 33% more memory.

To filter a preimage, one of the pyramid levels is selected based on the size of its bounding square box. That level is then point sampled and assigned to the respective output pixel. The primary benefit of this approach is that the cost of the filter is constant, requiring the same number of pixel accesses independent of the filter size. This performance gain is the result of the filtering that took place while creating the

FIGURE 39.23 Mip-map memory organization.

pyramid. Furthermore, if preimage areas are adequately approximated by squares, the direct convolution methods amount to point-sampling a pyramid. This approach was first applied to texture mapping in Catmull [1974] and described in Dungan et al. [1978].

There are several problems with the use of pyramids. First, the appropriate pyramid level must be selected. A coarse level may yield excessive blur, while the adjacent finer level may be responsible for aliasing due to insufficient bandlimiting. Second, preimages are constrained to be squares. This proves to be a crude approximation for elongated preimages. For example, when a surface is viewed obliquely the texture may be compressed along one dimension. Using the largest bounding square will include the contributions of many extraneous samples and result in excessive blur. These two issues were addressed in Williams [1983] and Crow [1984], respectively, along with extensions proposed by other researchers.

Williams proposed a pyramid organization called *mip map* to store color images at multiple resolutions in a convenient memory organization [Williams 1983]. The acronym “mip” stands for “multum in parvo,” a Latin phrase meaning “much in little.” The scheme supports trilinear interpolation, where both intra- and interlevel interpolation can be computed using three normalized coordinates: u , v , and d . Both u and v are spatial coordinates used to access points within a pyramid level. The d coordinate is used to index, and interpolate between, different levels of the pyramid. This is depicted in Figure 39.23.

The quadrants touching the east and south borders contain the original red, green, and blue (RGB) components of the color image. The remaining upper left quadrant contains all the lower-resolution copies of the original. The memory organization depicted in Figure 39.23 clearly supports the earlier claim that the memory cost is 4/3 times that required for the original input. Each level is shown indexed by the $[u, v, d]$ coordinate system, where d is shown slicing through the pyramid levels. Since corresponding points in different pyramid levels have indices which are related by some power of two, simple binary shifts can be used to access these points across the multiresolution copies. This is a particularly attractive feature for hardware implementation.

The primary difference between mip maps and ordinary pyramids is the trilinear interpolation scheme possible with the $[u, v, d]$ coordinate system. Since they allow a continuum of points to be accessed, mip maps are referred to as pyramidal parametric data structures. In Williams’s implementation, a box filter was used to create the mip maps, and a triangle filter was used to perform intra- and interlevel interpolation. The value of d must be chosen to balance the tradeoff between aliasing and blurring. Heckbert suggests

$$d^2 = \max \left(\left(\frac{\partial u}{\partial x} \right)^2 + \left(\frac{\partial v}{\partial x} \right)^2, \left(\frac{\partial u}{\partial y} \right)^2 + \left(\frac{\partial v}{\partial y} \right)^2 \right) \quad (39.22)$$

FIGURE 39.24 Summed-area table calculation.

where d is proportional to the span of the preimage area, and the partial derivatives can be computed from the surface projection [Heckbert 1983].

39.7.2 Summed-Area Tables

An alternative to pyramidal filtering was proposed by Crow [1984]. It extends the filtering possible in pyramids by allowing rectangular areas, oriented parallel to the coordinate axes, to be filtered in constant time. The central data structure is a preintegrated buffer of intensities, known as the **summed-area table**. This table is generated by computing a running total of the input intensities as the image is scanned along successive scanlines. For every position P in the table, we compute the sum of intensities of pixels contained in the rectangle between the origin and P . The sum of all intensities in any rectangular area of the input may easily be recovered by computing a sum and two differences of values taken from the table. For example, consider the rectangles R_0 , R_1 , R_2 , and R shown in Figure 39.24. The sum of intensities in rectangle R can be computed by considering the sum at $[x_1, y_1]$, and discarding the sums of rectangles R_0 , R_1 , and R_2 . This corresponds to removing all areas lying below and to the left of R . The resulting area is rectangle R , and its sum S is given as

$$S = T[x_1, y_1] - T[x_1, y_0] - T[x_0, y_1] + T[x_0, y_0] \quad (39.23)$$

where $T[x, y]$ is the value in the summed-area table indexed by coordinate pair $[x, y]$.

Since $T[x_1, y_0]$ and $T[x_0, y_1]$ both contain R_0 , the sum of R_0 was subtracted twice in Equation 39.23. As a result, $T[x_0, y_0]$ was added back to restore the sum. Once S is determined, it is divided by the area of the rectangle. This gives the average intensity over the rectangle, a process equivalent to filtering with a Fourier window (box filtering).

There are two problems with the use of summed-area tables. First, the filter area is restricted to rectangles. This is addressed in Glassner [1986], where an adaptive, iterative technique is proposed for obtaining arbitrary filter areas by removing extraneous regions from the rectangular bounding box. Second, the summed-area table is restricted to box filtering. This, of course, is attributed to the use of unweighted averages that keeps the algorithm simple. In Perlin [1985] and Heckbert [1986], the summed-area table is generalized to support more sophisticated filtering by repeated integration.

It is shown that by repeatedly integrating the summed-area table n times, it is possible to convolve an orthogonally oriented rectangular region with an n th-order box filter (B-spline). The output value is computed by using $(n + 1)^2$ weighted samples from the preintegrated table. Since this result is independent of the size of the rectangular region, this method offers a great reduction in computation over that of direct convolution. Perlin called this a selective image filter because it allows each sample to be blurred by different amounts.

Repeated integration has rather high memory costs relative to pyramids. This is due to the number of bits necessary to retain accuracy in the large summations. Nevertheless, it allows us to filter rectangular or elliptical regions, rather than just squares as in pyramid techniques. Since pyramid and summed-area tables both require a setup time, they are best suited for input that is intended to be used repeatedly, i.e., stationary background scenes or texture maps. In this manner, the initialization overhead can be amortized over each use.

39.8 Example: Image Scaling

In this section, we demonstrate the role of reconstruction and antialiasing in image scaling. The resampling process will be explained in one dimension rather than two, since resampling is carried out on each axis independently. For example, the horizontal scanlines are first processed, yielding an intermediate image, which then undergoes a second pass of interpolation in the vertical direction. The result is independent of the order: processing the vertical lines before the horizontal lines gives the same results.

A skeleton of a C program that resizes an image in two passes is given below. The input image is assumed to have **INheight** rows and **INwidth** columns. The first pass visits each row and resamples them to have width **OUTwidth**. The second pass visits each column of the newly formed intermediate image and resamples them to have height **OUTheight**:

```
INwidth  = input image width (pixels/row);
INheight = input image height (rows/image);
OUTwidth  = output image width (pixels/row);
OUTheight = output image height (rows/image);
filter    = convolution kernel to use to filter image;
offset    = inter-pixel offset (stride);

allocate an intermediate image of size OUTwidth by INheight;

offset = 1;
for(y=0; y<INheight; y++) {          /* process rows */
    src = pointer to row y of input image;
    dst = pointer to row y of intermediate image;
    resample1-D(src, dst, INwidth, OUTwidth, filter, offset);
}

offset = OUTwidth;
for(x=0; x<w; x++) {                 /* process columns */
    src = pointer to column x of intermediate image;
    dst = pointer to column x of output image;
    resample1-D(src, dst, INheight, OUTheight, filter, offset);
}
```

Function **resample1-D** is the workhorse of the resizing operation. The inner workings of this function will be described later. In addition to the input and output pointers and dimensions, **resample1-D** must be passed **filter**, an integer code specifying which convolution kernel to apply. In order to operate on both rows and columns, the parameter **offset** is given to denote the distance between successive pixels in the scanline. Horizontal scanlines (rows) have **offset = 1** and vertical scanlines (columns) have **offset = OUTwidth**.

There are two operations which **resample1-D** must be able to handle: magnification and minification. As mentioned earlier, these two operations are closely related. They both require us to project each output sample into the input, center a kernel, and convolve. The only difference between magnification and minification is the shape of the kernel. The magnification kernel is fixed at $h(x)$, whereas the minification kernel is $ah(ax)$, for $a < 1$. The width of the kernel for minification is due to the need for a low-pass filter to perform antialiasing. That filter now has a narrower response than that of the interpolation function. Consequently, we exploit the following well-known Fourier transform pair:

$$h(ax) \longleftrightarrow \frac{1}{a} H\left(\frac{f}{a}\right) \quad (39.24)$$

This equation expresses the reciprocal relationship between the spatial and frequency domains. Notice that multiplying the spatial axis by a factor of a results in dividing the frequency axis and the spectrum values

by that same factor. Since we want the spectrum values to be left intact, we use $ah(ax)$ as the convolution kernel for blurring, where $a > 1$. This implies that the shape of the kernel changes as a function of scale factor when we are downsampling the input. This was not the case for magnification.

A straightforward method to perform 1-D resampling is given below. It details the inner workings of the **resample1-D** function outlined earlier. In addition, a few interpolation functions are provided. More such functions can easily be added by the user:

```
#define PI                3.1415926535897931160E0
#define SGN(A)           ((A) > 0 ? 1 : ((A) < 0 ? -1 : 0 ))
#define FLOOR(A)         ((int) (A))
#define CEILING(A)       ((A)==FLOOR(A) ? FLOOR(A) : SGN(A)+FLOOR(A))
#define CLAMP(A,L,H)     ((A)<=(L) ? (L) : (A)<=(H) ? (A) : (H))

```

There are several points worth mentioning about this code. First, the filter width **fwidth** of each of the supported kernels is initialized for use in interpolation (for magnification). We then check to see if the scale factor **scale** is less than one to rescale **fwidth** accordingly. Furthermore, we set **fscale**, the filter amplitude scale factor, to 1 for interpolation, or **scale** for minification. We then visit each of **OUTlen** output pixels, and project them back into the input, where we center the filter kernel. The kernel overlaps a range of input pixels from **left** to **right**. All pixels in this range are multiplied by a corresponding kernel value. The products are added in an accumulator **acc** and assigned to the output buffer.

Note that the **CLAMP** macro is necessary to prevent us from attempting to access a pixel beyond the extent of the input buffer. By clamping to either end, we are effectively replicating the border pixel for use with a filter kernel that extends beyond the image.

In order to accommodate the processing of rows and columns, the variable **offset** is introduced to specify the interpixel distance. When processing rows, **offset = 1**. When processing columns, **offset** is set to the width of a row.

This code can accommodate a polynomial transformation by making a simple change to the evaluation of **u**. Rather than computing $u = x/\text{scale}$, we may let u be expressed by a polynomial. The method of forward differences is recommended to simplify the computation of polynomials [Wolberg 1990].

The code given above suffers from three limitations, all dealing with efficiency:

1. A division operation is used to compute the inverse projection. Since we are dealing with a linear mapping function, the new position at which to center the kernel may be computed incrementally. That is, there is a constant offset between each projected output sample. Accordingly, **left** and **right** should be computed incrementally as well.
2. The set of kernel weights used in processing the first scanline applies equally to all the remaining scanlines as well. There should be no need to recompute them each time. This matter is addressed in the code supplied by Schumacher [1992].
3. The kernel weights are evaluated by calling the appropriate filter function with the normalized distance from the center. This involves a lot of run-time overhead, particularly for the more sophisticated kernels that require the evaluation of a sinc function, division, and several multiplies.

Additional sophisticated algorithms to deal with these issues are given in Wolberg [1990].

39.9 Research Issues and Summary

The computer graphics literature is replete with new and innovative work addressing the demands of sampling, reconstruction, and antialiasing. Nonuniform sampling has become important in computer graphics because it facilitates variable sampling density and it allows us to trade structured aliasing for noise. Recent work in adaptive sampling and nonuniform reconstruction is discussed in Glassner [1995]. Excellent surveys in nonuniform reconstruction, which is also known as scattered-data interpolation, can be found in Franke and Nielson [1991] and Hoschek and Lasser [1993]. These problems are also of direct

consequence to image compression. The ability to determine a unique minimal set of samples to completely represent a signal within some specified error tolerance remains an active area of research. The solution must be closely coupled with a nonuniform reconstruction method. Although traditional reconstruction methods are well understood within the framework described in this chapter, the analysis of nonuniform sampling and reconstruction remains challenging.

We now summarize the basic principles of sampling theory, reconstruction, and antialiasing that have been presented in this chapter. We have shown that a continuous signal may be reconstructed from its samples if the signal is bandlimited and the sampling frequency exceeds the Nyquist rate. These are the two necessary conditions for image reconstruction to be possible. Since sampling can be shown to replicate a signal's spectrum across the frequency domain, ideal low-pass filtering was introduced as a means of retaining the original spectrum while discarding its copies. Unfortunately, the ideal low-pass filter in the spatial domain is an infinitely wide sinc function. Since this is difficult to work with, nonideal reconstruction filters are introduced to approximate the reconstructed output. These filters are nonideal in the sense that they do not completely attenuate the spectra copies. Furthermore, they contribute to some blurring of the original spectrum. In general, poor reconstruction leads to artifacts such as jagged edges.

Aliasing refers to the phenomenon that occurs when a signal is undersampled. This happens if the reconstruction conditions mentioned above are violated. In order to resolve this problem, one of two actions may be taken. Either the signal can be bandlimited to a range that complies with the sampling frequency, or the sampling frequency can be increased. In practice, some combination of both options is taken, leaving some relatively unobjectionable aliasing in the output.

Examples of the concepts discussed thus are concisely depicted in [Figure 39.25](#) through [39.27](#). They attempt to illustrate the effects of sampling and low-pass filtering on the quality of the reconstructed signal and its spectrum. The first row of [Figure 39.25](#) shows a signal and its spectrum, bandlimited to 0.5 cycle/pixel. For pedagogical purposes, we treat this signal as if it were continuous. In actuality, though, it is a 256-sample horizontal cross section taken from a digital image. Since each pixel has four samples contributing to it, there is a maximum of two cycles per pixel. The horizontal axes of the spectrum account for this fact.

The second row shows the effect of sampling the signal. Since $f_s = 1$ sample/pixel, there are four copies of the baseband spectrum in the range shown. Each copy is scaled by $f_s = 1$, leaving the magnitudes intact. In the third row, the 64 samples are shown convolved with a sinc function in the spatial domain. This corresponds to a rectangular pulse in the frequency domain. Since the sinc function is used here for image reconstruction, it must have an amplitude of unity value in order to interpolate the data. This forces the height of the rectangular pulse in the frequency domain to vary in response to f_s .

A few comments on the reciprocal relationship between the spatial and frequency domains are in order here, particularly as they apply to the ideal low-pass filter. We again refer to the variables A and W as the sinc amplitude and bandwidth. As a sinc function is made broader, the value $1/2W$ is made to change, since W is decreasing to accommodate zero crossings at larger intervals. Accordingly, broader sinc functions cause more blurring, and their spectra reflect this by reducing the cutoff frequency to some smaller W . Conversely, narrower sinc functions cause less blurring, and W takes on some larger value. In either case, the amplitude of the sinc function or its spectrum will change. That is, we can fix the amplitude of the sinc function so that only the rectangular pulse of the spectrum changes height $A/2W$ as W varies. Alternatively, we can fix $A/2W$ to remain constant as W changes, forcing us to vary A . The choice depends on the application.

When the sinc function is used to interpolate data, it is necessary to fix A to 1. Therefore, as the sampling density changes, the positions of the zero crossings shift, causing W to vary. This makes the amplitude of the spectrum's rectangular pulse change. On the other hand, if the sinc function is applied to bandlimit, not interpolate, the input signal, then it is important to fix $A/2W$ to 1 so that the passband frequencies remain intact. Since W is once again varying, A must change proportionately to keep $A/2W$ constant. Therefore, this application of the ideal low-pass filter requires the amplitude of the sinc function to be responsive to W .

In the examples presented below, our objective is to interpolate (reconstruct) the input, and so $A = 1$ regardless of the sampling density. Consequently, the height of the spectrum of the reconstruction filter changes. To make the Fourier transforms of the filters easier to see, we have not drawn the frequency

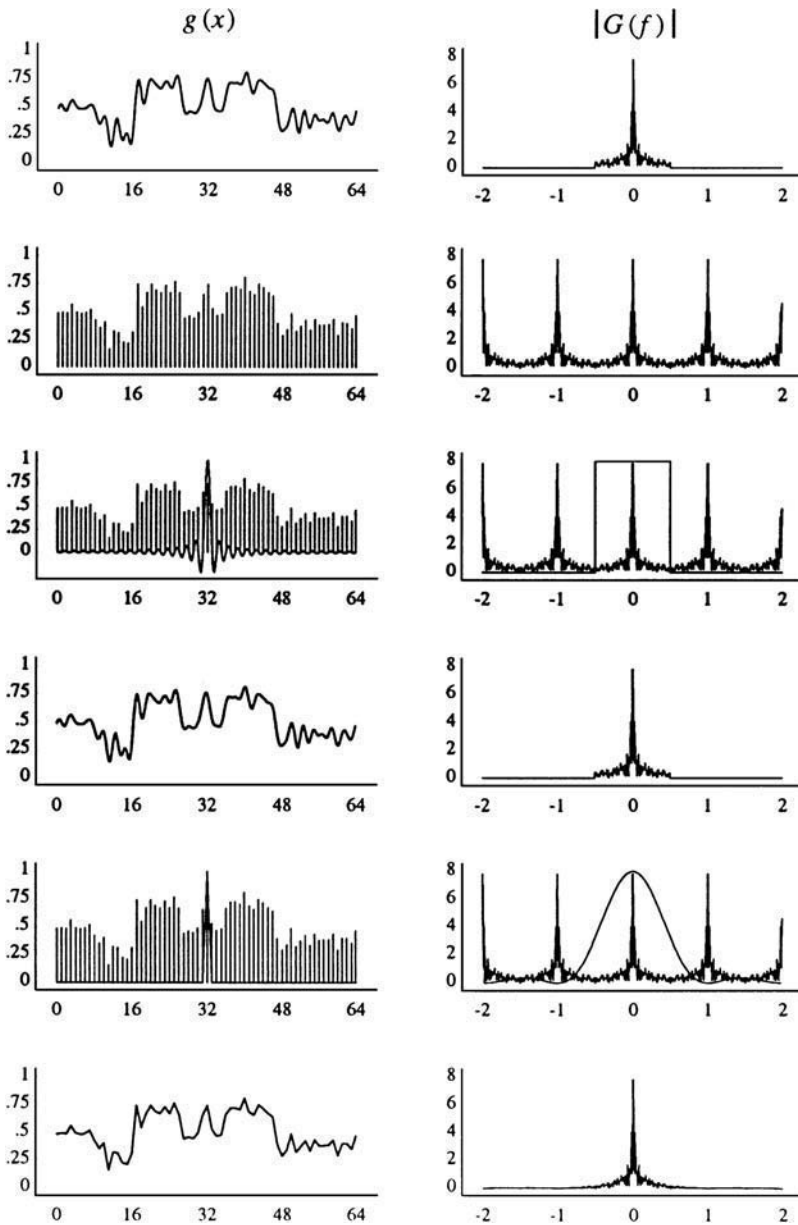

FIGURE 39.25 Sampling and reconstruction (with an adequate sampling rate).

response of the reconstruction filters to scale. Therefore, the rectangular pulse function in the third row of Figure 39.25 actually has height $A/2W = 1$. The fourth row of the figure shows the result after applying the ideal low-pass filter. As sampling theory predicts, the output is identical to the original signal. The last two rows of the figure illustrate the consequences of nonideal reconstruction filtering. Instead of using a sinc function, a triangle function corresponding to linear interpolation was applied. In the frequency domain this corresponds to the square of the sinc function. Not surprisingly, the spectrum of the reconstructed signal suffers in both the passband and the stopband.

The identical sequence of filtering operations is performed in Figure 39.26. In this figure, though, the sampling rate has been lowered to $f_s = 0.5$, meaning that only one sample is collected for every

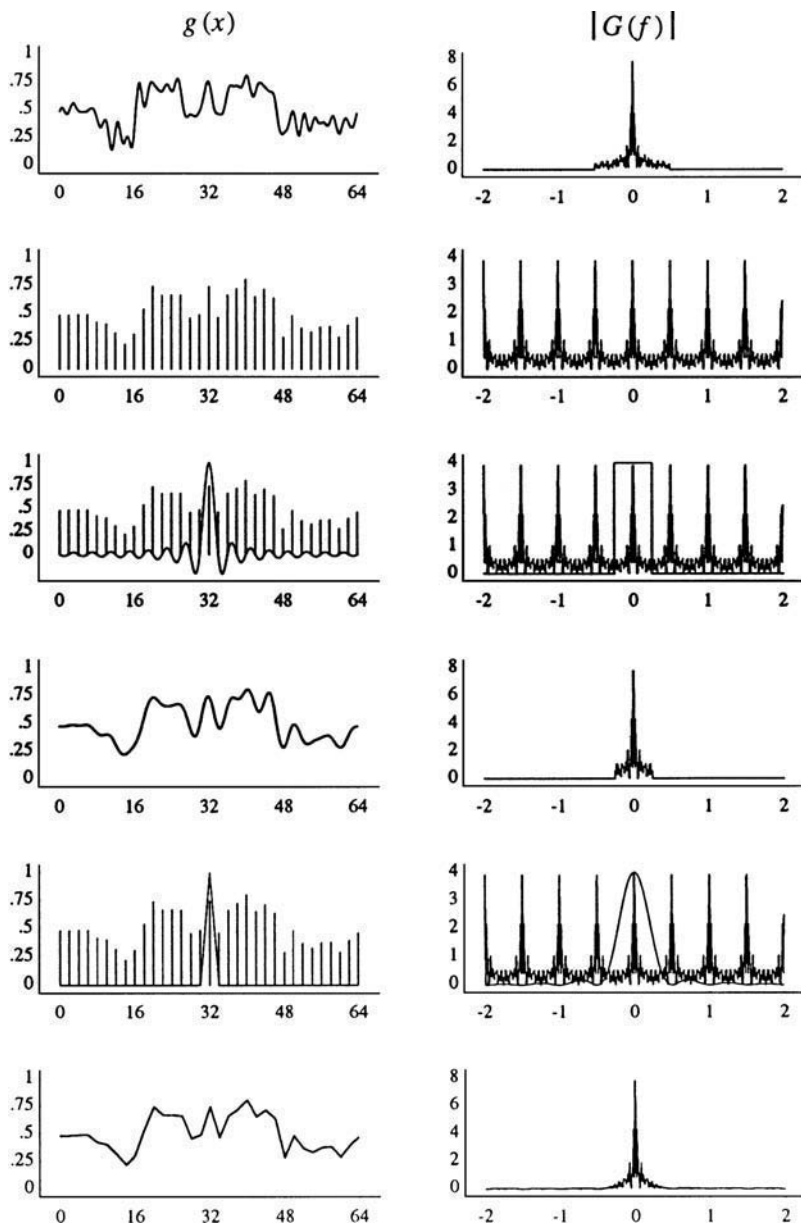

FIGURE 39.26 Sampling and reconstruction (with an inadequate sampling rate).

two output pixels. Consequently, the replicated spectra are multiplied by 0.5, leaving the magnitudes at 4. Unfortunately, this sampling rate causes the replicated spectra to overlap. This, in turn, gives rise to aliasing, as depicted in the fourth row of the figure. Applying the triangle function to perform linear interpolation also yields poor results.

In order to combat these artifacts, the input signal must be bandlimited to accommodate the low sampling rate. This is shown in the second row of Figure 39.27, where we see that all frequencies beyond $W = 0.25$ are truncated. This causes the input signal to be blurred. In this manner we have traded aliasing for blurring, a far less objectionable artifact. Sampling this function no longer causes the replicated copies to overlap. Convolution with an ideal low-pass filter now properly isolates the bandlimited spectrum.

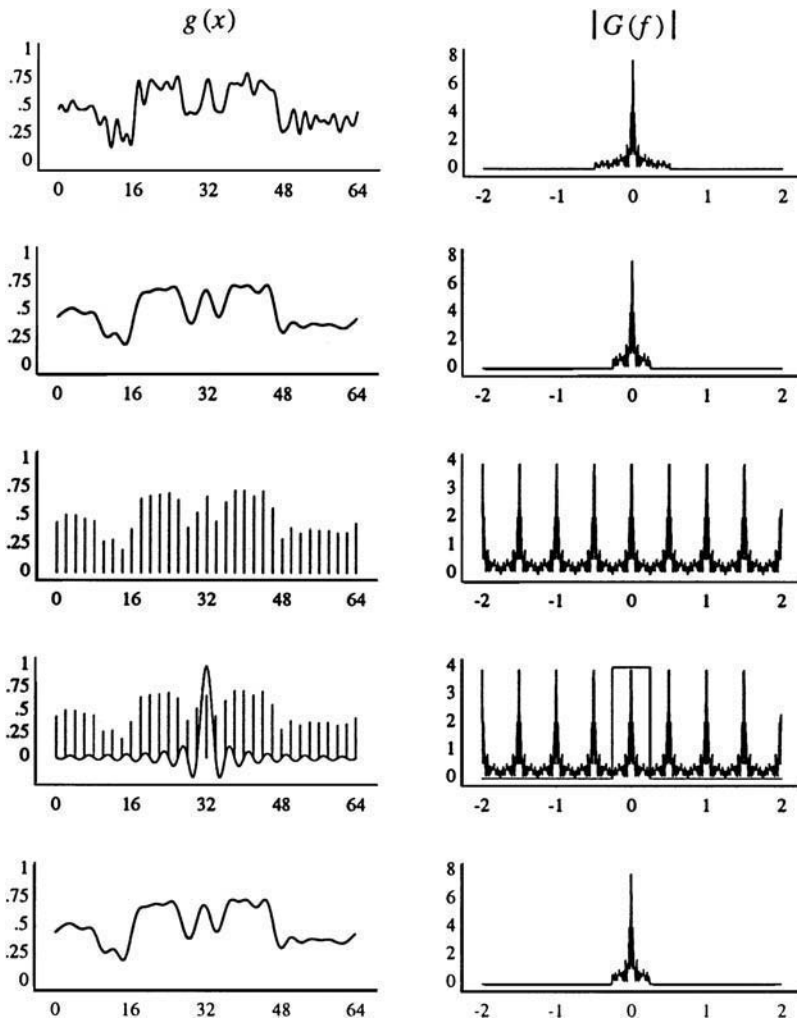

FIGURE 39.27 Antialiasing filtering, sampling, and reconstruction stages.

Defining Terms

Adaptive supersampling: Supersampling with samples distributed more densely in areas of high intensity variance.

Aliasing: Artifacts due to undersampling a signal. This condition prevents the signal from being reconstructed from its samples.

Antialiasing: The filtering necessary to combat aliasing. This generally requires bandlimiting the input before sampling to remove the offending high frequencies that will fold over in the frequency spectrum.

Area sampling: An antialiasing method that treats a pixel as an area, not a point. After projecting the pixel to the input, all samples in the preimage are averaged to compute a representative sample.

Bandlimiting: The act of truncating all frequency components beyond some specified frequency. Useful for antialiasing, where offending high frequencies must be removed to prevent aliasing.

Frequency leakage: A condition in which the stopband is allowed to persist, permitting it to fold over into the passband range.

Gibbs phenomenon: Overshoots and undershoots caused by reconstructing a signal with truncated frequency components.

Nyquist rate: The minimum sampling frequency. It is twice the maximum signal frequency.

Passband: Consists of all frequencies that must be retained by the applied filter.

Point sampling: Each output pixel is a single sample of the input image. This approach generally leads to aliasing because a pixel is treated as a point, not an area.

Prefilter: The low-pass filter (blurring) applied to achieve antialiasing by bandlimiting the input image prior to resampling it onto the output grid.

Preimage: The projected area of an output pixel as it is mapped to the input image.

Pyramid: A multiresolution data structure generated by successively bandlimiting and subsampling the original image to form a hierarchy of images at ever decreasing resolutions. Useful for accelerating antialiasing. Filtering limited to square regions and unweighted averaging.

Reconstruction: The act of recovering a continuous signal from its samples. Interpolation.

Stopband: Consists of all frequencies that must be suppressed by the applied filter.

Summed-area table: Preintegrated buffer of intensities generated by computing a running total of the input intensities as the image is scanned along successive scanlines. Useful for accelerating antialiasing. Filtering limited to rectangular regions and unweighted averaging.

Supersampling: An antialiasing method that collects more than one regularly spaced sample per pixel.

40.1 Introduction

The main goal of computer animation is to synthesize the desired motion effect, a mix of natural phenomena, perception, and imagination. The animator designs the object's dynamic behavior with a mental representation of causality. The animator imagines how it moves, becomes misshapen, or reacts when pushed, pressed, pulled, or twisted. So, the animation system must provide the user with motion control tools able to translate his or her wishes from his or her own language.

Computer animation methods may also aid understanding of physical laws by adding motion control to data in order to show evolution over time. Visualization has become an important way to validate new models created by scientists. When the model evolves over time, computer simulation is generally used to obtain the evolution of time, and computer animation is a natural way to visualize the results obtained from the simulation. Computer animation may be defined as a technique in which the illusion of movement is created by displaying on a screen, or recording on a recording device, a series of individual states of a dynamic scene. Formally, any computer animation sequence may be defined as a set of objects characterized by state variables evolving over time. For example, a human character is normally characterized using its joint angles as state variables.

To produce a computer animation sequence, the animator has two principal techniques available. The first is to use a model that creates the desired effect. A good example is the growth of a green plant. The second is used when no model is available. In this case, the animator produces by hand the real-world motion to be simulated. Initially, most computer-generated films were produced using the second approach: motion capture, traditional computer animation techniques like keyframe animation, spline interpolation, etc. Then, animation languages, scripted systems, and director-oriented systems were developed. More recently,

motion has been planned at a task level and computed using physical laws. Nowadays, researchers develop models of behavioral animation and simulation of autonomous creatures using artificial intelligence (AI) and agent technology.

40.1.1 Classification of Methods

We will start with the classification introduced by Magnenat Thalmann and Thalmann [1991], based on the method of controlling motion and according to characters' interactions. A *motion control method* specifies how a character is animated and may be characterized according to the type of information to which it is privileged in animating the character. For example, in a keyframe system for an articulated body, the privileged information to be manipulated is joint angles. In a forward dynamics-based system, the privileged information is a set of forces and torques; of course, in solving dynamic equations, joint angles are also obtained in this system, but we consider these to be derived information. In fact, any motion control method must eventually deal with geometric information (typically joint angles), but only geometric motion control methods are explicitly privileged to this information at the level of animation control.

The nature of privileged information for the motion control of characters falls into three categories: geometric, physical, and behavioral. These categories give rise to three corresponding categories of motion control method:

The first approach corresponds to methods on which the animator relies heavily: motion capture, shape transformation, parametric keyframe animation. *Animated objects are locally controlled*. Methods are normally driven by geometric data. Typically, the animator provides a lot of geometric data corresponding to a local definition of the motion.

The second approach guarantees realistic motion by using physical laws, especially dynamic simulation. The problem with this type of animation is controlling the motion produced by simulating the physical laws that govern motion in the real world. The animator should provide physical data corresponding to the complete definition of a motion. The motion is obtained by the dynamic equations of motion relating the forces, torques, constraints, and the mass distribution of objects. As trajectories and velocities are obtained by solving the equations, we may consider *the animated objects as globally controlled*. Functional methods based on biomechanics are also part of this class.

The third type of animation is called **behavioral animation** and takes into account the relationships between each object and the other objects. Moreover, the control of animation may be performed at a task level, but we may also consider *the animated objects as autonomous creatures*.

40.2 Underlying Principles and Best Practices

40.2.1 Geometric and Kinematic Methods

40.2.1.1 Introduction

In this group of methods, the privileged information is of a geometric or kinematic nature. Typically, motion is defined in terms of coordinates, angles, and other shape characteristics, or it may be specified using velocities and accelerations, but no force is involved. Among the techniques based on geometry and kinematics, we will discuss motion capture, motion retargeting, keyframing, inverse kinematics (IK), and procedural animation. Although these methods have been mainly concerned with determining the displacement of objects, they may also be applied in calculating deformations of objects.

40.2.1.2 Motion Capture

Motion capture consists of measuring and recording direct actions of a real person or animal for immediate or delayed analysis and playback. The technique is especially used today in production environments for 3-D character animation, like movies and games. It involves mapping measurements onto the motion of the digital character.

FIGURE 40.1 Motion capture.

We may distinguish two main kinds of systems: optical and magnetic.

Optical motion capture systems — These are based on small reflective sensors, called *markers*, attached to an actor's body and on several infrared cameras focused on performance space. By tracking the positions of the markers, one can get locations for corresponding key points in the animated model. For example, we attach markers at a person's joints and record the position of markers from several different directions. We then reconstruct the 3-D position of each key point at each time. The main advantage of this method is freedom of movement; it does not require any cabling. There is, however, one main problem: occlusion, that is, a lack of data resulting from hidden markers. An example is when the performer lies on his or her back. Another problem comes from the lack of an automatic way to distinguish reflectors when they get very close to each other during motion. These problems may be minimized by adding more cameras — but at a higher cost, of course. Most optical systems operate with four or six cameras, but for high-end applications like movies, 16 cameras are usual. A good example of an optical system is the Vicon system. Researchers in computer vision try to develop similar systems based on simple video cameras.

Magnetic motion capture systems — These require the real actor to wear a set of sensors (see Figure 40.1), which are capable of measuring their spatial relationship to a centrally located magnetic transmitter. The position and orientation of each sensor is then used to drive an animated character. One problem is the need to synchronize receivers. The data stream from the receivers to a host computer consists of 3-D positions and orientations for each receiver. For human body motion, eleven sensors are generally needed: one on the head, one on each upper arm, one on each hand, one in the center of chest, one on the lower back, one on each ankle, and one on each foot. To calculate the rest of the necessary information, the most common method is inverse kinematics.

Motion capture methods offer advantages and disadvantages. Let us consider the case of human walking. A walking motion may be recorded and then applied to a computer-generated 3-D character. It will provide a very good motion, because it comes directly from reality. However, motion capture does not bring any new concept to animation methodology. For any new motion, it is necessary to record the reality again. Moreover, motion capture is not appropriate in real-time simulation activities, where the situations and actions of people cannot be predicted, and in dangerous situations, where one cannot involve a human actor.

40.2.1.3 Motion Retargeting

There is a great interest in recording motion using motion capture systems (magnetic or optical), and then attempting to alter such a motion to create a sense of individuality. This process is tedious, and there is

no reliable method at this stage. Even if it is fairly easy to correct one posture by modifying its angular parameters (with an inverse kinematics engine, for instance), it becomes a difficult task to perform this over the whole motion sequence while ensuring that some spatial constraints are respected over a certain time range and that no discontinuities arise. When one tries to adapt a captured motion to a different character, the constraints are usually violated, leading to problems such as feet going into the ground or a hand being unable to reach an object that the character should grab. The problem of adaptation and adjustment is usually referred to as the motion retargeting problem.

Witkin and Popovic [1995] proposed a technique for editing motions by modifying the motion curves through warping functions, producing some of the first interesting results. In a more recent paper [Popovic and Witkin, 1999], they have extended their method to handle physical elements, such as mass and gravity, and described how to use characters with different numbers of degrees of freedom. Their algorithm is based on the reduction of the character to an abstract character, which is much simpler and only contains the degrees of freedom that are useful for a particular animation. The edition and modification are then computed on this simplified character and mapped again onto the end-user skeleton.

Bruderlin and Williams [1995] have described some basic facilities to change the animation, by modifying the motion parameter curves. The user can define a particular posture at time t , and the system is then responsible for smoothly blending the motion around t . These researchers also introduced the notion of the motion displacement map, which is an offset added to each motion curve.

The term *motion retargeting problem* was introduced by Gleicher [1998]. He designed a space–time constraints solver, into which every constraint is added, leading to a big optimization problem. He mainly focused on optimizing his solver, to avoid enormous computation time, and achieved very good results. Bindiganavale and Badler [1998] also addressed the motion retargeting problem, introducing new elements: using the zero-crossing of the second derivative to detect significant changes in the motion, using visual attention tracking (and the way to handle the gaze direction), and applying inverse kinematics to enforce constraints by defining six subchains (the two arms and legs, the spine, and the neck). Finally, Lee and Shin [1999] used in their system a coarse-to-fine hierarchy of B-splines to interpolate the solutions computed by their inverse kinematics solver. They also reduced the complexity of the IK problem by analytically handling the degrees of freedom for the four human limbs.

40.2.1.4 Keyframe

This is an old technique consisting of the automatic generation of intermediate frames, called *inbetweens*, based on a set of keyframes supplied by the animator. Originally, the inbetweens were obtained by interpolating the keyframe images themselves. As linear interpolation produces undesirable effects — such as lack of smoothness in motion, discontinuities in the speed of motion, and distortions in rotations — spline interpolation methods are used. *Splines* can be described mathematically as piecewise approximations of cubic polynomial functions. Two kinds of splines are very popular: interpolating splines, with C1 continuity at knots, and approximating splines, with C2 continuity at knots. For animation, the most interesting splines are the interpolating splines: cardinal splines, Catmull-Rom splines, and Kochanek-Bartels [1984] splines (see [Section 40.7](#)).

A way to produce better images is to interpolate parameters of the model of the object itself. This technique is called **parametric keyframe animation** and is used in most commercial animation systems. In a parametric model, the animator creates keyframes by specifying the appropriate set of parameter values. Parameters are then interpolated and images are finally constructed individually from the interpolated parameters. Spline interpolation is generally used for the interpolation.

40.2.1.5 Inverse Kinematics

This direct kinematics problem consists of finding the position of end-point positions (e.g., hand, foot) with respect to a fixed-reference coordinate system as a function of time without regard to the forces or the moments that cause the motion. Efficient and numerically well behaved methods exist for the transformation of position and velocity from joint-space (joint angles) to Cartesian coordinates (end of the limb). Parametric keyframe animation is a primitive application of direct kinematics.

Basically, the problem is to determine a joints configuration for which a desired task, usually expressed in Cartesian space, is achieved. For example, the shoulder, elbow, and wrist configurations must be determined so that the hand precisely reaches a position in space. The equations that arise from this problem are generally nonlinear and difficult to solve. In addition, a resolution technique must also deal with the difficulties described below. For the positioning and animation of articulated figures, the weighting strategy is the most frequent: some typical examples are given by Badler et al. [1987] and Zhao et al. [1994] for posture manipulation, and by Phillips et al. [1990, 1991] for achieving smooth solution blending.

40.2.1.6 Procedural Animation

Procedural animation corresponds to the creation of a motion by a procedure specifically describing the motion. Procedural animation should be used when the motion can be described by an algorithm or a formula. For example, consider the case of a clock based on the pendulum law:

$$\alpha = A \sin(\omega t + \phi)$$

A typical animation sequence may be produced using a program such as the following:

```
create CLOCK (...);  
for FRAME:=1 to NB_FRAMES  
    TIME:=TIME+1/25;  
    ANGLE:=A*SIN (OMEGA*TIME+PHI);  
    MODIFY (CLOCK, ANGLE);  
    draw CLOCK;  
    record CLOCK  
    erase CLOCK
```

40.2.2 Character Deformations

Modeling and deformation of 3-D characters, and especially human bodies, during the animation process is an important but difficult problem. Researchers have devoted significant efforts to the representation and deformation of the human body's shape. Broadly, we can classify their models into two categories: the surface model and the multilayered model.

The *surface model* [Magenat Thalmann and Thalmann, 1987] is conceptually simple, containing a skeleton and an outer skin layer. The envelope is composed of planar or curved patches. One problem with this model is that it requires the tedious input of the significant points or vertices that define the surface. Another problem is that it is hard to control the realistic evolution of the surface across joints. Surface singularities or anomalies can easily be produced.

The *multilayered model* [Chadwick et al., 1989] contains a skeleton layer, intermediate layers which simulate the physical behavior of muscle, bone, fat tissue, etc., and a skin layer. Since the overall appearance of a human body is very much influenced by its internal muscle structures, the multilayered model is the most promising for realistic human animation. The key advantage of the layered methodology is that once the layered character is constructed, only the underlying skeleton need be scripted for an animation; consistent yet expressive shape deformations are generated automatically. Henne [1990] represents the skin by a mesh of bicubic surface patches, whose control points deform at joints in accordance with several constraints such as elasticity, area preservation, and implicit repulsive force fields that mimic bones and muscles. Deformations that occur away from joints are ignored by this approach. Yoshimoto [1992] showed that implicit formulations like **metaballs** provide efficient ways of creating beautiful virtual humans at a reduced storage cost. Thalmann et al. [1996] extended this approach by combining implicit surfaces and B-spline patches. Ellipsoids and ellipsoidal metaballs represent the gross shape of bone, muscle, and fat tissue. The motion/deformation of each primitive with respect to underlying joints is specified via a graphical interface. A skin of fixed topology is extracted by casting rays from the

skeleton segments in a star-shaped manner and using the intersection points as control points of B-spline patches.

More recent work aims at mimicking more closely the actual anatomy of humans or animals. Wilhelms [1997] developed an interactive tool for designing and animating monkeys and cats. In her system, ellipsoids or triangular meshes represent bones and muscle. Each muscle is a generalized cylinder made up of a certain number of cross-sections that consist, in turn, of a certain number of points. The muscles show a relative incompressibility when deformed. In their work on anatomically modeling the human musculature, Scheepers et al. [1997] stressed the role of underlying components (muscles, tendons, etc.) on the form. They use three volume-preserving geometric primitives for three different types of muscles:

Ellipsoids are used for rendering fusiform muscles.

Multibelly muscles are represented by a set of ellipsoids positioned along two spline curves.

Tubular-shaped bicubic patches provide a general muscle model.

Isometric contraction is handled by introducing scaling factors and tension parameters. The skin is obtained by fitting bicubic patches to an implicit surface created from the geometric primitives.

Porcher-Nedel and Thalmann [1998] introduced the idea of abstracting muscles by an action line (a polyline in practice), representing the force produced by the muscle on the bones, and a surface mesh deformed by an equivalent mass-spring mesh. In order to smooth out mesh discontinuities, they employ special springs, termed *angular springs*, which tend to restore the initial curvature of the surface at each vertex. However, angular springs cannot deal with local inversions of the curvature. Aubel and Thalmann [2001] also use an action line and a muscle mesh. The action line, represented by a polyline with any number of vertices, is moved for each posture using a predefined behavior and a simple, physically based simulation. It is then used as a skeleton for the surface mesh, and the deformations are produced in a usual way. Seo et al. [2000] propose a very fast method of deformation for MPEG-4-based applications.

40.3 Physics-based Methods

40.3.1 Balance Control

Balance control is an essential problem for the realistic computer animation of articulated figures, and of humans in particular. While most people take for granted the action of keeping balance, it is a challenge for neurophysiologists to understand the mechanisms of balance in human and animal beings [Roberts, 1995]. Here, we focus on techniques for balance control in static equilibrium developed in the computer graphics community and well suited to the postural control problem. It requires only the additional information of the body mass distribution. Clearly, more advanced methods are required in dynamic situations.

The center of mass is an important characteristic point of a figure. In the computer graphics community, Phillips and Badler [1991] offered the first control of the center of mass by constraining the angular values of the ankle, knee, and hip joints of the leg that supports most of the weight. A more general approach to the control of the center of mass, called inverse kinetics, has been proposed by Boulic et al. [1994, 1996]. The constraint on the position of the center of mass is solved at the differential level with a special-purpose Jacobian matrix that relates differential changes of the joint coordinates to differential changes of the Cartesian coordinates of the center of mass. Recently, Baerlocher and Boulic [2001] extended the control of mass properties to the moments of inertia of the articulated structure.

40.3.2 Dynamic Simulation

A great deal of work exists on the dynamics of articulated bodies [Huston, 1990], and efficient direct dynamics algorithms have been developed in robotics for structures with many degrees of freedom [Featherstone, 1986; SDFAST, 1990]. In computer animation, these algorithms have been applied to the dynamic simulation of the human body [MacKenna and Zeltzer, 1996]. Given a set of external forces (like gravity or wind) and internal forces (due to muscles) or joint torques, these algorithms compute the motion of the

articulated body according to the laws of rigid body dynamics. Impressive animations of passive structures like falling bodies on stairs can be generated in this way with little input from the animator. On the other hand, such an approach can turn adjustments into a tedious task, because the animator has only indirect control over the animation. More generally, it is impractical for an animator to specify a temporally coordinate sequence of force/torque activation to generate a desired active behavior [Multon et al., 1999]. This is the *inverse dynamics problem*, which has been addressed for walking in [Ko and Badler, 1996]. Impressive results have also been achieved by Hodgins et al. [1995] in the simulation of dynamic human activities such as running and jumping. Some controller architectures have been proposed by Lazlo et al. [1996] to generate a wide range of gaits and to combine elementary behaviors [Faloutsos et al., 2001]. The use of constraints to avoid the direct specification of torques has also been researched. For example, in the computer graphics community, the satisfaction of space–time constraints has been proposed by Witkin and Kass [1988] with the minimization of an objective function, such as the total energy expenditure.

40.3.2.1 Collision Detection and Response

In computer animation, collision detection and response are obviously more important. Some works have addressed collision detection and response. Hahn [1988] presented bodies in resting contact as a series of frequently occurring collisions. Baraff [1989] presented an analytical method for finding forces between contacting polyhedral bodies, based on linear programming techniques. He also proposed a formulation of the contact forces between curved surfaces that are completely unconstrained in their tangential movement. Bandi and Thalmann [1995] introduced an adaptive spatial subdivision of the object space based on octree structure and presented a technique for efficiently updating this structure periodically during the simulation. Volino and Magnenat Thalmann [1994] described a new algorithm for detecting self-collisions on highly discretized moving polygonal surfaces. This technique is based on geometrical shape regularity properties that permit avoiding many useless collision tests. Vassilev and Spanlang [2001] proposed to use the Z-buffer for collision detection to generate depth and normal maps. Computation time of their collision detection does not depend on the complexity of the body. However, the maps must be precomputed before simulation, restricting real-time application.

40.3.2.2 Cloth Animation

Weil [1986] pioneered cloth animation using an approximated model based on relaxation of the surface. Kunii and Godota [1990] used a hybrid model incorporating physical and geometrical techniques to model garment wrinkles. Aono [1990] simulated wrinkle propagation on a handkerchief using an elastic model. Terzopoulos et al. [1987] applied their general elastic to a wide range of objects, including cloth. Lafleur et al. [1991] and Carignan et al. [1992] have described complex interaction of clothes with synthetic actors in motion, which marked the beginning of a new era in cloth animation. However, there were still a number of restrictions on the simulation conditions of the geometrical structure and the mechanical situations, imposed by the simulation model or the collision detection. For this reason, Volino et al. [1995] proposed a mechanical model to deal with any irregular triangular meshes, handle high deformations despite rough discretization, and cope with complex interacting collisions. [Figure 40.2](#) shows examples of cloth animation.

Recently, research has focused on the real-time aspect of the animation of deformable objects using physical simulation. Baraff and Witkin [1998] have used the implicit Euler integration method to compute cloth simulation in real time. They stated that the bottleneck of real-time cloth simulation is the fact that the time step must be small in order to avoid instability. They described a method that can stably take large time steps, suggesting the possibility of real-time animation of simple objects. Meyer et al. [2000] and Desbrun et al. [1999] have used a hybrid explicit/implicit integration algorithm to animate real-time clothes; integrated with this is a voxel-based collision detection algorithm. Their method seems to be limited by the maximum number of polygons they can animate in real time. James and Pai [1999] also have worked on real-time simulation; their paper describes the boundary integral equation formulation of static linear elasticity and the related boundary element method discretization technique. Their model is not dynamic but a collection of static postures, which limits its potential applications. DeBunne et al. [2000]

FIGURE 40.2 Cloth animation.

have recently introduced a technique for animating soft bodies in real time. However, their method works on volumetric meshes. Therefore, it is not applicable to thin objects such as cloth.

Recently, for cloth animation on moving characters, Cordier et al. [2002] have proposed a real-time approach based on a classification into several categories, depending on how the garment is laid on and whether it sticks to, or flows on, the body surface. For instance, a tight pair of trousers will mainly follow the movement of the legs, whereas a skirt will float around the legs. Based on this approach, the MIRACloth system can be used for building and animating the garments on virtual actors. MIRACloth is a general animation framework in which different types of animation can be associated with the different objects: static, rigid, and deformable (keyframe, mechanical simulation). The methodology for building garments relies on the traditional garment design in real life. The 2-D patterns are created through a polygon editor, which are then taken to the 3-D simulator and placed around the body of a virtual actor. The process of seaming brings the patterns together, and the garment can then be animated with a moving virtual actor.

40.4 Behavioral Methods

40.4.1 Artificial and Virtual Life

This kind of research is strongly related to the research efforts in behavioral animation introduced by Reynolds's study [1987] in his distributed behavioral model simulating flocks of birds, herds of land animals, and schools of fish. For birds, the simulated flock is an elaboration of a particle system, with the simulated birds being the particles. A flock is assumed to be the result of the interactions between the behaviors of individual birds. Working independently, the birds try both to stick together and avoid collisions with one another and with other objects in their environment.

In a module of behavioral animation, the positions, velocities, and orientations of the actors are known from the system at any time. The animator may control several global parameters: for example, weight of the obstacle avoidance component, weight of the convergence to the goal, weight of the centering of the group, maximum velocity, maximum acceleration, minimum distance between actors. The animator provides data about the leader trajectory and the behavior of other birds relative to the leader. Wilhelms [1990] proposes a system based on a network of sensors and effectors. Ridsdale [1990] proposes a method that

guides lower-level motor skills from a connectionist model of skill memory, implemented as collections of trained neural networks. Another approach to behavioral animation is based on timed and parameterized **L-systems** [Noser et al., 1992] with conditional and pseudostochastic productions. With this production-based approach, a user may create any realistic or abstract shape, play with fascinating tree structures, and generate any concept of growth and life development in the resulting animation.

40.4.2 Virtual Sensors

40.4.2.1 Perception through Virtual Sensors

In a typical behavioral animation scene, the actor perceives the objects and the other actors in the environment, providing information on their nature and position. This information is used by the behavioral model to decide the action to take, resulting in a motion procedure. In order to implement perception, virtual humans should be equipped with visual, tactile, and auditory sensors. These **virtual sensors** should be used as a basis for implementing everyday human behavior, such as visually directed locomotion, handling objects, and responding to sounds and utterances. For synthetic audition [Noser and Thalmann, 1995], one must model a sound environment where the synthetic actor can directly access positional and semantic sound source information of audible sound events. Simulating the haptic system corresponds roughly to a collision detection process.

But the most important perceptual subsystem is the vision system. The concept was first introduced by Renault et al. [1990] as a main information channel between the environment and the virtual actor. Reynolds [1993] more recently described an evolved, vision-based behavioral model of coordinated group motion. Tu and Terzopoulos [1994] also proposed artificial fish with perception and vision. In the Renault method, each pixel of vision input has the semantic information that gives the object projected on this pixel, and numerical information that gives the distance to this object. So it is easy to know, for example, that there is a table straight ahead at 3 meters. The synthetic actor perceives the environment from a small window in which the environment is rendered from the actor's point of view. Noser et al. [1995] proposed the use of an octree as the internal representation of the environment seen by an actor, because it can represent the visual memory of an actor in a 3-D environment with static and dynamic objects.

40.5 Crowds and Groups

Animating crowds [Musse and Thalmann, 2001] is challenging both in character animation and in virtual city modeling. Although different textures and colors may be used, the similarity of the virtual people would be soon detected even by nonexperts: for example, "Everybody walks the same in this virtual city!" Hence, it is useful to have a fast and intuitive way to generate motions with different personalities (depending on gender, age, emotions, etc.) from a sample motion, such as a genuine walking motion. The basic problem is to be able to generate variety among a finite set of motion requests and then to apply it either to an individual or to a member of a crowd. Very good tools are also required to tune the motion [Emering et al., 1998].

Bouvier et al. [1996, 1997] used a combination of particle systems and transition networks to model human crowds in visualizations of urban spaces. Lower-level behavior enabled people to avoid obstacles using attraction and repulsion forces analogous to physical electric forces. Higher-level behavior is modeled by transition networks, with transitions depending on timing, visiting of certain points, changes of local densities, and global events. Brogan and Hodgins [1994] simulated group behavior for systems with significant dynamics. They presented an algorithm for controlling the movements of creatures traveling as a group. The algorithm has a two steps: first, a perception model determines the creatures and obstacles visible to each individual, and then a placement algorithm determines the desired position for each individual, given the locations and velocities of perceived creatures and obstacles. Simulated systems included groups of legged robots, bicycle riders, and point-mass systems.

FIGURE 40.3 Crowd simulation.

Musse and Thalmann's [2001] proposed solution addresses two main issues: crowd structure and crowd behavior. Considering crowd structure, our approach deals with a hierarchy composed of crowd, groups, and agents, in which the groups are the most complex structure, containing the information to be distributed among the individuals. Concerning crowd behavior, the virtual agents are endowed with different levels of autonomy. They can either act according to an innate and scripted crowd behavior (programmed behavior), react as a function of triggered events (reactive or autonomous behavior), or be guided by an interactive process during simulation (guided behavior) [Musse et al., 1998]. Figure 40.3 shows a crowd guided by a leader.

Intelligence, memory, intention, and perception are focalized in the group structure. Also, each group can obtain one leader. This leader can be chosen randomly by the crowd system, be defined by the user, or emerge from the sociological rules.

For emergent crowds, Ulicny and Thalmann [2001] proposed a behavior model based on combinations of rules [Rosenblum et al., 1998] and finite state machines [Cremer et al., 1995] for controlling agents' behavior using a layered approach. The first layer deals with the selection of higher-level complex behavior appropriate to the agent's situation; the second layer implements these behaviors using low-level actions provided by the virtual human [Boulic et al., 1997]. At the higher level, rules select complex behaviors (such as *flee*) according to the agent's state (constituted by attributes) and the state of the virtual environment (conveyed by events). In rules, it is specified for whom (e.g., a particular agent or agents in particular group) and when (e.g., at a defined time, after receiving an event, or when some attribute reaches a specified value) the rule is applicable, and what is the consequence of rule firing (e.g., change of agent's high-level behavior or attribute). At the lower level, complex behaviors are implemented by hierarchical, finite state machines.

40.6 Facial Animation

The goal of facial animation systems has always been to obtain a high degree of realism using optimum-resolution facial mesh models and effective deformation techniques. Various muscle-based facial models with appropriate parameterized animation systems have been developed for facial animation [Parke, 1982;

FIGURE 40.4 Facial expressions.

Waters, 1987; Terzopoulos et al., 1990]. The facial action coding system [Friesen, 1978] defines high-level parameters for facial animation; several other systems are based on this one. Most facial animation systems typically use the following steps:

Define an animation structure on a facial model by parameterization.

Define building blocks or basic units of the animation in terms of these parameters, such as static expressions and visemes (visual counterparts of phonemes).

Use these building blocks as keyframes and define various interpolation and blending functions on the parameters to generate words and sentences from visemes and emotions from expressions (see Figure 40.4). The interpolation and blending functions contribute to the realism of a desired animation effect.

Generate the mesh animation from the interpolated or blended keyframes. Given the tools of parameterized face modeling and deformation, the most challenging task in facial animation is the design of realistic facial expressions and visemes.

The complexity of the keyframe-based facial animation system increases when we incorporate natural effects, such as coarticulation for speech animation and blending among a variety of facial expressions during speech. The use of speech synthesis systems and the subsequent application of coarticulation to the available temporized phoneme information is a widely accepted approach [Grandstrom, 1999; Hill et al., 1988].

Coarticulation is a phenomenon observed during fluent speech, in which facial movements corresponding to one phonetic or visemic segment are influenced by those corresponding to the neighboring segments. Two main approaches taken for coarticulation are those of Pelachaud [1991] and Cohen and Massaro [1993]. Both these approaches are based on the classification of phoneme groups and their observed interaction during speech pronunciation. Pelachaud arranged the phoneme groups according to the deformability and context dependence in order to decide the influence of the visemes on each other. Muscle contraction and relaxation times were also considered, and the facial action units were controlled accordingly.

For facial animation, the MPEG-4 standard is particularly important [MPEG-4]. The facial definition parameter (FDP) set and the facial animation parameter (FAP) set are designed to encode facial shape and animation of faces, thus reproducing expressions, emotions, and speech pronunciation. The FDPs are defined by the locations of the feature points and are used to customize a given face model to a particular face. They contain 3-D feature points, such as mouth corners and contours, eye corners, eyebrow centers, etc. FAPs are based on the study of minimal facial actions and are closely related to muscle actions. Each FAP value is simply the displacement of a particular feature point from its neutral position, expressed in terms of facial animation parameter units (FAPUs). The FAPUs correspond to fractions of distances between key facial features (e.g., the distance between the eyes). For example, the facial animation engine developed at MIRALab uses the MPEG-4 facial animation standard [Kshishagar et al., 1999] for animating 3-D facial models in real time. This parameterized model is capable of displaying a variety of facial expressions, including speech pronunciation, with the help of 66 low-level FAPs.

Recently, efforts in the field of phoneme extraction have resulted in software systems capable of extracting phonemes from both synthetic and natural speech and generating lip-synchronized speech animation from these phonemes. This creates a complete talking head system. It is possible to mix emotions with speech in a natural way, thus imparting to the virtual character an emotional behavior. Ongoing efforts concentrate on imparting emotional autonomy to the virtual face, enabling a dialogue between real and virtual humans with natural emotional responses. Kshirsagar and Magnenat Thalmann [2001] use a statistical analysis of the facial feature point movements. As the data is captured for fluent speech, the analysis reflects the dynamics of facial movements related to speech production. The results of the analysis were successfully applied for a more realistic speech animation. This has enabled us to blend various facial expressions and speech easily. Use of MPEG-4 feature points for data capture and facial animation enabled us to restrict the quantity of data being processed, at the same time offering more flexibility with respect to the facial model. We would like to improve the effectiveness of expressive speech further by the use of various time envelopes for expressions that may be linked to the meaning of the sentence. Kshirsagar and Magnenat Thalmann [2002] have also developed a system incorporating a personality model, for an emotionally autonomous virtual human.

40.7 Algorithms

40.7.1 Kochanek–Bartels Spline Interpolation

The method consists of interpolating splines with three parameters for local control: tension, continuity, and bias. Consider a list of points \mathbf{P}_i and the parameter t along the spline to be determined. A point \mathbf{V} is obtained from each value of t from only the two nearest given points along the curve (one behind \mathbf{P}_i , one in front of \mathbf{P}_{i+1}). But the tangent vectors \mathbf{D}_i and \mathbf{D}_{i+1} at these two points are also necessary. This means that we have

$$\mathbf{V} = \mathbf{THC}^T \tag{40.1}$$

where T is the matrix $[t^3, t^2, t, 1]$, H is the Hermite matrix, and C is the matrix $[\mathbf{P}_i, \mathbf{P}_{i+1}, \mathbf{D}_i, \mathbf{D}_{i+1}]$. The Hermite matrix is given by

$$H = \begin{bmatrix} 2 & -2 & 1 & 1 \\ -3 & 3 & -2 & -1 \\ 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 \end{bmatrix} \tag{40.2}$$

This equation shows that the tangent vector is the average of the source chord $\mathbf{P}_i - \mathbf{P}_{i-1}$ and the destination chord $\mathbf{P}_{i+1} - \mathbf{P}_i$. Similarly, the source derivative (tangent vector) \mathbf{DS}_i and the destination derivative (tangent vector) \mathbf{DD}_i may be considered at any point \mathbf{P}_i .

FIGURE 40.5 Variation of tension: the interpolation in b is more tense than the interpolation in a.

FIGURE 40.6 Variation of continuity: the interpolation in b is more discontinuous than the interpolation in a.

FIGURE 40.7 A biased interpolation at K_2 .

Using these derivatives, Kochanek and Bartels [1984] propose the use of three parameters to control the splines: tension, continuity, and bias.

The tension parameter t controls how sharply the curve bends at a point P_i . As shown in Figure 40.5, in certain cases a wider, more exaggerated curve may be desired; in other cases, the desired path may be much tighter.

The continuity c of the spline at a point P_i is controlled by the parameter c . Continuity in the direction and speed of motion is not always desirable. Animating a bouncing ball, for example, requires the introduction of a discontinuity in the motion of the point of impact, as shown in Figure 40.6.

The direction of the path as it passes through a point P_i is controlled by the bias parameter b . This feature allows the animator to have a trajectory anticipate or overshoot a key position by a certain amount, as shown in Figure 40.7.

Equations combining the three parameters may be obtained:

$$DS_i = 0.5[(1 - t)(1 + c)(1 - b)(P_{i+1} - P_i) + (1 - t)(1 - c)(1 + b)(P_i - P_{i-1})] \quad (40.3)$$

$$DD_i = 0.5[(1 - t)(1 - c)(1 - b)(P_{i+1} - P_i) + (1 - t)(1 + c)(1 + b)(P_i - P_{i-1})] \quad (40.4)$$

A spline is then generated using Equation 1, with DD_i and DS_{i+1} instead of D_i and D_{i+1} .

40.7.2 Principle of Behavioral Animation

A simulation is produced in a synchronous way by a behavioral loop such as

```
t_global ← 0.0
code to initialize the animation environment
while (t_global < t_final) {
code to update the scene
  for each actor
code to realize the perception of the environment
code to select actions based on sensorial input, actual state and specific behavior
  for each actor
code executing the above selected actions
  t_global ← t_global + t_interval
}
```

The global time t_{global} serves as synchronization parameter for the different actions and events. Each iteration represents a small time step. The action to be performed by each actor is selected by its behavioral model for each time step. The action selection takes place in three phases. First, the actor perceives the objects and the other actors in the environment, which provides information on their nature and position. This information is used by the behavioral model to decide the action to take, which results in a motion procedure with its parameters (e.g., grasp an object or walk with a new speed in a new direction). Finally, the actor performs the motion.

40.8 Research Issues and Summary

Computer animation should not be considered simply as a tool to enhance spatial perception by moving the virtual camera or rotating objects. More sophisticated animation techniques than keyframe animation must be widely used. Computer animation tends to be based more and more on physics and behavioral models. In the future, the application of computer animation to the scientific world will become common in many scientific areas: fluid dynamics, molecular dynamics, thermodynamics, plasma physics, astrophysics, etc. Real-time complex animation systems will be developed, taking advantage of virtual reality (VR) devices and simulation methods. An integration between simulation methods and VR-based animation will lead to systems allowing the user to interact with complex, time-dependent phenomena, providing interactive visualization and interactive animation. Moreover, real-time synthetic actors will be part of virtual worlds, and people will communicate with them through broadband multimedia networks. Such applications will only become possible through the development of new approaches to real-time motion, based on artificial intelligence and agent technology.

Defining Terms

Behavioral animation: Behavior of objects is driven by providing high-level directives indicating a specific behavior without any other stimulus.

L-systems: Production-based approach to generate any concept of growth and life development in the resulting animation.

Metaballs: Shapes based on implicit surfaces; they are employed to simulate the gross behavior of bone, muscle, and fat tissue.

Parametric keyframe animation: The animator creates keyframes by specifying the appropriate set of parameter values. Parameters are then interpolated and, finally, images are individually constructed from the interpolated parameters.

Performance animation: Consists of measuring and recording direct actions of a real person or animal for immediate or delayed analysis and playback.

- Procedural animation:** Corresponds to the creation of a motion by a procedure specifically describing the motion. Procedural animation may be specified using a programming language or an interactive system.
- Space–time constraints:** Method for creating automatic character motion by specifying *what* the character has to be, *how* the motion should be performed, what the character's *physical structure* is, and what physical *resources* are available to the character to accomplish the motion.
- Virtual sensors:** Used as a basis for implementing everyday human behavior, such as visually directed locomotion, handling objects, and responding to sounds and utterances. Virtual humans should be equipped with visual, tactile, and auditory sensors.

Further Information

Several textbooks on computer animation have been published:

- Capin, T., Pandzic, I., and Magnenat Thalmann, N. 1999. *Avatars in Networked Virtual Environments*, John Wiley & Sons, New York.
- Magnenat Thalmann, N., and Thalmann, D., Eds. 1996. *Interactive Computer Animation*, Prentice Hall, Englewood Cliffs, NJ.
- Parent, R. 2001. *Computer Animation: Algorithms and Techniques*, Morgan Kaufmann, San Francisco.
- Vince, J. 1992. *3-D Computer Animation*, Addison-Wesley, Reading, MA.

There is one journal dedicated to computer animation: *The Journal of Visualization and Computer Animation*. This journal has been published by John Wiley & Sons, in Chichester, UK, since 1990. In January 2004, this journal changed its name to *Computer Animation and Virtual Worlds*.

Although computer animation is always represented in major computer graphics conferences like SIGGRAPH, Computer Graphics International (CGI), Pacific Graphics, and Eurographics, there are only two annual conferences dedicated to computer animation:

Computer Animation, organized each year in Geneva by the Computer Graphics Society. Proceedings are published by the IEEE Computer Society Press.

Symposium on Computer Animation, organized by SIGGRAPH and Eurographics.

41.1 Introduction

Volume visualization is a method of extracting meaningful information from volumetric data using interactive graphics and imaging. It is concerned with volume data representation, modeling, manipulation, and rendering [20] [91] [92] [154]. Volume data are 3-D (possibly time-varying) entities that may have information inside them, might not consist of tangible surfaces and edges, or might be too voluminous to be represented geometrically. They are obtained by sampling, simulation, or modeling techniques. For example, a sequence of 2-D slices obtained from magnetic resonance imaging (MRI), computed tomography (CT), functional MRI (fMRI), or positron emission tomography (PET), is 3-D reconstructed into a volume model and visualized for diagnostic purposes or for planning of treatment or surgery. The same technology is often used with industrial CT for nondestructive inspection of composite materials or mechanical parts. Similarly, confocal microscopes produce data which are visualized to study the morphology of biological structures. In many computational fields, such as computational fluid dynamics, the results of simulations typically running on a supercomputer are often visualized as volume data for analysis

and verification. Recently, the subarea of *volume graphics* [96] has been expanding, and many traditional geometric computer graphics applications, such as CAD and flight simulation, have been exploiting the advantages of volume techniques.

Over the years, many techniques have been developed to render volumetric data. Because methods for displaying geometric primitives were already well established, most of the early methods involved approximating a surface contained within the data using geometric primitives. When volumetric data are visualized using a surface rendering technique, a dimension of information is essentially lost. In response to this, volume rendering techniques were developed that attempt to capture all the 3-D data in a single 2-D image. Volume rendering conveys more information than surface rendering images, but at the cost of increased algorithm complexity and, consequently, increased rendering times. To improve interactivity in volume rendering, many optimization methods, both for software and for graphics accelerator implementations, as well as several special-purpose volume rendering machines, have been developed.

41.2 Volumetric Data

A volumetric data set is typically a set V of samples (x, y, z, v) , also called *voxels*, representing the value v of some property of the data, at a 3-D location (x, y, z) . If the value is simply 0 or an integer i within a set I , with a value of 0 indicating background and the value of i indicating the presence of an object O_i , then the data is referred to as binary data. The data may instead be multivalued, with the value representing some measurable property of the data, including, for example, color, density, heat or pressure. The value v may even be a vector, representing, for example, velocity at each location; results from multiple scanning modalities, such as anatomical (CT, MRI) and functional imaging (PET, fMRI); or color (RGB) triples, such as the Visible Human cryosection data set [82]. Finally, the volume data may be time-varying, in which case V becomes a 4-D set of samples (x, y, z, t, v) .

In general, the samples may be taken at purely random locations in space, but in most cases the set V is isotropic, containing samples taken at regularly spaced intervals along three orthogonal axes. When the spacing between samples along each axis is a constant, but there may be three different spacing constants for the three axes, the set V is anisotropic. Since the set of samples is defined on a regular grid, a 3-D array (also called the *volume buffer*, 3-D *raster*, or simply the *volume*) is typically used to store the values, with the element location indicating position of the sample on the grid. For this reason, the set V will be referred to as the array of values $V(x, y, z)$, which is defined only at grid locations.

Alternatively, either rectilinear, curvilinear (structured), or unstructured grids are employed (e.g., [203]). In a *rectilinear* grid, the cells are axis-aligned, but grid spacings along the axes are arbitrary. When such a grid has been nonlinearly transformed while preserving the grid topology, the grid becomes *curvilinear*. Usually, the rectilinear grid defining the logical organization is called *computational space*, and the curvilinear grid is called *physical space*. Otherwise, the grid is called *unstructured* or *irregular*. An unstructured or irregular volume data set is a collection of cells whose connectivity must be specified explicitly. These cells can be of an arbitrary shape, such as tetrahedra, hexahedra, or prisms.

41.3 Rendering via Geometric Primitives

Several techniques have been developed that approximate a surface contained within the volumetric data by ways of geometric primitives, most commonly triangles, which can then be rendered using conventional graphics accelerator hardware. A surface can be defined by applying a binary segmentation function $B(v)$ to the volumetric data, where $B(v)$ evaluates to 1 if the value v is considered part of the object, and evaluates to 0 if the value v is part of the background. The surface is then contained in the region where $B(v)$ changes from 0 to 1.

Most commonly, $B(v)$ is either a step function

$$B(v) = 1, \forall v \geq v_{iso}$$

FIGURE 41.1 A grid cell with voxel values as indicated, intersected by an iso-surface (iso-value = 125). This is base case # 1 of the Marching Cube algorithm: a single triangle separating surface interior (black vertex) from exterior (white vertices). The positions of the triangle vertices are estimated by linear interpolation along the cell edges.

(where v_{iso} is called the *isovalue*) or an interval $[v_1, v_2]$ in which

$$B(v) = 1, \forall v \in [v_1, v_2]$$

(where $[v_1, v_2]$ is called the *isointerval*).

For the former, the resulting surface is called the *isosurface*; for the latter, the resulting structure is called the *isocontour*. Several methods for extracting and rendering isosurfaces have been developed; a few are briefly described here. The *Marching Cubes* algorithm [127] was developed to approximate an iso-valued surface with a triangle mesh. The algorithm breaks down the ways in which a surface can pass through a grid cell into 256 cases, based on the $B(v)$ membership of the eight voxels that form the cell's vertices. By way of symmetry, the 256 cases reduce to 15 base topologies, although some of these have duals, and a technique called *asymptotic decider* [165] can be applied to select the correct dual case and thus prevent the incidence of holes in the triangle mesh. For each of the 15 cases (and their duals), a generic set of triangles representing the surface is stored in a lookup table. Each cell through which a surface passes maps to one of the base cases, with the actual triangle vertex locations being determined using linear interpolation of the cell vertices on the cell edges (see Figure 41.1). A normal value is estimated for each triangle vertex, and standard graphics hardware can be utilized to project the triangles, resulting in a relatively smooth shaded image of the iso-valued surface.

41.4 Direct Volume Rendering: Prelude

Representing a surface contained within a volumetric data set using geometric primitives can be useful in many applications. However, there are several main drawbacks to this approach. First, geometric primitives can only approximate surfaces contained within the original data. Adequate approximations may require an excessive amount of geometric primitives. Therefore, a trade-off must be made between accuracy and space requirements. Second, because only a surface representation is used, much of the information contained within the data is lost during the rendering process. For example, in CT scanned data, useful information is contained not only on the surfaces, but also within the data. Also, amorphous phenomena, such as clouds, fog, and fire, cannot be represented adequately using surfaces, and therefore must have a volumetric representation and must be displayed using volume rendering techniques.

Before moving to techniques that visualize the data directly without going through an intermediate surface extraction step, we discuss some of the general principles that govern the theory of discretized functions and signals, such as the discrete volume data. We also present some specialized theoretical concepts relevant to the context of volume visualization.

41.5 Volumetric Function Interpolation

The volume grid V only defines the value of some measured property $f(x, y, z)$ at discrete locations in space. If one requires the value of $f(x, y, z)$ at an off-grid location (x, y, z) , a process called interpolation must be employed to estimate the unknown value from the known grid samples $V(x, y, z)$. There are many

FIGURE 41.2 Popular filters in the spatial domain: box, linear, and Gaussian.

FIGURE 41.3 Magnification via interpolation with (a) a box filter; and (b) a bi-linear filter. The latter gives a much more pleasing result.

possible interpolation functions (also called *filters* or *filter kernels*). The simplest interpolation function is known as zero-order interpolation, which is actually just a nearest-neighbor function. That is, the value at any location (x, y, z) is simply that of the grid sample closest to that location:

$$f(x, y, z) = V(\text{round}(x), \text{round}(y), \text{round}(z)) \quad (41.1)$$

This gives rise to a box filter (the black curve in Figure 41.2). With this interpolation method, there is a region of constant value around each sample in V . The human eye is very sensitive to the jagged edges and unpleasant staircasing that result from a zero-order interpolation. Therefore, this kind of interpolation generally gives the poorest visual results. See Figure 41.3a.

Linear or first-order interpolation (the magenta curve in Figure 41.2) is the next-best choice, and its 2-D and 3-D versions are called bilinear and trilinear interpolation, respectively. In 3-D, it can be written as three stages of seven linear interpolations, because the filter function is separable in higher dimensions. The first four linear interpolations are along x :

$$f(u, v_{0,1}, w_{0,1}) = (1 - u)V(0, v_{0,1}, w_{0,1}) + uV(1, v_{0,1}, w_{0,1}) \quad (41.2)$$

Using these results, two linear interpolations along y follow:

$$f(u, v, w_{0,1}) = (1 - v)f(u, 0, w_{0,1}) + vf(u, 1, w_{0,1}) \quad (41.3)$$

One final interpolation along z yields the interpolation result:

$$f(x, y, z) = f(u, v, w) = (1 - w)f(u, v, 0) + wf(u, v, 1) \quad (41.4)$$

Here the u, v, w are the distances (assuming a cell of size 1^3 , without loss of generality) of the sample at (x, y, z) from the lower, left, rear voxel in the cell containing the sample point (e.g., the voxel with value 50

in Figure 41.1). A function interpolated with a linear filter no longer suffers from staircase artifacts; see Figure 41.3b. However, it has discontinuous derivatives at cell boundaries, which can lead to noticeable banding when the visual quantities change rapidly from one cell to the next.

A second-order interpolation filter that yields a $f(x, y, z)$ with a continuous first derivative is the cardinal spline function (see the blue curve in Figure 41.2), whose 1-D function is given by

$$h(u) = \begin{cases} (a+2)|u|^3 - (a+3)|u|^2 + 1 & 0 \leq |u| < 1 \\ a|u|^3 - 5a|u|^2 + 8a|u| - 4a & 1 \leq |u| \leq 2 \\ 0 & |u| > 2 \end{cases} \quad (41.5)$$

Here, u measures the distance of the sample location to the grid points that fall within the extent of the kernel, and $a = -0.5$ yields the Catmull–Rom spline, which interpolates a discrete function with the lowest third-order error [101]. The 3-D version of this filter $h(u, v, w)$ is separable, that is, $h(u, v, w) = h(u)h(v)h(w)$, and therefore interpolation in 3-D can be written as a three-stage nested loop.

A more general form of the cubic function has two parameters. The interpolation results obtained with different settings of these parameters have been investigated by Mitchell and Netravali [146]. In fact, the choice of filters and their parameters always presents trade-offs between the sensitivity to noise, sampling frequency ripple, aliasing (see discussion later in this section), ringing, and blurring, and there is no optimal setting that works for all applications. Marschner and Lobb [136] extended the filter discussion to volume rendering and created a challenging volumetric test function with a uniform frequency spectrum that can be employed to observe visually the characteristics of different filters. Finally, Möller et al. [149] applied a Taylor series expansion to devise a set of optimal n th order filters that minimize the $(n+1)$ th order error.

Generally, higher filter quality comes at the price of wider spatial extent (compare Figure 41.2) and therefore larger computational effort. The best filter possible in the numerical sense is the *sinc* filter, but it has infinite spatial extent and also has noticeable ringing [146]. Sinc filters make excellent, albeit expensive, interpolation filters when used in truncated form and multiplied by a window function [136] [215], possibly adaptive to local detail [131]. In practice, first-order or linear filters give satisfactory results for most applications, providing good cost–quality trade-offs, but cubic filters are also used. Zero-order filters give acceptable results when the discrete function has already been sampled at a very high rate, for example, in high-definition function lookup tables [239].

All filters presented thus far are grid-interpolating filters, that is, their interpolation yields $f(x, y, z) = V(x, y, z)$ at grid points [217]. When presented with a uniform grid signal, they also interpolate a uniform $f(x, y, z)$ everywhere. This is not the case with a Gaussian filter function (the red curve in Figure 41.2), which can be written as

$$h(u, v, w) = b \cdot e^{-a(u^2+v^2+w^2)} \quad (41.6)$$

Here, a determines the width of the filter and b is a scale factor. The Gaussian has infinite continuity in the interpolated function’s derivative, but it introduces a slight ripple (about 0.1%) into an interpolated uniform function. The Gaussian is most popular when a radially symmetric interpolation kernel is needed [237] [162] and for grids that assume that the frequency spectrum of $f(x, y, z)$ is radially band-limited [216] [161].

It should be noted that interpolation cannot restore sharp edges that may have existed in the original function $f_{org}(x, y, z)$ prior to sampling into the grid. Filtering will always smooth or somewhat *lowpass* the original function. Nonlinear filter kernels [83] or transformations of the interpolated results [158] are needed to re-create sharp edges, as we shall see later.

A frequent artifact that can occur is *aliasing*. Aliasing results from inadequate sampling and gives rise to strange patterns that did not exist in the sampled signal. Proper prefiltering (band-limiting) must be performed whenever a signal is sampled below its *Nyquist limit* (i.e., twice the maximum frequency that occurs in the signal). The interested reader may consult standard texts, such as [246] and [47], for more detail.

The gradient of $f(x, y, z)$ is also of great interest in volume visualization, mostly for the purpose of estimating the amount of light reflected from volumetric surfaces toward the eye (e.g., strong gradients

indicate stronger surfaces and therefore stronger reflections). There are three popular methods to estimate a gradient from the volume data [148]. The first computes the gradient vector at each grid point via a process called *central differencing*:

$$\begin{bmatrix} g_x \\ g_y \\ g_z \end{bmatrix} = \begin{bmatrix} V(x-1, y, z) \\ V(x, y-1, z) \\ V(x, y, z-1) \end{bmatrix} - \begin{bmatrix} V(x+1, y, z) \\ V(x, y+1, z) \\ V(x, y, z+1) \end{bmatrix} \quad (41.7)$$

It then interpolates the gradient vectors at (x, y, z) using any of the filters described above. The second method also uses central differencing, but it does this at (x, y, z) by interpolating the required support samples on the fly. The third method is the most direct and employs a gradient filter [8] in each of the three axis directions to estimate the gradients. These three gradient filters could be simply the (u, v, w) partial derivatives of the filters described previously, or they could be a set of optimized filters [148].

The third method gives the best results because it only performs one interpolation step, whereas the other two methods have lower complexity and often have practical application-specific advantages. An important observation is that gradients are much more sensitive to the quality of the interpolation filter because they are used in illumination calculations, which consist of higher-order functions that involve the normal vectors, which in turn are calculated from the gradients via normalization [149].

41.6 Volume Rendering Techniques

The next subsections explore various fundamental volume rendering techniques. Volume rendering is the process of creating a 2-D image directly from 3-D volumetric data; hence it is often called direct volume rendering. Although several of the methods described in these subsections render surfaces contained within volumetric data, these methods operate on the actual data samples, without generating the intermediate geometric primitive representations used by the algorithms in the previous section.

Volume rendering can be achieved using an object-order, an image-order, or a domain-based technique. Hybrid techniques have also been proposed. *Object-order* volume rendering techniques use a forward mapping scheme in which the volume data is mapped onto the image plane. In *image-order* algorithms, a backward mapping scheme is used in which rays are cast from each pixel in the image plane through the volume data to determine the final pixel value. In a *domain-based* technique, the spatial volume data are first transformed into an alternative domain, such as compression, frequency, or wavelet, and then a projection is generated directly from that domain.

41.6.1 Image-Order Techniques

There are four basic volume rendering modes: x-ray rendering, maximum intensity projection (MIP), isosurface rendering, and full volume rendering. The third mode is just a special case of the fourth. These four modes share two common operations:

They all cast rays from the image pixels, sampling the grid at discrete locations along their paths.

They all obtain the samples via interpolation, using the methods described earlier.

The modes differ, however, in how the samples taken along a ray are combined. In x-ray, the interpolated samples are simply summed, giving rise to a typical image obtained in projective diagnostic imaging (Figure 41.4a). In MIP, only the interpolated sample with the largest value is written to the pixel (Figure 41.4b). In full volume rendering (Figure 41.4c and Figure 41.4d), on the other hand, the interpolated samples are further processed to simulate the light transport within a volumetric medium according to one of many possible models. In the remainder of this section, we shall concentrate on the full volume rendering mode because it provides the greatest degree of freedom, although rendering algorithms have been proposed that merge the different modes into a hybrid image generation model [74].

FIGURE 41.4 Ct head rendered in the four main volume rendering modes: (a) x-ray; (b) MIP; (c) Iso-surface; and (d) Translucent.

The fundamental element in full volume rendering is the volume rendering integral. In this section, we shall assume the *low-albedo* scenario, in which a certain light ray only scatters once before leaving the volume. The low-albedo *optical model* was first described by [10] and [89], and then formally derived by [137]. It computes, for each cast ray, the quantity $I_\lambda(\mathbf{x}, \mathbf{r})$, which is the amount of light of wavelength λ coming from ray direction \mathbf{r} that is received at point \mathbf{x} on the image plane:

$$I_\lambda(\mathbf{x}, \mathbf{r}) = \int_0^L C_\lambda(s) \mu(s) \exp\left(-\int_0^s \mu(t) dt\right) ds \quad (41.8)$$

Here, L is the length of ray \mathbf{r} . We can think of the volume as being composed of particles with certain mass density values μ (sometimes called *light extinction values* [137]). These values, as well as the other quantities in this integral, are derived from the interpolated volume densities $f(x, y, z)$ via some mapping function. The particles can contribute light to the ray in three different ways: via emission [189], transmission, and reflection [219]. Thus, $C_\lambda(s) = E_\lambda(s) + T_\lambda(s) + R_\lambda(s)$. The latter two terms, T_λ and R_λ , transform light received from surrounding light sources, whereas the former, E_λ , is due to the light-generating capacity of the particle. The reflection term takes into account the specular and diffuse material properties of the particles. To account for the higher reflectivity of particles with larger mass densities, one must weight $C_{\lambda g}$ by μ . In low-albedo, we track only the light that is received on the image plane. Thus, in Equation 41.8, C_λ is the portion of the light of wavelength λ available at location s that is transported in the direction of \mathbf{r} . This light then gets attenuated by the mass densities of the particles along \mathbf{r} , according to the exponential attenuation function.

$R_\lambda(s)$ is computed via the standard illumination equation [47]:

$$R(s) = k_a C_a + k_d C_i C_o(s) (N(s) \cdot L(s)) + k_s C_i (N(s) \cdot H(s))^{ns} \quad (41.9)$$

where we have dropped the subscript λ for reasons of brevity. Here, C_a is the ambient color, k_a is the ambient material coefficient, C_i is the color of the light source, C_o is the color of the object (determined by the density–color mapping function), k_d is the diffuse material coefficient, N is the normal vector (determined by the gradient), L is the light direction vector, k_s is the specular material coefficient, H is the half-vector, and ns is the Phong exponent.

The analytic volume rendering integral cannot, in the general case, be computed efficiently. However, an approximation of Equation 41.8 can be formulated using a Taylor expansion of the exponential and a discrete Riemann sum, where the rays interpolate a set of samples, most commonly spaced apart by a distance Δs :

$$I_\lambda(x, r) = \sum_{i=0}^{L/\Delta s-1} C_\lambda(i\Delta s)\alpha(i\Delta s) \cdot \prod_{j=0}^{i-1} (1 - \alpha(j\Delta s)) \quad (41.10)$$

Here, α is the material *opacity*, a measure of its optical density. It determines the percentage of light allowed to pass and to be emitted at a given sample point s [182] (α - 1.0-transparency, assuming values in the range $\{0.0, 1.0\}$). Note that Equation 41.10 is a recursive equation in $(1 - \alpha)$. It can be conveniently computed via the recursive *front-to-back compositing* formula [121] [182]:

$$\begin{aligned} c &= C(i\Delta s)\alpha(i\Delta s)(1 - \alpha) + c \\ \alpha &= \alpha(i\Delta s)(1 - \alpha) + \alpha \end{aligned} \quad (41.11)$$

Thus, a practical implementation of volumetric ray casting would traverse the volume from front to back, calculating colors and opacities at each sampling site, weighting these colors and opacities by the current accumulated transparency $(1 - \alpha)$, and adding these terms to the accumulated color and transparency to form the terms for the next sample along the ray. An attractive property of the front-to-back traversal is that a ray can be stopped once α approaches 1.0, which means that light originating from structures farther back is completely blocked by the cumulative opaque material in front. This provides for accelerated rendering and is called *early ray termination*. An alternative form of Equation 41.11 is the *back-to-front compositing* equation:

$$\begin{aligned} c &= c(1 - \alpha(i\Delta s)) + C(i\Delta s) \\ \alpha &= \alpha(1 - \alpha(i\Delta s)) + \alpha(i\Delta s) \end{aligned} \quad (41.12)$$

Back-to-front compositing is a generalization of the Painter's algorithm. It does not enjoy the speed-up opportunities of early ray termination and is therefore less frequently used.

Equation 41.10 assumes that a ray interpolates a volume that stores at each grid point a color vector (usually a [red, green, blue] = RGB triple), as well as an α value [121] [122]. The mapping of voxel densities to colors C_o (in Equation 41.9) and α is implemented as a set of mapping functions, often implemented as 2-D tables, called *transfer functions*. By way of the transfer functions, users can interactively change the properties of the volume data set. Most applications give access to four mapping functions: $R(d)$, $G(d)$, $B(d)$, $A(d)$, where d is the value of a grid voxel, typically in the range of $[0,255]$ for 8-bit volume data. Thus, users can specify semitransparent materials by mapping their densities to opacities <1.0 , which allows rays to acquire a mix of colors that is due to all traversed materials. More advanced applications also give users access to transfer functions that map $k_s(d)$, $k_d(d)$, $ns(d)$, and others. Wittenbrink pointed out that the colors and opacities at each voxel should be multiplied *prior* to interpolation to avoid artifacts on object boundaries [245].

The model in Equation 41.10 is called the *preclassified model*, because voxel densities are mapped to colors and opacities prior to interpolation. This model cannot resolve high-frequency detail in the transfer functions (see Figure 41.5 for an example), and also typically gives blurry images under magnification [158]. An alternative model that is more often used is the *post-classified model*. Here, the raw volume values are interpolated by the rays, and the interpolation result is mapped to color and opacity:

$$I_\lambda(x, r) = \sum_{i=0}^{L/\Delta s-1} C_\lambda(f(i\Delta s), g(i\Delta s))\alpha(f(i\Delta s)) \prod_{j=0}^{i-1} (1 - \alpha(f(j\Delta s))) \quad (41.13)$$

The function value $f(i\Delta s)$ and the gradient vector $g(i\Delta s)$ are interpolated from $f_d(x, y, z)$ using a 3-D interpolation kernel, and C_λ and α are now the transfer and shading functions that translate the

FIGURE 41.5 Transfer function aliasing. When the volume is rendered pre-classified, then both the top row (density d_1) and the bottom row (density d_2) voxels receive a color of zero, according to the transfer function shown on the left. At ray sampling this voxel neighborhood at s would then interpolate a color of zero as well. On the other hand, in post-classified rendering, the ray at s would interpolate a density close to density d_{12} (between d_1 and density d_2) and retrieve the strong color associated with density d_{12} in the transfer function.

FIGURE 41.6 Pre-classified (left column) versus post-classified rendering (right column). The latter yields sharper images since the opacity and color classification is performed after interpolation. This eliminates the blurry edges introduced by the interpolation filter.

interpolated volume function values into color and opacity. This generates considerably sharper images (see Figure 41.6).

Post-classified rendering eliminates only some of the problems that come with busy transfer functions. Consider again Figure 41.5a, now assuming a very narrow peak in the transfer function at d_{12} . With this kind of transfer function, a ray that is point-sampling the volume at s may easily miss interpolating d_{12} . However, the ray may have interpolated d_{12} , had it just sampled the volume at $s + \delta s$. Preintegrated transfer functions [44] [186] solve this problem by precomputing a 2-D table that stores the analytical volume rendering integration for all possible density pairs (d_f, d_b) . This table is then indexed during rendering by each ray sample pair (d_b, d_f) , interpolated at sample locations Δs apart; see Figure 41.5b. The preintegration assumes a piecewise linear function within the density pairs, thus guaranteeing that no transfer function detail falling between two interpolated (d_f, d_b) fails to be considered in the discrete ray integration.

FIGURE 41.7 Object-order volume rendering with kernel splatting implemented as footprint mapping.

Finally, note that a quick transition from 0 to 1 at some density value d_i in the opacity transfer function selects the isosurface $d_{iso} = d_i$. Thus, isosurface rendering is merely a subset of full volume rendering, in which the ray hits a material with $d = d_{iso}$ and then immediately becomes opaque and terminates.

41.6.2 Object-Order Techniques

Object-order techniques decompose the volume into a set of basis elements or *basis functions*, which are individually projected onto the screen and assembled into an image. If the volume rendering mode is x-ray or MIP, then the basis functions can be projected in any order, because in x-ray and MIP the volume rendering integral degenerates to a commutative sum or MAX operation. In contrast, depth ordering is required when solving for the generalized volume rendering integral (Equation 41.8). Early work represented the voxels as disjointed cubes, which gave rise to the *cuperille* representation [61] [76] [77]. Because a cube is equivalent to a nearest neighbor kernel, the rendering results were inferior. Therefore, more recent approaches have turned to kernels of higher quality.

To understand better the issues associated with object-order projection, it helps to view the volume as a field of basis functions h , with one such basis kernel located at each grid point where it is modulated by the grid point's value (see Figure 41.7, where two such kernels are shown). This ensemble of modulated basis functions then makes up the continuous object representation. That is, one could interpolate a sample anywhere in the volume simply by adding up the contributions of the modulated kernels that overlap at the location of the sample value. Hence, one could still traverse this ensemble with rays and render it in image-order. However, a more efficient method emerges when realizing that the contribution of a voxel j with value d_j is given by

$$d_j \cdot \int h(s) ds$$

where s follows the line of kernel integration along the ray. Further, if the basis kernel is radially symmetric, then the integration

$$\int h(s) ds$$

is independent of the viewing direction. Therefore, one can perform a preintegration of

$$\int h(s) ds$$

and store the result into a lookup table. This table is called the kernel *footprint*, and the kernel projection process is referred to as *kernel splatting* or simply *splatting*. If the kernel is a Gaussian, then the footprint is also a Gaussian. Because the kernel is identical for all voxels, we can use it for all voxels. We can generate an image by going through the list of object voxels in depth order and performing the following steps for each (see again Figure 41.7):

1. Calculate the screen-space coordinate of the projected grid point.
2. Center the footprint around that point and stretch it according to the image magnification factor.

FIGURE 41.8 Sheet-buffered splatting: (a) axis-aligned — the entire kernel within the current sheet is added; (b) image-aligned — only slices of the kernels intersected by the current sheet-slab are added.

3. Rasterize the footprint to the screen, using the preintegrated footprint table and multiplying the indexed values by the voxel's value [237] [238] [239]. This rasterization can either be performed via fast DDA procedures [130] [153] or, in graphics hardware, by texture-mapping the footprint (basis image) onto a polygon [31].

There are three types of splatting: composite-only, axis-aligned sheet-buffered and image-aligned sheet-buffered. The *composite-only* method was proposed first [238] and is the most basic one (see Figure 41.7). Here, the object points are traversed in either front-to-back or back-to-front order. Each is first assigned a color and opacity using the shading equation (Equation 41.9) and the transfer functions. Then, each point is splatted into the screen's color and opacity buffers, and the result is composited with the present image (Equation 41.11). In this approach, color bleeding and slight sparkling artifacts in animated viewing may be noticeable, because the interpolation and compositing operations cannot be separated due to the preintegration of the basis (interpolation) kernel [239].

An attempt to solve this problem led to the *axis-aligned sheet-buffered* splatting approach [237] (see Figure 41.8a). Here, the grid points are organized into sheets (basically, the volume slices most parallel to the image plane), assigned a color and opacity, and splatted into the sheet's color and opacity buffers. The important difference is that now all splats within a sheet are added and not composited, whereas only subsequent sheets are composited. This prevents potential color bleeding of voxels located in consecutive sheets, due to the more accurate reconstruction of the opacity layer. The fact that the voxel sheets must be formed by the volume slices most parallel to the viewing axis leads to a sudden switch of the compositing order when the major viewing direction changes and an orthogonal stack of volume slices must be used to organize the voxels. This causes noticeable popping artifacts, where some surfaces suddenly reflect less light and others more [152].

The solution to this problem is to align the compositing sheet with the image plane at all times, which gives rise to the *image-aligned sheet-buffered* splatting approach [152] (see Figure 41.8b). Here, a slab is advanced across the volume, and all kernels that intersect the slab are sliced and projected. Kernel slices can also be preintegrated into footprints. Thus, this sheet-buffered approach differs from the original one in that each voxel must be considered more than once. The image-aligned splatting method provides the most accurate reconstruction of the voxel field prior to compositing and eliminates both color bleeding and popping artifacts. It is also best suited for post-classified rendering, because the density (and gradient) field is reconstructed accurately in each sheet. However, it is more expensive due to the multiple splatting of a voxel.

The divergence of rays under perspective viewing causes undersampling of the volume portions farther away from the viewpoint. This leads to aliasing in these areas, especially noticeable as disturbing flickering of small features in interactive roaming and time-animated viewing. Lowpassing can eliminate the artifacts caused by aliasing and replace them by visually more pleasing blur [157] [212]. For perspective rendering, the amount of required lowpassing increases with distance from the viewpoint. Kernel-based approaches

can achieve this progressive lowpassing by simply stretching the footprints of the voxels as a function of depth, because stretched kernels act as lowpass filters [157] [212]. Elliptical weighted average (EWA) splatting [255] provides a general framework to define the screen-space shape of the footprints, and their mapping into a generic footprint, for generalized grids under perspective viewing. An equivalent approach for ray casting is to split the rays in more distant volume slices to maintain the proper sampling rate [170]. Kreeger et al. [113] proposed an improvement of this scheme that splits and merges rays in an optimal way.

A major advantage of object-order methods is that only the points (or other basis primitives, such as tetrahedral or hexagonal cells [240]) that make up the object must be stored. This can be advantageous when the object has an intricate shape, with many pockets of empty space [142]. While ray casting would spend much effort traversing (and storing) the empty space, kernel-based or *point-based* objects will not consider the empty space, neither during rendering nor for storage. However, there are trade-offs, because the rasterization of a footprint takes more time than the commonly used trilinear interpolation of ray samples. This is because the radially symmetric kernels employed for splatting must be larger than the trilinear kernels to ensure proper blending. Hence, objects with compact structure are more favorably rendered with image-order methods or hybrid methods (see [Section 41.6.3](#)). Another disadvantage of object-order methods is that early ray termination is not available to cull occluded material early from the rendering pipeline. The object-order equivalent is early point elimination, which is more difficult to achieve than early ray termination. Finally, image-order methods allow the extension of ray casting to ray tracing, in which secondary and higher-order rays are spawned at reflection sites. This facilitates mirroring on shiny surfaces, interreflections between objects, and soft shadows.

There are a number of ways to store and manage point-based objects. These schemes are distinguished mainly by their ability to exploit spatial coherence during rendering. The least spatial coherence results from storing the (nonair) points sorted by density [30]. It is best suited to sparse objects, and it allows fast isocontour selection via binary search. The method also requires that the points be depth-sorted during rendering or, at least, tossed into depth bins [155]. A compromise is struck by Ihm and Lee [86] who sort points by density within volume slices only, which gives implicit depth-ordering when used in conjunction with an axis-aligned sheet-buffer method. A number of approaches exist that organize the points into run length-encoded (RLE) lists, which allow the spatial coordinates to be computed incrementally when traversing the runs [102] [161].

A number of surface-based splatting methods have also been described. These do not provide the flexibility of volume exploration via transfer functions, because the original volume is discarded after the surface has been extracted. They only allow a fixed geometric representation of the object that can be viewed at different orientations and with different shadings. A popular method is *shell-rendering* [220], which extracts from the volume (possibly with a sophisticated segmentation algorithm) a certain thin or thick surface or contour and represents it as a closed shell of points. Shell-rendering is fast, because the number of points is minimized and its data structure has high cache coherence.

41.6.3 Hybrid Techniques

Hybrid techniques seek to combine the advantages of the image-order and object-order methods. That is, they use object-centered storage for fast selection of relevant material (a hallmark of object-order methods), and they use early ray termination for fast occlusion culling (a hallmark of image-order methods).

The shear-warp algorithm [116] is such a hybrid method. In shear-warp, the volume is rendered by a simultaneous traversal of RLE voxel and pixel runs, where opaque pixels and transparent voxels are efficiently skipped during these traversals [184]. Further speed comes from the fact that sampling only occurs in the volume slices via bilinear interpolation and that the ray grid resolution matches that of the volume slices. Therefore, the same bilinear weights can be used for all rays within a slice. The caveat is that the image must first be rendered from a sheared volume onto a so-called base plane, that is, aligned with the volume slice most parallel to the true image plane. After completing the base-plane rendering, the base plane image must be warped onto the true image plane, and the resulting image is displayed. All of this combined enables frame rates in excess of 10 frames/s on a current PC, for a 128^3 volume.

41.6.4 Domain Volume Rendering

In domain rendering, the spatial 3-D data is first transformed into another domain, such as compression, frequency, and wavelet domain, and then a projection is generated directly from that domain or with the help of information from that domain. *Frequency* domain rendering applies the Fourier slice projection theorem, which states that a projection of the 3-D data volume from a certain view direction can be obtained by extracting a 2-D slice perpendicular to that view direction out of the 3-D Fourier spectrum, and then by inverse Fourier transforming it. This approach obtains the 3-D volume projection directly from the 3-D spectrum of the data. Therefore, it reduces the computational complexity for volume rendering from $O(N^3)$ to $O(N^2 \log(N))$ [41] [132] [218]. A major problem of frequency domain volume rendering is that the resulting projection is a line integral along the view direction, which does not exhibit any occlusion or attenuation effects. Totsuka and Levoy [218] proposed a linear approximation to the exponential attenuation [189] and an alternative shading model to fit the computation within the frequency domain rendering framework.

Compression domain rendering performs volume rendering from compressed scalar data without decompressing the entire data set, and therefore reduces the storage, computation, and transmission overhead of otherwise large volume data. For example, Ning and Hesselink [167] [168] first applied vector quantization in the spatial domain to compress the volume and then directly rendered the quantized blocks using regular spatial domain volume rendering algorithms. Fowler and Yagel [50] combined differential pulse-code modulation and Huffman coding, and developed a lossless volume compression algorithm, but their algorithm is not coupled with rendering. Yeo and Liu [253] applied a discrete cosine transform-based compression technique to overlapping blocks of the data. Chiueh et al. [21] applied the 3-D Hartley transform to extend the JPEG still-image compression algorithm [223] to the compression of subcubes of the volume. They performed frequency domain rendering on the subcubes before compositing the resulting subimages in the spatial domain. Each of the 3-D Fourier coefficients in each subcube was then quantized, linearly sequenced through a 3-D zigzag order, and then entropy encoded. In this way, they alleviated the problem of lack of attenuation and occlusion in frequency domain rendering while achieving high compression ratios, fast rendering speed (compared to spatial volume rendering), and improved image quality over conventional frequency domain rendering techniques. More recently, Guthe et al. [65] and Sohn et al. [202] have used principles from MPEG encoding to render time-varying data sets in the compression domain.

The *wavelet transform* [22] [37] has been used by a number of researchers to reduce the storage of volume data sets before rendering [63] [159] [235]. Guthe and Strasser [66] have recently used the wavelet transform to render very large volumes at interactive frame rates on texture mapping hardware. They employ a wavelet pyramid encoding of the volume to reconstruct, on the fly, a decomposition of the volume into blocks of different resolutions. Here, the resolution of each block is chosen based on the local error committed and the resolution of the screen area onto which the block is projected. Each block is rendered individually with 3-D texture-mapping hardware, and the block decomposition can be used for a number of frames, which amortizes the work spent on the inverse wavelet transform to construct the blocks.

41.7 Acceleration Techniques

The high computational complexity of volume rendering has led to a great variety of approaches to its acceleration. Acceleration techniques generally seek to take advantage of properties of the data, such as empty space, occluded space, and entropy, as well as properties of the human perceptual system, such as its insensitivity to noise over structural artifacts [56].

A number of techniques have been proposed to accelerate the grid traversal of rays in image-order rendering. Examples are the 3-D digital differential analyzer (DDA) method [1] [53], in which new grid positions are calculated by fast integer-based incremental arithmetic, and the template-based method [250], in which templates of the ray paths are precomputed and used during rendering to identify quickly the voxels to visit. Early ray termination can be sophisticated into a Russian roulette scheme [35] in which

some rays terminate with lower and others with higher accumulated opacities. This capitalizes on the human eye's tolerance of error masked as noise [129]. In the object-order techniques, fast differential techniques to determine the screen-space projection of the points and to rasterize the footprints [130] [153] are also available.

Most of the object-order approaches deal well with empty space — they simply do not store and process it. In contrast, ray casting relies on the presence of the entire volume grid, because it requires it for sample interpolation and address computation during grid traversal. Although opaque space is quickly culled via early ray termination, the fast leaping across empty space is more difficult. A number of techniques are available to achieve this. The simplest form of space leaping is facilitated by enclosing the object in a set of boxes, possibly hierarchical, and quickly determining and testing the rays' intersection with each of the boxes before engaging in a more time-consuming volumetric traversal of the material within [99]. A better geometrical approximation is obtained by a polyhedral representation, chosen crudely enough to maintain ease of intersection. In fact, one case utilizes conventional graphics hardware to perform the intersection calculation, in which one projects the polygons twice to create two Z- (depth) buffers. The first Z-buffer is the standard closest-distance Z-buffer; the second is a farthest-distance Z-buffer. Because the object is completely contained within the representation, the two Z-buffer values for a given image plane pixel can be used as the starting and ending points of a ray segment on which samples are taken. This algorithm has been known as *PARC* (polygon-assisted ray casting) [201]. It is part of the *VolVis* volume visualization system [3] [4], which also provides a multialgorithm progressive refinement approach for interactivity. By using available graphics hardware, the user is given the ability to manipulate interactively a polyhedral representation of the data. When the user is satisfied with the placement of the data, light sources, and viewpoint, the Z-buffer information is passed to the *PARC* algorithm, which produces a ray-cast image.

A different technique for empty-space leaping was devised by Zuiderveld et al. [254] and by Cohen and Shefer [24], who introduced the concept of *proximity clouds*. Proximity clouds employ a distance transform of the object to accelerate the rays in regions far from the object boundaries. In fact, since the volume densities are irrelevant in empty volume regions, one can simply store the distance transform values in their place and, therefore, storage is not increased. Because the proximity clouds are the isodistance layers around the object's boundaries, they are insensitive to the viewing direction. Thus, rays that ultimately miss the object are often still slowed down. To address this shortcoming, Sramek and Kaufman [204] proposed a view-sensitive extension of the proximity clouds approach. Wan et al. [224] place a sphere at every empty voxel position, where the sphere radius indicates the closest nonempty voxel. They apply this technique to navigation inside hollow volumetric objects, as occurring in virtual colonoscopy [81], and reduce a ray's space traversal to just a few hops until a boundary wall is reached. Finally, Meissner et al. [143] suggested an algorithm that quickly recomputes the proximity cloud when the transfer function changes.

Proximity clouds only handle the quick leaping across empty space, but methods are also available that traverse occupied space faster when the entropy is low. These methods generally utilize a hierarchical decomposition of the volume in which each nonleaf node is obtained by lowpass filtering its children. Commonly, this hierarchical representation is formed by an octree [139], because these are easy to traverse and store. An *octree* is the 3-D extension of a quadtree [190], which is the 2-D extension of a binary tree. Most often, a nonleaf node stores the average of its children, which is synonymous with a box filtering of the volume, but more sophisticated filters are possible. Octree do not have to be balanced [241], or fully expanded into a single-root node or single-voxel leaf nodes. The last two give rise to a brick-of-bricks decomposition, in which the volume is stored as a flat hierarchy of bricks of size n^3 to improve cache coherence in the volume traversal. Parker et al. [172] [173] utilize this decomposition for the ray casting of very large volumes. They also give an efficient indexing scheme to find quickly the memory address of the voxels located in the 8-neighborhood required for trilinear interpolation.

When octrees are used for entropy-based rendering, nonleaf nodes store either an entropy metric of their children, such as standard deviation [35], minimum–maximum range [241], or Lipschitz range [208], or

a measure of the error committed when the children are not rendered, such as the root mean square or the absolute error [66]. The idea is to have the user specify a tolerable error before the frame is rendered or to make the error dependent on the time maximally allowed to render the frame, which is known as *time-critical rendering*. In either case, the rays traversing the volume will advance across the volume but also will transcend up and down the octree, based on the metric used. This will either accelerate or decelerate the rays on their path. A method called β -acceleration will also make this traversal sensitive to the rays' accumulated opacity so far. The philosophy here is that the observable error from using a coarser node will be relatively small when it is weighted by a small transparency in Equation 41.11. Note, however, that the interpolated opacity must be normalized to unit stepsize before it is used in the compositing equation (see Chapter 6 in [126]).

Octrees are also easily used with object-order techniques, such as splatting. Laur and Hanrahan [117] have proposed an implementation that approximates nonleaf octree nodes by kernels of a radius that is twice the radius of the children's kernels, which gives rise to a magnified footprint. They store the children's average, and an error metric based on their standard deviation, in each parent node and use a preset error to select the nodes during rendering. This work was later generalized to hierarchies of elliptical kernels, found via wavelet analysis [234]. Although both of these works use nonleaf nodes during rendering, other splatting approaches only exploit them for fast occlusion culling. Lee and Ihm [118] and Mora et al. [151] store the volume as a set of bricks, which they render in conjunction with a dynamically computed hierarchical occlusion map to cull voxels quickly within occluded bricks from the rendering pipeline. An alternative scheme, which performs occlusion culling on a finer scale than the box-basis of an octree decomposition, is to calculate an occlusion map in which each pixel represents the average of all pixels within the box-neighborhood covered by a footprint [155].

Another form of acceleration (and volume compression) is to employ more efficient sampling grids, such as the body-centered Cartesian (BCC) lattice [28]. In 3-D, BCC grids reduce the number of grid samples by 30%, without loss of frequency content or accuracy. BCC grids are particularly attractive for splatting, because they reduce the number of points that must be rasterized and rendered [216]. Neophytou and Mueller [161] extended the use of these grids to 4-D volume rendering, where they reduce the data set to 50% of the original number of samples.

A comprehensive system for accelerated software-based volume rendering is the UltraVis system devised by Knittel [110]. It can render 256^3 volume at 10 frames/s. It achieves this by optimizing cache performance during both volume traversal and shading. This concept is rooted in the fact that good cache management is key to achieve fast volume rendering, since the data are so massive. As we have mentioned before, this was also realized by Parker et al. [172] [173], and it plays a key role in both custom and commodity hardware approaches, as we shall see later. The UltraVis system manages the cache by dividing it into four blocks: one block each for volume bricks, transfer function tables, image blocks, and temporary buffers. Because the volume can only map into a private cache block, it can never be swapped out by a competing data structure, such as a transfer function table or an image tile array. This requires that the main memory footprint of the volume is four times higher, because no volume data may be stored in an address space that would map outside the volume's private cache slots. By using a bricked volume decomposition in conjunction with a flock of rays traced simultaneously across the brick, the brick's data must only be brought in once before it can be discarded, when all rays have finished its traversal. A number of additional acceleration techniques give further performance.

Another type of acceleration is achieved by breaking the volume integral of Equation 41.10 or Equation 41.13 into segments and storing the composited color and opacity for each partial ray in a data structure [11] [156]. The idea is then to recombine these partial rays into complete rays for images rendered at viewpoints near the one for which the partial rays were originally obtained. This saves the cost of fully integrating all rays for each new viewpoint and reduces it to the much lower expense of compositing a few partial segments per ray. An alternative method, which uses a precomputed triangle mesh to achieve similar goals for isosurface volume rendering, was proposed by Chen et al. [18]. Yagel and Shi [252] warped complete images to nearby viewpoints, aided by a depth buffer.

41.8 Classification and Transfer Functions

In volume rendering, we seek to explore volumetric data using visuals. This exploration process aims to discover and emphasize interesting structures and phenomena embedded in the data, while deemphasizing or completely culling away occluding structures that are currently not of interest. Clipping planes and more general clipping primitives [233] provide geometric tools to remove or displace occluding structures in their entirety. On the other hand, transfer functions, which map the raw volume density data to color and transparencies, can alter the overall look and feel of the data set in a continuous fashion.

The exploration of a volume via transfer functions constitutes a navigation task, which is performed in a 4-D transfer function space, assuming three axes for RGB color and one for transparency (or opacity). It is often easier to specify colors in HSV (hue, saturation, value) color space, because this provides separate mappings for color and brightness. Simple algorithms exist to convert the HSV values into the RGB triples used in volume rendering [47].

Given the large space of possible settings, choosing an effective transfer function can be a daunting task. It is generally more convenient to gather more information about the data before the exploration via transfer functions begins. The easiest presentation of support data is in the form of 1-D histograms, which are data statistics collected as a function of raw density or some other quantity. A histogram of density values can be a useful indicator to point out dominant structures with narrow density ranges. A fuzzy classification function [39] can then be employed to assign different colors and opacities to these structures (see Figure 41.9). This works well if the data are relatively noise-free, if the density ranges of the features are well isolated, and if few distinct materials (e.g., bone, fat, and skin) are present. In most applications, however, this is not the case. In these settings, it helps to include the first and second derivatives into the histogram-based analysis [103].

The magnitude of the first derivative (the gradient strength) is useful because it peaks at densities where interfaces between different features exist (see Figure 41.10). Plotting a histogram of first derivatives over density yields an arc that peaks at the interface density. Knowing the densities at which feature boundaries exist narrows the transfer function exploration task considerably. One may now visualize these structures by assigning different colors and opacities within a narrow interval around these peaks. Levoy [121] showed that a constant width of (thick) surface can be obtained by making the width of the chosen density interval a linear function of the gradient strength. Kindlmann and Durkin [103] proposed a technique that uses the first and second derivatives to generate feature-sensitive transfer functions automatically. This method provides a segmentation of the data, in which the segmentation metric is a histogram of the first and second derivatives. Tenginakai et al. [214] extended the arsenal of metrics to higher-order moments, and computed from them additional measures, such as kurtosis and skew, in small neighborhoods. These measures can provide better delineations of features in histogram space.

FIGURE 41.10 The relationship of densities and their first and second derivatives at an object boundary (shown as the box in the picture on the right).

FIGURE 41.11 Simple contour graph. The first topological event occurs when the two inner contours are born at an iso-value of 10. The second topological event occurs at the iso-value at which the two inner contours just touch and give way to a single contour at iso-value = 30.

Another proposed analysis method is based on maxima in cumulative Laplacian-weighted density histograms [174].

Automated segmentation of images and volumes remains a difficult task and is, in many cases, observer- and task-dependent. In this regard, semisupervised segmentation algorithms, in which users guide the segmentation process in an interactive fashion, have a competitive edge. There are two examples of such systems: the PAVLOV architecture, which implements an interactive region-grow to delineate volumetric features of interest [112], and the dual-domain approach of Kniss et al. [106] [107]. These researchers embed Kindlemann's algorithm into an interactive segmentation application. Here, users work simultaneously within two domains (i.e., the histogram-coupled transfer function domain and the volume rendering domain) to bring out certain features of interest. For this to be effective, an interactive (hardware-based) volume renderer is required.

Another way to analyze the data is to look for topological changes in the isocontours of the volume, such as a merge or split of two contours (see Figure 41.11). These events are called *critical points*. By topologically sorting the critical points as a function of density, one can construct a contour graph, contour tree, or hyper Reeb graph, which yields a roadmap for an exploration of the volume [7] [17] [54] [115] [195] [213]. One can use the contour graph to come up with an automatic transfer function (simply position an isosurface between two nodes), or one can use it to guide users in the volume exploration process. A large number of critical points are potentially generated, especially when the data are noisy.

All of the methods presented so far base the transfer function selection on a prior analysis of the volume data. Another suggested strategy has been to render a large number of images with arbitrary transfer function settings and present these to the user, who then selects a subset of these for further refinement by application of genetic algorithms. This approach has been taken by the Design Galleries project [135], which is based in part on the method published by He et al. [75]. A good sample of all of the existing

approaches (interactive trial and error, metric-based, contour graph, and design galleries) was presented in a symposium panel [178].

41.9 Volumetric Global Illumination

In the local illumination equation (Equation 41.9), the global distribution of light energy is ignored and shading calculations are performed assuming full visibility of and a direct path to all light sources. Although this is useful as a first approximation, the incorporation of global light visibility information (shadows, one instance of global illumination) adds a great deal of intuitive information to the image. This low-albedo [89] [200] lighting simulation has the ability to cast soft shadows by volume density objects. Generous improvements in realism are achieved by incorporating a high-albedo lighting simulation [89] [200], which is important in a number of applications (e.g., clouds [137], skin [68], and stone [38]). Although some use hierarchical and deterministic methods, most of these simulations use stochastic techniques to transport lighting energy among the elements of the scene.

We wish to solve the illumination transport equation for the general case of global illumination. The reflected illumination $I(\gamma, \omega)$ in direction ω at any voxel γ can be described as the integral of all incident radiation from directions ω' , modulated by the phase function $q(\omega, \omega')$:

$$I(\gamma, \omega) = \int_V \int_{\Gamma} q(\omega, \omega') I(\gamma, \omega') d\omega' dv \quad (41.14)$$

where Γ is the set of all directions and V is the set of all voxels v . This means that the illumination at any voxel is dependent on the illumination at every other voxel. In practice, this integral equation is solved by finite repeated projection of energy among voxels. This leads to a finite energy transport path, which is generally sufficient for visual fidelity.

In physics, equations of this sort are solved via *Monte Carlo simulations*. A large set of rays is cast from the energy sources into the volume, and at each voxel a “die is rolled” to determine how much energy is absorbed and how much energy is scattered and in what direction. After much iteration, the simulation is stopped and a final scattering of the radiosity volume is performed toward an arbitrarily positioned eye point.

A practical implementation of this process is volumetric backprojection. Backprojection is usually performed on a voxel-by-voxel basis, because this is the most obvious and direct method of computation. For example, in volumetric ray tracing [200], as illumination is computed for a volume sample, rays are cast toward the light sources, sampling the partial visibility of each. In computing high-albedo scattering illumination, Max [137] used the method of discrete ordinates to transport energy from voxel to voxel. For calculations of volumetric radiosity, voxels are usually regarded as discrete elements in the usual radiosity calculation on pairs of elements, thereby computing on a voxel-by-voxel basis [188] [200]. Particle tracing methods for global illumination track paths of scattered light energy through space, starting at the light sources [87].

In many cases, the backprojection can be reorganized into a single sweep through the volume, processing slice by slice. Because sunlight travels in parallel rays in one direction only, Kajiya and Herzen [89] calculated the light intensity of a cloudlike volume, one horizontal slice at a time. A similar technique was demonstrated as part of the Heidelberg ray-tracing model [140], in which shadow rays were propagated simultaneously, slice by slice and in the same general direction as rendering. Dache et al. [32] described a backprojection approach that scatters the energy in the volume by a multipass, slice-by-slice sweep at random angles. He also devised a custom hardware architecture for a cache-efficient implementation of this algorithm.

Kniss et al. [108] [109] proposed a single-pass algorithm that approximates the scattering of light within a volume by a recursive slice-blurring operation, starting at the light source. The profile of the blurring filter is determined by the user-specified phase function. The method exploits 3-D texture-mapping hardware in conjunction with a dual image buffer, and runs at interactive frame rates. One buffer, the repeatedly blurred (light) buffer, contains the transported and scattered light energy on its path away from the source;

the other (frame) buffer holds the energy headed for the eye and is attenuated by the densities along the path to the eye. At each path increment, energy is transferred from the light buffer to the frame buffer.

41.10 Special-Purpose Rendering Hardware

The high computational cost of direct volume rendering makes it difficult for sequential implementations and general-purpose computers to deliver the targeted level of performance, although recent advances in commodity graphics hardware have started to blur these boundaries (as we shall see in [Section 41.11](#)). This situation is aggravated by the continuing trend toward higher and higher resolution data sets. For example, to render a data set of 1024^3 16-bit voxels at 30 frames per second requires 2 GB of storage, a memory transfer rate of 60 GB per second, and approximately 300 billion instructions per second, assuming 10 instructions per voxel per projection.

In the same way that the special requirements of traditional computer graphics led to high-performance graphics engines, volume visualization naturally lends itself to special-purpose volume renderers that separate real-time image generation from general-purpose processing. Most recent research focuses on accelerators for ray casting of regular data sets. Ray casting offers room for algorithmic improvements while still allowing for high image quality. More recent architectures [78] include VOGUE [111], VIRIM [64], Cube-4 [180] [181], VIZARD I and II [144] [145], and the commercial VolumePro500 board [179] (an ASIC implementation of the Cube-4 architecture) and VolumePro1000 [249] board.

Cube-4 [180] [181] has only simple and local interconnections, thereby allowing for easy scalability of performance. Instead of processing individual rays, Cube-4 manipulates a group of rays at a time. As a result, the rendering pipeline is directly connected to the memory. Accumulating compositors replace the binary compositing tree. A pixel-bus collects and aligns the pixel output from the compositors. Cube-4 is easily scalable to very high resolutions of 1024^3 16-bit voxels and true real-time performance implementations of 30 frames per second. The VolumePro500 board was the final design, in the form of an ASIC, and was released to market by Mitsubishi Electric in 1999 [179]. VolumePro has hardware for gradient estimation, classification, and per-sample Phong illumination. It is a hardware implementation of the shear-warp algorithm, but with true trilinear interpolation, which affords very high quality. The final warp is performed on the PC's graphics card. VolumePro streams the data through four rendering pipelines, maximizing memory throughput by using a two-level memory block- and bank-skewing mechanism to take advantage of the burst mode of its SDRAMs. No occlusion culling or voxel skipping is performed. Advanced features, such as gradient magnitude modulation of opacity and illumination, supersampling, cropping, and cut planes, are also available. The system renders 500 million interpolated, Phong-illuminated, composited samples per second, which is sufficient to render volumes with up to 16 million voxels (e.g., 256^3 volumes) at 30 frames per second.

41.11 General-Purpose Rendering Hardware

Another opportunity to accelerate volume rendering is to utilize the texture mapping capability of graphics hardware. The first such implementation was devised by Cabral et al. [14] and ran on SGI Reality Engine workstations. There are two ways to go about this. One represents the volume either as a stack of 2-D textures, one texture per volume slice, or as one single 3-D texture, which requires more sophisticated hardware. In the former case, three texture stacks are needed: one for each major viewing direction. An image is then rendered by choosing the stack that is most parallel to the image plane and rendering the textured polygons to the screen in front-to-back or back-to-front order. If the machine has 3-D texture capabilities, then one specifies a set of slicing planes parallel to the screen and composites the interpolated textures in depth order. The 3-D texturing approach generally provides better images, because an arbitrarily small slice distance can be chosen and no popping caused by texture stack switching can occur. Although the early approaches did not provide any shading, Gelder and Kim [58] introduced a fast technique to preshade the volume on the fly and then slice and composite an RGB volume to obtain an image with shading effects. Westermann and Ertl [236] introduced a fast multipass approach to display shaded isosurfaces.

The emergence of advanced PC graphics hardware has made texture-mapped volume rendering accessible to a much broader community, at less than 2% of the cost of the workstations that were previously required. However, the decisive factor triggering the revolution that currently dominates the field was the decision of manufacturers (e.g., NVidia, ATI, and 3-DLabs) to make two of the main graphics pipeline components programmable. These two components are the vertex shaders, which are the units responsible for vertex transformations, and the fragment shaders, which are the units that take over after the rasterizer. The first implementation that used these new commodity GPUs for volume rendering was published by Rezk-Salama et al. [185], who used the stack-or-textures approach, because 3-D texturing was not supported at that time. They overcame the undersampling problems associated with the large interslice distance at off-angles by interpolating, on the fly, intermediate slices, using the register combiners in the fragment shader compartment. Engel et al. [44] replaced this technique by the use of preintegrated transfer function tables (see [Section 41.8](#)).

To compute the gradients required for shading, one must also load a gradient volume into the texture memory. The interpolation of a gradient volume without subsequent normalization is generally incorrect, but the artifacts are not always visible. Meissner and Guthe [141] use a shading cube texture instead, which eliminates this problem. Even the most recent texture-mapping hardware cannot reach the performance of the specialized volume rendering hardware, such as VolumePro500 and the VolumePro 1000, at least not when volumes are rendered by brute force. Therefore, current research efforts have concentrated on reducing the load for the fragment shaders. Level-of-detail methods have been devised that rasterize lower-resolution texture blocks whenever the local volume detail or projected resolution allows them to do so [66] [120]. Li and Kaufman [124] [125] proposed an alternative approach that approximates the object by a set of texture boxes, which efficiently clips empty space from the rasterization.

41.12 Irregular Grids

All the algorithms discussed previously handle only regular gridded data. Irregular gridded data come in a large variety [203], including curvilinear data and unstructured (scattered) data, where no explicit connectivity is defined between cells (one can even be given a scattered collection of points that can be turned into an irregular grid by interpolation [166] [138]). Figure 41.12 illustrates the most prominent grid types, and [Figure 41.13](#) shows an example of a translucent rendering of an irregular grid data set.

One approach to rendering irregular grids is the use of feed-forward (or projection) methods, where the cells are projected onto the screen one by one, accumulating their contributions incrementally to the final image [242] [138] [240] [196]. The projection algorithm that has gained popularity is the projected tetrahedra (PT) algorithm by Shirley and Tuchman [196]. It uses the projected profile of each

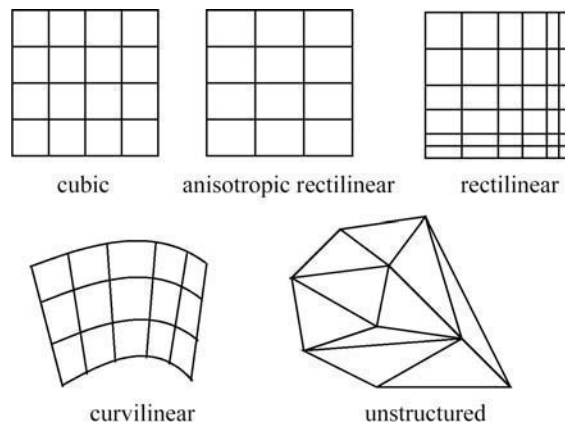

FIGURE 41.12 Various grid types in 2-D.

FIGURE 41.13 Visualization of an irregular grid dataset: combustion chamber.

tetrahedron with respect to the image plane to decompose it into a set of triangles. The color and opacity values for each triangle vertex are approximated using ray integration through the thickest point of the tetrahedron. The resulting semitransparent triangles are sorted in depth order and then rendered and composited using polygonal graphics hardware. Stein et al. [209] sort the cells before they are split into tetrahedra, and they utilize 2-D texture-mapping hardware to accelerate opacity interpolation and provide the correct per-pixel opacity values to avoid artifacts. Although their method can only handle linear transfer functions without artifacts, Röttger et al. [187] introduced the concept of preintegrated volume rendering to allow for arbitrary transfer functions. They created a 3-D texture map to provide hardware support in interpolating along the ray between the front and back faces of a tetrahedral cell. In this texture map, two of the three coordinates correspond to values at the cell entry and exit points, with the third coordinate mapping to the distance through the cell. This texture map is then approximated using 2-D texture mapping.

Cell projection methods require a sorted list of cells to be passed to the hardware. Starting with the work of Max et al. [138] and Williams [243], there has been substantial progress in the development of accurate visibility ordering algorithms [198] [27]. Graphics hardware architecture was also proposed, but not yet realized, by King et al. [104], which can both rasterize and sort tetrahedral meshes in hardware.

An alternative technique to visualize irregular grids is ray casting [57] [221]. Ray-casting methods tend to be more exact than projective techniques because they are able to “stab” or integrate the cells in depth order, even in the presence of cycles. This is generally not possible in cell-by-cell projection methods. Many ray-casting approaches employ the plane sweep paradigm, which is based on processing geometric entities in an order determined by passing a line or a plane over the data. Pioneered by Giertsen [59] for use in volume rendering, the method is based on a sweep plane that is orthogonal to the viewing plane (e.g., orthogonal to the y -axis). Events in the sweep are determined by vertices in the data set and by values of y that correspond to the pixel rows. When the sweep plane passes over a vertex, an active cell list (ACL) is updated accordingly, so that it stores the set of cells currently intersected by the sweep plane. When the sweep plane reaches a y -value that defines the next row of pixels, the current ACL is used to process that row, casting rays corresponding to the values of x that determine the pixels in the row, through a regular grid (hash table) that stores the elements of the ACL. This method has three major advantages:

- It is unnecessary to store explicitly the connectivity between the cells.

- It replaces the relatively expensive operation of 3-D ray casting with a simpler 2-D regular-grid ray casting.

- It exploits coherence of the data between scanlines.

Since the work of Giertsen, a number of works have employed the sweep paradigm, most using a sweep plane parallel to the image plane. Some of these methods are assisted by hardware [251] [236]; others are pure software implementations [13] [46] [197]. The ZSweep [46] algorithm is very fast and has excellent memory efficiency. It sweeps the plane from front to back and rasterizes the cell faces as they are encountered by the sweep plane. This keeps the memory footprint low, because only the

active cell set must held in memory. Finally, Hong and Kaufman [79] [80] have proposed a very fast ray-casting technique, which exploits the special topology of curvilinear grids, and Mao et al. [133] [134] first resample an irregular grid into an arrangement of ellipsoidal kernels, which can then be quickly projected from any viewpoint using splatting.

41.13 High-Dimensional and Multivalued Data

The following important extensions to the 3-D scalar data sets have been discussed so far:

- Data sets of higher dimensionality, such as time-varying 3-D data sets or general n -D data.
- Data volumes composed of field vectors (such as flow and strain), or attribute vectors.

The latter can either be *multichannel*, such as the RGB color volumes obtained by cryosectioning the Visible Human [82], or *multimodal*, that is, spatially collocated volumes acquired by scanning an object with multiple modalities, such as MRI, PET, and CT.

There have been significant developments in the rendering of time-varying volumetric data sets. These typically exploit time coherency for compression and acceleration [2] [66] [128] [194] [211] [235], but other methods have also been designed that allow general viewing [6] [9] [69] [70] [71] [100] [161] [232] of high-dimensional (n -D) data sets and require a more universal data decomposition.

The rendering of multimodal volumes requires the mixing of the data at some point in the rendering pipeline. There are at least three locations at which this can happen [15]:

- At the image level (after rendering of the individual volumes)
- At the accumulation level (before compositing)
- At the illumination level (before shading and transfer function lookup)

Multichannel data, such as RGB data obtained by photographing slices of real volumetric objects, have the advantage that there is no longer a need to search for suitable color transfer functions to reproduce the original look of the data. On the other hand, the photographic data do not provide easy mapping to densities and opacities, which are required to compute normals and other parameters needed to bring out structural object detail in surface-sensitive rendering. One can overcome the perceptual nonlinearities of the RGB space by computing gradients and higher derivatives in the perceptually uniform color space $L^*u^*v^*$ [42]. In this method, the RGB data are first converted into the $L^*u^*v^*$ space, and the color distance between two voxels is calculated by their Euclidian distance in that color space.

41.14 Volume Graphics

Volume graphics, [20] [96] an emerging subfield of volume visualization, is concerned with the synthesis, modeling, manipulation, and rendering of volumetric geometric objects, stored in a volume buffer of voxels. Unlike the discussion so far, which has focused mainly on sampled and computed data sets, volume graphics is concerned primarily with modeled geometric scenes and commonly with those that are represented in a regular volume buffer. As an approach, volume graphics has the potential to greatly advance the field of 3-D graphics by offering a comprehensive alternative to traditional surface graphics.

Although the 3-D raster representation seems more natural for empirical imagery than for geometric objects, due to its ability to represent interiors and digital samples, the advantages of this representation are also attracting traditional surface-based applications that deal with the modeling and rendering of synthetic scenes made from geometric models. The geometric model is *voxelized* (3-D scan-converted) into a set of voxels that “best” approximate the model. Each of these voxels is then stored in the volume buffer, together with the voxel precomputed view-independent attributes. The voxelized model can be either binary (see [45] [84] [93] [94] [98]) or volume sampled (see [33] [51] [205] [226]), which generates alias-free density voxelization of the model. Some surface-based application examples are the rendering of fractals [169], hypertextures [176], fur [90], foliage, grass, and hair [163], gases [43], clouds [36] [137], and other complex models [199], including CAD models and terrain models for flight simulators [25]

[62] [96] [183] [225] [248]. Furthermore, in many applications involving sampled data, such as medical imaging, the data must be visualized along with synthetic objects that may not be available in digital form, such as scalpels, prosthetic devices, injection needles, radiation beams, and isodose surfaces. These geometric objects can be voxelized and intermixed with the sampled organ in the voxel buffer [97]. An alternative is to leave these geometric objects in a polygonal representation and render the assembly of volumetric and polygonal data in a hybrid rendering mode [114] [123] [200].

In the following subsections, we describe the volumetric approach to several common volume graphics modeling techniques. We describe the generation of object primitives from geometric models (voxelization) and images (reconstruction), 3-D antialiasing, solid texturing, modeling of amorphous and natural phenomena, modeling by block operations, constructive solid modeling, volume sculpting, volume deformation, and volume animation.

41.14.1 Voxelization

An indispensable stage in volume graphics is the synthesis of voxel-represented objects from their geometric representation. This stage, called *voxelization*, is concerned with converting geometric objects from their continuous geometric representation into a set of voxels that “best” approximates the continuous object. As this process mimics the scan-conversion process that pixelizes (rasterizes) 2-D geometric objects, it is also referred to as 3-D *scan-conversion*. In 2-D rasterization, the pixels are drawn directly onto the screen to be visualized, and filtering is applied to reduce the aliasing artifacts. However, the voxelization process does not render the voxels but merely generates a database of the discrete digitization of the continuous object.

A voxelization algorithm for any geometric object should meet several criteria:

Separability criterion — First, it must be efficient and accurate, and it must generate discrete surfaces that are thick enough so that they cannot be penetrated by a crossing line [23].

Minimality criterion — Second, the discrete surfaces should only contain those voxels indispensable to satisfying the separability requirement, such that a faithful delineation of the object’s shape is warranted [23].

Smoothness criterion — Third, the generated discrete object should have smooth boundaries to ensure the antialiased gradient estimation necessary for high-quality volume rendering [226].

One practical meaning of separation is apparent when a voxelized scene is rendered by casting discrete rays from the image plane into the scene. The penetration of the background voxels (which simulate the discrete ray traversal) through the voxelized surface causes the appearance of a hole in the final image of the rendered surface. Another type of error might occur when a 3-D flooding algorithm is employed either to fill an object or to measure its volume, surface area, or other properties. In this case, the nonseparability of the surface causes a leakage of the flood through the discrete surface. Unfortunately, the extension of the 2-D definition of separation to the third dimension and to voxel surfaces is not straightforward, because voxelized surfaces cannot be defined as an ordered sequence of voxels and a voxel on the surface does not have a specific number of adjacent surface voxels. Furthermore, there are important topological issues, such as the separation of both sides of a surface, which cannot be well defined by employing 2-D terminology. The theory that deals with these topological issues is called 3-D *discrete topology*. We next sketch some basic notions and informal definitions used in this field.

41.14.2 Fundamentals of 3-D Discrete Topology

The 3-D discrete space is a set of integral grid points in 3-D Euclidean space defined by their Cartesian coordinates (x, y, z) . A voxel is the unit cubic volume centered at the integral grid point. The voxel value is mapped onto $\{0,1\}$: the voxels assigned 1 are called the *black* voxels, representing opaque objects, and those assigned 0 are the *white* voxels, representing the transparent background. Besides this binary representation, there are also nonbinary approaches in which the voxel value is mapped onto the interval

[0,1], representing either partial coverage, variable densities, or graded opacities. Due to its larger dynamic range of values, this approach supports 3-D antialiasing and thus supports higher-quality rendering.

Two voxels are *26-adjacent* if they share a vertex, an edge, or a face. Every voxel has 26 such adjacent voxels: eight share a vertex (corner) with the center voxel, twelve share an edge, and six share a face. Accordingly, face-sharing voxels are defined as *6-adjacent*, and edge-sharing and face-sharing voxels are defined as *18-adjacent*. Here, we shall use the prefix N to define the adjacency relation, where $N = 6, 18,$ or 26 . A sequence of voxels having the same value (e.g., black) is called an N -*path* if all consecutive pairs are N -adjacent. A set of voxels W is N -*connected* if there is an N -path between every pair of voxels in W . An N -*connected component* is a maximal N -connected set.

Given a 2-D discrete 8-connected black curve, there are sequences of 8-connected white pixels (8-component) that pass from one side of the black component to the other without intersecting it. This phenomenon is a discrete disagreement with the continuous case, where there is no way of penetrating a closed curve without intersecting it. To avoid such a scenario, it has been the convention to define *opposite* types of connectivity for the white and black sets. Opposite types in 2-D space are 4 and 8; in 3-D space, 6 is opposite to 26 or to 18.

Assume that a voxel space, denoted by Σ , includes one subset of black voxels S . If $\Sigma - S$ is not N -connected, that is, if $\Sigma - S$ consists of at least two white N -connected components, then S is said to be N -*separating* in Σ . Loosely speaking, in 2-D, an 8-connected black path that divides the white pixels into two groups is 4-separating, and a 4-connected black path that divides the white pixels into two groups is 8-separating.

There are no analogous results in 3-D space. Let W be an N -separating surface. A voxel $p \in W$ is said to be an N -*simple voxel* if $W - p$ is still N -separating. An N -separating surface is called N -*minimal* if it does not contain any N -simple voxel. A *cover* of a continuous surface is a set of voxels such that every point of the continuous surface lies in a voxel of the cover. A cover is said to be a *minimal cover* if none of its subsets is also a cover. The cover property is essential in applications that employ space subdivision for fast ray tracing [60]. The subspaces (voxels) that contain objects must be identified along the traced ray. Note that a cover is not necessarily separating; on the other hand, as mentioned previously, it may include simple voxels. In fact, even a minimal cover is not necessarily N -minimal for any N [23].

41.14.3 Binary Voxelization

An early technique for the digitization of solids was spatial enumeration, which employs point or cell classification methods either in an exhaustive fashion or by recursive subdivision [119]. However, subdivision techniques for model decomposition into rectangular subspaces are computationally expensive and thus inappropriate for medium- or high-resolution grids. Instead, objects should be directly voxelized, preferably generating an N -separating, N -minimal, and covering set, where N is application-dependent. The voxelization algorithms should follow the same paradigm as the 2-D scan-conversion algorithms; they should be incremental and accurate, use simple arithmetic (preferably integer only), and have a complexity that is not more than linear with the number of voxels generated.

The literature on 3-D scan-conversion is relatively small. Danielsson [34] and Mokrzycki [147] independently developed similar 3-D curve algorithms in which the curve is defined by the intersection of two implicit surfaces. Voxelization algorithms have been developed for 3-D lines, 3-D circles, and a variety of surfaces and solids, including polygons, polyhedra, and quadric objects [98]. Efficient algorithms have been developed for voxelizing polygons using an integer-based decision mechanism embedded within a scan-line filling algorithm [93]; for parametric curves, surfaces, and volumes using an integer-based forward differencing technique [94]; and for quadric objects, such as cylinders, spheres, and cones using “weaving” algorithms by which a discrete circle or line sweeps along a discrete circle or line [26]. While these pioneering attempts focused more on efficiency and accuracy, later algorithms focused also on adherence to the topological requirements (i.e., to the separability and minimality criteria). Huang et al. [84] devised such an algorithm for the voxelization of polygon meshes, employing a geometric measure for each candidate voxel to determine its N -simplicity.

FIGURE 41.14 Binary sphere yields jagged surfaces when rendered.

41.14.4 Antialiased Voxelization

The previous subsection discussed binary voxelization, which generates topologically and geometrically consistent models but exhibits object space aliasing, caused by the binary classification of voxels into the $\{0,1\}$ set. Therefore, the resolution of the 3-D raster ultimately determines the precision of the discrete model, and imprecise modeling results in jagged surfaces, known as *object space aliasing*. This leads to image space aliasing during the rendering (see Figure 41.14). To avoid the aliasing, one must employ object-space prefiltering, in which scalar-valued voxels represent the percentage of spatial occupancy of a voxel [227], an extension of the 2-D line antialiasing method of Gupta and Sproull [67]. The scalar-valued voxels determine a fuzzy set such that the boundary between inclusion and exclusion is smooth. Direct visualization from such a fuzzy set avoids image aliasing.

Some research on voxelization and debinarization of sampled volume data sets has focused on generating a distance volume for subsequent use in manipulation [12] or rendering [51]. The latter also employed an elastic surface wrap, called *surface nets*, to enable the generation of smoother distance fields. By means of the distance volume, one can then estimate smooth gradients and achieve pleasing renderings without jagged surfaces. Sramek and Kaufman [205] [206] showed that the optimal sampling filter for central difference gradient estimation in areas of low curvature is a one-dimensional box filter of width $2\sqrt{3}$ voxel units, oriented perpendicular to the surface. Since most volume rendering implementations utilize the central difference gradient estimation filter and trilinear sample interpolation, the oriented box filter is well suited for voxelization. Furthermore, this filter is an easily computed linear function of the distance from the triangle. Binary parametric surfaces and curves can be antialiased using a (slower) 3-D splatting technique.

Later methods have focused on providing more efficient algorithms for antialiased triangle voxelization, suitable for both software [33] [88] and hardware implementations [33] [45]. Because conventional graphics hardware only rasterizes points, lines, and triangles, higher-order primitives must be expressed as combinations of these basic primitives, most often as triangles. To voxelize solid objects, one can first voxelize the boundary as a set of triangles, then fill the interior using a volumetric filling procedure. A commodity hardware-based voxelization algorithm was proposed by Fang and Chen [45], which performs the voxelization on a per-volume sheet basis by slicing the polymesh (with antialiasing turned on) and storing the result in a 3-D (volumetric) texture map.

Dachille and Kaufman [33] devised a more accurate software method (in terms of the antialiasing), that employs fast, incremental arithmetic for rapid voxelization of polymeshes on a per-triangle basis. Figure 41.15 depicts the boundary region affected by the antialiased voxelization of a triangle and the profile of its voxelization. All voxels within the translucent surface, which is at a constant distance from the triangle, must be updated during the voxelization and assigned values corresponding to the distance to the triangle surface. The general idea of the algorithm is to voxelize a triangle by scanning a bounding box of the triangle in raster order. For each voxel in the bounding box, a filter equation (similar to that of [205]) is evaluated and the result stored in memory. The value of the equation is a linear function of the distance from the triangle. The result is stored using a fuzzy algebraic union operator — the *max* operator. A similar algorithm was also implemented on the VolumePro volume rendering board [33].

FIGURE 41.15 (a) The 3-D region of influence around a triangle, (b) the density profile of the oriented box filter along a line perpendicular to the triangle surface primitive. Here, T is the width of the triangle (usually very close to 0) and W is the width of the filter profile. The anti-aliased voxelization will maintain this profile everywhere within the red region of the triangle shown in (a). It is assumed that the iso-surface is positioned at a density value of 0.5, in the center of the profile. This ensures that the central difference operator meets a smooth boundary.

41.14.5 Block Operations and Constructive Solid Modeling

An intrinsic characteristic of the volume buffer is that adjacent objects in the scene are also represented by neighboring memory cells. Therefore, rasters lend themselves to various meaningful grouping-based operations, such as *bitblt* in 2-D, or *voxblt* in 3-D [95]. These include transfer of volume buffer rectangular blocks (cuboids) while supporting voxel-by-voxel operations between source and destination blocks. Block operations add a variety of modeling capabilities, which aid in the task of image synthesis and form the basis for the efficient implementation of a 3-D “room manager”: the extension of window management to the third dimension.

Constructive solid geometry (CSG) is one of the most important modeling methods in computer graphics and computer-aided design (CAD). It allows complicated objects to be built as variously ordered unions, intersections, and differences of simpler objects, which may be bounded primitives or half-spaces. It is supported by Boolean algebra and a set of well understood, regularized set operations. Because the volume buffer lends itself to Boolean operations that can be performed on a voxel-by-voxel basis during the voxelization stage, it is advantageous to use CSG as the modeling paradigm with volumetric objects. Subtraction, union, and intersection operations between two discretized 3-D objects are accomplished at the voxel level, thereby reducing the original problem of evaluating a CSG tree during rendering time down to a 1-D Boolean operation between pairs of voxels during a preprocessing stage.

The volume buffer also allows a major extension of the traditional CSG paradigm, because it can also be employed to manipulate physical properties associated with objects, such as scalar or even vector and tensor fields. In *constructive volume geometry* (CVG) [19], the combinational operations, mostly defined in the real domain, can subsequently be used to model complex interior structures of objects and amorphous phenomena in a constructive manner, with a generalization of the well known CSG operators.

In CVG, combinational operators are defined on unbounded spatial objects and are constructed from simple arithmetic operations on scalars through a series of operational decompositions. The operations on scalars are normally defined in the real domain. The basic CVG operators include union, intersection, difference, and blending. With the flexibility and accuracy of the real domain, complex operators, such as those for data filtering and volume deformation, can easily be specified. CVG operates on both the interior and the exterior of objects and, therefore, preserves the main geometrical properties in volumetric data sets, such as volume density and multiple isosurfaces. Physical properties, such as colors, are defined and manipulated in the same way as geometry. CVG accommodates objects that are defined mathematically by scalar fields and those built from digitized volumetric data sets.

For two point-sampled binary objects, the Boolean operations of CSG or *voxblt* are trivially defined. However, the Boolean operations applied to volume-sampled models are analogous to those of fuzzy set

FIGURE 41.16 Voxelized objects with anti-aliased boundaries.

theory (see [40]). The volume-sampled model is a density function $d(x)$ over R^3 , where d is 1 inside the object, 0 outside the object, and $0 < d < 1$ within the soft region of the filtered surface. Some of the common operations — intersection, complement, difference, and union — between two objects A and B are defined as follows:

$$\begin{aligned}
 d_{A \cap B} &= \min(d_A(x), d_B(x)) \\
 d_{\bar{A}} &= 1 - d_A(x) \\
 d_{A-B} &= \min(d_A(x), 1 - d_B(x)) \\
 d_{A \cup B} &= \max(d_A(x), d_B(x))
 \end{aligned}
 \tag{41.15}$$

By performing the CVG operations in Equation 41.15 between sampled volumes, as obtained with 3-D scanners, complex geometric models can be generated. Volume-sampled models can also function as matte volumes [39] for various matting operations, such as performing cut-aways and merging multiple volumes into a single volume using the union operation.

The only law of set theory that is no longer true is the excluded-middle law:

$$A \cap \bar{A} \neq \emptyset$$

and

$$A \cup \bar{A} \neq \text{Universe}$$

The use of the *min* and *max* functions causes discontinuity at the region where the soft regions of the two objects meet, because the density value at each location in the region is determined solely by one of the two overlapping objects. In order to preserve continuity on the cut-away boundaries between the material and the empty space, one could use an alternative set of Boolean operators based on algebraic sum and algebraic product [40] [176]:

$$\begin{aligned}
 d_{A \cap B} &= d_A(x)d_B(x) \\
 d_{\bar{A}} &= 1 - d_A(x) \\
 d_{A-B} &= d_A(x) - d_A(x)d_B(x) \\
 d_{A \cup B} &= d_A(x) + d_B(x) - d_A(x)d_B(x)
 \end{aligned}
 \tag{41.16}$$

Unlike the *min* and *max* operators, algebraic sum and product operators result in

$$A \cup A \neq A$$

which is undesirable. A consequence, for example, is that during modeling via sweeping, the resulting model is sensitive to the sampling rate of the swept path [227].

Once a CVG model has been constructed in voxel representation, it is rendered in the same way as any other volume buffer. This makes, for example, volumetric ray tracing [200] or splatting [150] [193] of

constructive solid models straightforward. Texture-mapping, hardware-assisted rendering approaches will further promote the interactive modeling via CVG. Moreover, it is interesting to observe that the volume compositions generated via CVG and those constructed with the multimodal or multivalued data sets discussed earlier share a number of rendering challenges that will make attractive a common rendering, compositing, and modeling framework, most suitably using a volumetric scenegraph [160] [244].

41.14.6 Texture Mapping and Solid Texturing

One type of object complexity involves objects that are enhanced with texture mapping, photo mapping, environment mapping, or solid texturing. *Texture mapping* is commonly implemented during the last stage of the rendering pipeline, and its complexity is proportional to the object complexity. In volume graphics, however, texture mapping is performed during the voxelization stage, and the texture color is stored in each voxel in the volume buffer.

In *photo mapping*, six orthogonal photographs of the real object are projected back onto the voxelized object. Once this mapping is applied, it is stored with the voxels themselves during the voxelization stage and, therefore, does not degrade the rendering performance. Texture and photo mapping are also viewpoint-independent attributes, implying that once the texture is stored as part of the voxel value, texture mapping need not be repeated. This important feature is exploited, for example, by voxel-based flight simulators (see Figure 41.17) and in CAD systems.

A central feature of volumetric representation is that, unlike surface representation, it is capable of representing inner structures of objects, which can be revealed and explored with appropriate manipulation and rendering techniques. This capability is essential for the exploration of sampled or computed objects. Synthetic objects are also likely to be solid rather than hollow. One method for modeling various solid types is *solid texturing*, in which a procedural function or a 3-D map models the color of the objects in 3-D. During the voxelization phase, each voxel belonging to the objects is assigned a value by the texturing function or the 3-D map. This value is then stored as part of the voxel information. On the other hand, if solid texturing is to be used as a means to enrich a volume data set with more detail, without increasing the stored resolution of the data set, then the texturing function can also be evaluated during rendering time, at the ray-sampling locations. The statistical invariance under translation makes solid textured objects appear “carved out” of the simulated material (e.g., a voxelized chair or a CT head made of wood) [191].

The most important solid texturing basis functions are noise [175], turbulence, and n th closest [247]. Perlin’s *noise* function [175] returns a pseudorandom value, in the range of $(-1, 1)$, by interpolating the gradient vector between predetermined lattice points. The *turbulence* basis function gives the impression

FIGURE 41.17 A satellite image, photo-mapped into voxelized terrain.

of Brownian motion (or turbulent flow) by summing noise values at decreasing frequencies, introducing a self-similar $1/f$ pattern, where f is the frequency of the noise. The n th-closest basis function [247] places feature points at random locations in R^3 and calculates the distance from a surface point to each of the n th-closest feature points. Combinations of these distances can then be used to index a color spline.

41.14.7 Amorphous Phenomena

Solid texturing produces objects that have simple surface definitions. However, many objects, such as fur, have surface definitions that are much more complex. Others, such as clouds, fire, and smoke, have no well defined surface at all. Although translucent objects can be represented by surface methods, these methods cannot efficiently support the modeling and rendering of amorphous phenomena, which are volumetric in nature and lack any tangible surfaces. A common modeling and rendering approach is based on a function that, for any input point in 3-D, calculates some object features, such as density, reflectivity, or color. These functions can then be rendered by ray casting, which casts a ray from each pixel into the function domain. Along the passage of the ray, at constant intervals, the function is evaluated to yield a sample. All samples along each ray are combined to form the pixel color.

Perlin and Hoffert [176] introduced a technique, called *hypertextures*, that allows for the production of such complex textures through the manipulation of surface densities. That is, rather than just coloring an object's surface with a texture map, its surface structure is changed (during rendering) using a 3-D texture function. Hypertextures introduce the idea of *soft objects*: objects with a large boundary region, modeled using an object density function $D(x)$. As with solid textures, combinations of noise and turbulence — together with two new density modulation functions, bias (controls the density variation across the soft region) and gain (controls the rate at which density changes across the midrange of the soft region) — are used to manipulate $D(x)$ to create hypertextured objects. Satherley and Jones [191] showed that nongeometric data sets, such as volumes, can be augmented with hypertextures by first performing a distance transform on them and then applying the hypertexture framework on the resulting distance volume, within the soft region of the object.

The modeling of amorphous detail via volumetric techniques has found a number of applications, including the texel approach introduced by Kajiya and Kay [90] for the rendering of fur, which was later extended by Neyret [163] for the rendering of foliage, grass, and hair. Other researchers have used volumetric representations to model and render fractals [73], gases [43] [48], and clouds [36] [108] [137].

Instead of using procedural functions based on noise functions, better renditions of physical, time-varying behavior can be obtained by modeling the actual underlying physical processes, such as smoke, fire, and water flow, via application of the Navier–Stokes equations [49] [164] [207] or lattice propagation methods [72] [229]. Although this requires much larger computational effort, recent advances in graphics hardware have yielded powerful SIMD processors that can run the required numerical solvers or lattice calculations at speedups of an order of magnitude or more, compared to traditional CPUs. For reasons of efficiency, the flow calculations are often performed on relatively coarse grids. Therefore, global illumination algorithms, such as photon maps [87], Monte Carlo volume renderers, or splats that are texture mapped with phenomena detail [105] [229], are often used to visually enhance the level of detail for visualization.

41.14.8 Natural Phenomena

Natural phenomena, such as the processes of thawing, natural weathering, and melting, are also inherently volumetric processes and are suitably modeled with volume graphics methods. Fujishiro and Aoki [55] have used a mathematical morphology operator to simulate the effects of thawing. Here, the volume model is thought of as being made of ice and is left in the open (warm) air to thaw. The mathematical morphology operator is a phenomenological modeling operator and is shown in their work to provide a good approximation of the physical model. Further, to simulate the relegation of water on the base of volumetric ice statues, a cellular automata mechanism is employed.

Dorsey et al. [38] model the weathering of stone by employing a simulation of the flow of moisture through the surface into the stone. Here, the model governs the erosion of material from the surface, and the weathering process is confined to a thick crust on the surface of the volume. Ozawa and Fujishiro [171] also use the mathematical morphology technique for the weathering of stone. By applying a spatially variant structuring element for the morphology, they are able to simulate the stochastic nature of real weathering phenomena. Other researchers have used physically based methods, such as Navier–Stokes solvers [16] or advanced cellular automata methods (Lattice–Boltzmann) [230] [231], to simulate the process of melting and flowing of viscous materials, as well as sand, mud, and snow [210]. Varadhan and Mueller [222] proposed a physically based method for the simulation of ablation on volumetric models. They demonstrated the visual effect of ablative processes, such as a beam of heat emitted from a blow torch. Users can control ablative properties, such as energy propagation, absorption, and material evaporation, via a simple transfer function interface.

41.14.9 Volume Sculpting

Surface-based sculpting has been studied extensively (e.g., [29] [192]), while volume sculpting was introduced later for clay or waxlike sculptures [85] and for comprehensive detailed sculpting [228]. The latter approach is a free-form interactive modeling technique based on the metaphor of sculpting and painting a voxel-based solid material, such as a block of marble or wood. There are two motivations for this approach. First, modeling topologically complex and highly detailed objects is still difficult in most CAD systems. Second, sculpting has proved useful in volumetric applications. For example, scientists and physicians often need to explore the inner structures of their simulated or sampled data sets by gradually removing material.

Real-time human interaction could be achieved in this approach. Because the actions of sculpting (e.g., carving, sawing) and painting are localized in the volume buffer, a localized rendering can be employed to reproject only affected pixels. *Carving* is the process of taking a preexisting volume-sampled tool to chip or chisel the object bit by bit. Because both the object and the tool are represented as independent volume buffers, the process of sculpting involves positioning the tool with respect to the object and performing a Boolean subtraction between the two volumes. *Sawing* is the process of removing a whole chunk of material at once, much like a carpenter sawing off a portion of wood. Unlike carving, sawing requires generating the volume-sampled tool on the fly, using a user interface. To prevent object space aliasing and to achieve interactive speed, 3-D splatting is employed.

An important issue in digital sculpting is the data structure used to represent the sculpted object during and after the sculpting process. Although earlier systems employed flat 3-D arrays, multiresolution data structures, such as octrees, are better suited to capture a high level of detail where needed and at the same time to keep the memory requirements low in large homogeneous regions. Bærentzen [5] suggested the use of octrees with dynamic resolution, where nodes are inserted at different levels in the octree. Hence, there is no longer a predefined leaf level, because leaf nodes may be inserted at any level. This has two important implications:

- Nonempty homogeneous regions may be grouped together and represented by a voxel at a lower level of subdivision, thereby storing the volume more efficiently.

- Fine details may be added at a high level of subdivision, whenever they are needed to capture the local detail of the sculpted object.

A related data structure was introduced by Frisken et al. [52], who extended the work on distance volumes (see Section 41.14.1) to adaptively sampled distance fields (ADFs) for use as a fundamental graphical data structure. A *distance field* is a scalar field that specifies the minimum distance to a shape, where the distance may be signed to distinguish between the inside and outside of the shape. In ADFs, distance fields are adaptively sampled according to local detail and stored in a spatial hierarchy for efficient processing. They subsequently used an improved version of ADFs as a data structure within the Kizamu sculpting system [177], targeted to design digital characters for the entertainment industry.

41.15 Conclusions

Many of the important concepts and computational methods of volume visualization have been presented. Briefly described were surface rendering algorithms for volume data, in which an intermediate representation of the data is used to generate an image of a surface contained within the data. Object-order, image-order, domain-based, and hardware-based rendering techniques were presented for generating images of surfaces within the data, as well as volume-rendered images that attempt to capture in the 2-D image all 3-D embedded information, thus enabling a comprehensive exploration of the volumetric data sets. Several optimization techniques that aim at decreasing the rendering time for volume visualization and realistic global illumination rendering were also described.

Although volumetric representations and visualization techniques seem more natural for sampled or computed data sets, their advantages are also attracting traditional geometric-based applications. This trend implies an expanding role for volume visualization, which has the potential to revolutionize the field of computer graphics as a whole, by providing an alternative to surface graphics, called volume graphics. The emerging interactive volume rendering capabilities on GPUs and specialized hardware will only accelerate this trend.

NASA Ames Research Center

42.1 Introduction

Virtual reality, also known as virtual environments or virtual worlds, is a new paradigm in computer-human interaction, in which three-dimensional computer-generated worlds, called virtual environments, are created which have the effect of containing objects that have their own location in three-dimensional space. The user's perception of this computer-generated world is as similar to the perception of the real world as the technology will allow, providing appropriate depth and three-dimensional structure cues. User perception in virtual reality can be via a variety of senses, including sight, sound, touch, and force. Virtual environments are often, but not necessarily, immersive, providing the effect of surrounding the user with virtual objects. Objects in the virtual environment are often autonomous and/or interactive. The user interacts with the virtual environment using several interaction techniques, with a stress on direct manipulation in three-dimensional space via interface metaphors from the real world, such as grab and point, where appropriate. In order to create the effect of interactive three-dimensional objects, the virtual environment must be processed and presented at a near-real-time rate of 10 frames/s or greater. The three-dimensional perception and interaction in the virtual environment, its real-world-like interface, and its inherently near-real-time response property make virtual reality a natural interface for three-dimensional applications, including training for real-world tasks.

More precisely, we define **virtual reality** as the use of computer systems and interfaces to create the effect of an interactive three-dimensional environment, called the virtual environment, which contains objects which have spatial presence. By **spatial presence**, we mean that objects in the environment effectively have the property of spatial location relative to and independent of the user in three-dimensional space. We call the effect of creating a three-dimensional environment which contains objects with a sense of spatial presence the virtual reality effect. The essence of virtual reality can be summed up in the idea of three-dimensional "things" in the virtual environment rather than (possibly animated) "pictures of things."

We are defining virtual reality as an interface: there is no statement of content in this definition. In particular there is nothing in the definition of virtual reality which implies an attempt to mimic or otherwise create the illusion of the real world in the computer-generated environment. While some applications such as real-world task training tasks may require mimicking the real world, other applications such as entertainment or scientific visualization use environments which do not attempt to duplicate the real world.

There has been some confusion about the meaning of the phrase “virtual reality,” which some people take to be an oxymoron. “Virtual” means “having the effect of being something without actually being that thing,” while the definition of “reality” appropriate for our purposes is “having the property of concrete existence.” Thus the phrase “virtual reality” translates as “having the effect of concrete existence without actually having concrete existence.” This definition is, to some extent, actually achieved in virtual reality systems and distinguishes virtual reality from conventional computer graphics.

Virtual reality is a young, interdisciplinary, growing research field. It is not possible to survey all interesting activities in virtual reality in this short chapter, nor is it possible to detail particular technologies without this chapter rapidly going out of date. I will therefore only survey the issues that arise in the design of a virtual reality system, with an emphasis on application development. Many of the results and principles described in this article are the result of experience rather than careful study.

42.2 Underlying Principles

The virtual reality effect is attained through the use of a combination of computer and human–computer interface technologies. While the virtual reality effect can be created using any one or combination of sensory modalities including sight, sound, touch, and force, we shall illustrate the virtual reality effect using the visual modality as an example. Later we shall comment on how the same effect is created using other sensory modalities.

The effect of the spatial presence of an object is provided for the visual sense by rendering the object using conventional three-dimensional computer graphics from the current point of view of the user. **Head tracking** technology is used to measure the position and orientation of the user’s head. The computer uses this head information to compute the position and orientation of the center of each of the user’s eyes. These eye data are used to set the point of view and perspective projection for the rendering of the three-dimensional virtual scene, once for each eye to create a stereoscopic effect. The graphics is displayed to the user, optionally in stereo, in a way which allows the user to move around to get varying views of the virtual environment.

Consider the case of a single motionless virtual object in the virtual environment: while the image presented to the user changes as the user moves about, that change approximately matches the expectations of the user’s cognitive system. The result is that the user’s cognitive system interprets the changing images as a motionless object being viewed from a moving point of view. We shall call this effect **spatial constancy**. It is the spatial constancy of virtual objects which results in the object’s sense of spatial presence. The virtual scene must be rendered from the user’s current point of view with a rate sufficient to provide spatial information about objects in the environment. For purposes of spatial constancy, a rate of 10 frames/s is sufficient, though a higher frame rate is required for interaction with environments which contain rapidly moving objects. Note that at 10 frames/s the environment still appears jerky and the frames are clearly discontinuous. Experience has shown, however, that 10 frames/s is sufficient for the effect of spatial constancy. For lower frame rates the effect of spatial constancy fails and the user perceives the scene as a succession of disconnected images. In general, the human cognitive system is very forgiving about endowing objects with the property of spatial constancy: slight delays in rendering, slightly inaccurate tracking, noticeably jerky motion, and low-quality graphics do not interfere with the effect of spatial constancy.

Interaction in the virtual environment is performed through the measurement of the user’s body motions and the interpretation of that motion as intentions by the computer system. Interaction in virtual environments is very different from the transactional, discrete interaction in conventional human–computer interfaces: interaction in virtual environments is inherently continuous, typically involving

spatial manual tasks such as picking, placing, and tracking. This continuous interaction requires accurate tracking and very fast response from the computer system in order to provide the user with appropriate feedback as to the state of the interaction.

The virtual reality effect is critically dependent on the virtual reality system providing a view of the virtual environment which corresponds as closely as possible with the user's head position and orientation as the user moves about. This requirement implies that there must be a minimal graphics frame rate and that the image presented to the user must correspond as closely as possible to the user's current head position and orientation, which implies a short delay between when that position and orientation are sampled and when the resulting rendered scene appears to the user. Thus there are two performance issues critical to the success of a virtual reality system: frame rate (analogous to bandwidth or throughput) and delay (analogous to latency).

Two considerations determine the required frame rate:

- Experience has shown that for the effect of spatial constancy to operate, the virtual scene must be rendered from the user's point of view with a frame rate of at least 10 frames/s. Failure to meet the 10 frame/s requirement will result in the failure of the virtual reality effect.
- If the virtual environment contains moving objects, the Shannon–Nyquist limit requires that the user “sample,” in other words see, that virtual object with a frequency at least twice that of the highest frequency of motion of the object. In actual practice the display rate should be at least four times that of the highest frequency of motion. This puts an application-dependent lower limit on the acceptable frame rate. Further, low frame rates have a noticeable impact on the ability to perform spatial manipulation tasks (Bryson 1993, Burdea and Coiffet 1994). Failure to meet this frame-rate requirement will result in an impaired ability the user to correctly perceive motions and interact with objects in the environment.

Two considerations determine the acceptable delay:

- Delays in head tracking can result in motion or simulator sickness, as the images seen by the user do not correspond with head motion as sensed by the user's vestibular system. How strongly a given delay induces motion sickness is determined by many factors, including head motion frequency and field of view of the virtual reality display. Larger fields of view and high-frequency head motions induce greater motion sickness for a given delay. Experience has indicated that delays of 0.1 s or less are acceptable for head motions limited by reasonable frequencies and wide fields of view.
- Delays in response to hand tracking impair the ability to perform manual tasks such as pick and place and tracking. The highest allowable delay is determined by the accuracy with which tasks must be performed and the frequency of motion of objects with which the user must interact. For example, the accuracy of tracking tasks, where the user's hand must track a nonperiodic target, has been shown to depend linearly on both the delay and the target object's frequency of motion.

These considerations are summarized in the *virtual reality performance requirements*:

- The graphical frame rate (animation rate) must be greater than two to three times the highest frequency of motion of objects in the environment and in all cases must be greater than 10 frames/s.
- The end-to-end delay in response to user input must be small for interaction with objects which have high-frequency motion and in all cases must be less than 0.1 s.

The displays used in virtual reality come in several forms. The most famous form is that of the **head-mounted display**, which places a display in front of the eyes, usually a separate display for each eye. Head-mounted displays are usually worn on the head and move with the user, so the user always sees the virtual environment (though such displays are sometimes externally supported), providing a strong sense of presence. Issues that arise with head-mounted displays include comfort, image quality, and field of view and will be discussed in more detail below. *Stationary displays* are fixed displays for the virtual environment. Stationary displays may be conventional workstation screens or large projection screens, and may be vertical

or horizontal or surround the user for a sense of immersion. Stereo display is typically provided in stationary displays via a time-multiplexed stereo signal, where a polarized image for each eye is displayed alternately, with polarized glasses worn by the user determining which image gets seen by which eye.

The virtual reality effect is attained through the use of head tracking and displays to provide various cues about the user's position and orientation in a three-dimensional environment. The human factors of visual perception, particularly depth perception and personal motion cues, are critical in the successful design of the virtual environment. Human depth cues include the following:

- *Head-motion parallax*: The relative motion of objects at various depths as the user's head moves about in the environment. Head-motion parallax is performed via head tracking.
- *Plane of focus (accommodation)*: The location of the focus plane in the environment. As this chapter is written, plane of focus is not supported as a depth cue by any available virtual reality system.
- *Stereopsis*: The differences in relative positions of objects in the virtual environment as seen by the user's two eyes. Stereopsis is supported by providing a different image to each eye, either using a separate display for each eye or single display with images for each typically eye appearing sequentially in time.
- *Occlusion*: If one object blocks the view of another object, the first object is closer. Occlusion is supported by conventional three-dimensional computer graphics systems via hidden surface rendering algorithms.
- *Perspective*: The relative location of an object in the user's field of view as determined by classical perspective transformations. Perspective includes such cues as apparent size and the fact that objects that appear lower in the field of view are perceived to be closer. Perspective is supported by conventional three-dimensional computer graphics systems. Wide-angle displays significantly enhance this cue.
- *Textures*: The appearance of a known texture at different depths gives strong depth cues. Textures are supported by higher-end conventional three-dimensional computer graphics systems.
- *Atmospheric effects*: Blurring and fog effects due to distance. Atmospheric effects are supported by higher-end conventional three-dimensional computer graphics systems.

Self-location and *self-motion* cues are dominated by perception of the object's motion in the user's peripheral field. Thus wide-angle displays significantly enhance the sense of location and the accurate detection of self-motion in the virtual environment.

Hand tracking supports interaction in the virtual environment. Hand tracking takes two forms: position and orientation tracking and gesture (command) tracking. Position and orientation tracking is performed with much the same technology as that used in head tracking. Gesture tracking is performed via a variety of technologies: buttons are often used for a small number of gestures, while measurement of the user's finger joint angles can be used to infer the hand gesture that the user is performing. This hand gesture can then be interpreted as a command to the system. An example is the interpretation of a closed fist as a "grab and move" command. The user's finger joint angles are measured via an instrumented glove-type device.

An understanding of the human factors of manual interaction is critical in the successful design of a virtual environment. One basic result is *Fitts' law*, which states that the shortest time to reach an object is proportional to the log of the ratio of the object's distance to its size. Another result is in the study of manual tracking of a randomly moving target. If error is measured as the mean square distance from the target to the location of the user's cursor, that tracking error is:

- Linearly dependent on the frequency of motion of the target, with target motion frequencies greater than 5 Hz being essentially untrackable
- Linearly dependent on end-to-end delays between the user's motions and the resulting motions of the user's cursor
- Linearly dependent (according to preliminary results) on the inverse of the frame rate of the display, even when the display is completely up to date when first shown

Thus for manual tracking errors depend on both delay and frame rate. As any realistic virtual reality system will have both delays and a finite frame rate, applications which require manual tracking should have frame rates which are as high as possible and delays which are as small as possible.

The virtual environment may appear at many scales: Application requirements entirely determine the scale at which objects in the environment should appear. Some applications, such as real-world simulations or training applications, will have a naturally fixed scale. Other applications, such as a molecular structure application, will naturally have the scale set so that very small objects will appear very large. Other applications will have no natural environment scale at all, leaving the scale setting up to the user.

The above observation about scale generalizes to all aspects of the virtual environment: while virtual reality uses metaphors from the real world in the design of environments, there is no need beyond application requirements for behavior in the virtual environment to match behavior in the real world. Virtual reality applications can be tailored to perform tasks which would be either more difficult or impossible in the real world. Thus effective performance of application tasks should be the guiding principle in virtual environment application design. This focus on the application task as the guiding design principle has led to the abandonment of a conventional interface layer such as the menus and sliders in conventional graphical user interfaces. As this chapter is written it remains to be seen if another layer of conventionality will appear in virtual reality beyond the basic “pick up and move” metaphor of the direct manipulation interface. The desire for a conventional interface is at odds with the opportunity for the creation of application-specific objects which also act as interface objects.

A significant variation on virtual reality is *augmented reality*. In augmented reality the virtual environment is superimposed on the real world. Augmented reality uses either see-through displays, which place the virtual environment in a semitransparent window on the real world, or mixing of video images of the real world with computer-generated images of the virtual world. The dominant application of augmented reality is *information overlays*, which display information about the real world in the virtual environment. These information overlays may match the three-dimensional position and orientation of real-world objects. This matching of virtual and real objects requires very high accuracy in the tracking of the user's position and orientation as well as models of real-world behaviors. In this chapter we shall treat augmented reality as a subset of virtual reality.

42.3 Best Practices

42.3.1 Display of the Virtual Environment

One of the guiding principles of virtual reality is to provide the same types of information about the virtual environment as are available for the real world. Thus there are several sensual modalities used to present the virtual environment, including visual, auditory, and haptic (touch and force) displays.

42.3.1.1 Visual Display

Visual display is one of the most important components of a virtual reality system. There are a number of quality considerations which arise in the selection of a visual display for virtual reality. In addition to the usual display quality considerations from conventional graphics such as color, contrast, brightness, and refresh rate, the following issues arise in virtual reality displays:

Resolution: Defined as the angle subtended by a pixel as viewed by the user. Note that this sense of resolution is very different from the conventional sense used in computer graphics. Resolution will be determined by the pixel spacing on the screen and field of view as determined by the optics. A rough estimate of the angular resolution of a pixel can be obtained by dividing the horizontal field of view by the number of pixels in the horizontal direction.

Pixel spacing: Many screen technologies, such as shadow-masked color cathode-ray tubes and liquid-crystal displays, have significant space between the pixels. This space is magnified by wide-field optics and can significantly deteriorate the image.

Field of view: A strong determinant of the immersiveness of a display. The field of view is determined by the physical screen size and the optics.

Optical quality: Because head-coupled displays are very close to the eyes, they require optics to provide a focused image. These optics also determine the field of view and may induce strong optical distortion.

There are a variety of display technologies available which are appropriate to virtual reality. They fall roughly into two classes: **head-coupled**, which move with the user's head as the user moves about, and stationary, which do not. Head-coupled displays place a screen in front of each of the user's eyes, and are often head-mounted, rigidly attached to the user's head. Head-coupled displays provide a strong sense of immersion, because the user sees the virtual scene no matter which way the user's head is turned. Head-mounted displays require focusing optics, which can often provide a wide field of view. Some head-mounted display designs use folded optics to provide a more balanced design. Augmented reality displays often use a half-silvered mirror for display, allowing the virtual scene to be overlaid on the real world.

A significant issue for displays is ergonomics, particularly user comfort. Head-mounted displays can be uncomfortable, leading to rejection by the user community. Stationary displays provide both enhanced comfort and a sharable experience, but at the cost of immersiveness. Which display is chosen will generally depend on the application requirements.

42.3.1.2 Audio Displays

Sound output is an important modality of display in virtual reality. There are roughly two levels of sophistication of sound output: non-spatially-localized (possibly stereo) and three-dimensional spatially localized sound display.

Non-spatially-localized sound display involves using conventional sound rendering techniques, such as sampling and waveform synthesis, to provide nonspatial sound cues such as those found in conventional graphics applications. Nonspatial sounds are typically used to provide feedback as to the occurrence of events such as object collision in the virtual environment and (potentially) data display by varying the characteristics of a continuous sound.

Three-dimensional spatial sound uses various techniques to render sound whose source has a perceived location in three-dimensional space. This sound source location may or may not correspond to a visual or haptic object at the same location in three-dimensional space. Spatially localized sound provides the cues used by the human auditory perceptual system, which are interpreted as the sound source being located in three-dimensional space. These cues include variations in volume from ear to ear, phase differences due to the time difference between when the sound arrives at the two ears, and the distortion of the sound due to the structures on the exterior of the human ear (pinnae).

The simplest method of providing three-dimensional spatially located sound is to surround the user with an array of speakers. A particular sound source is given a perceived spatial location by appropriately balancing the volume of that sound from each speaker, taking into consideration the user's head position as measured by the head-tracking technology. The use of multiple external speakers provides appropriate volume to the user's ears, though the other cues are not well provided.

A more sophisticated method provides spatially localized sound via headphones and appropriate signal processing of the sound source (Begault 1993). Careful measurements are made of the differences in volume, phase, and sound distortion by placing a small microphone in a human ear while moving a sound source about in space. These measured parameters are stored, associated with a location in space, and used to construct a convolution function as a function of three-dimensional position relative to the user. When a new sound is generated and associated with a three-dimensional location in the virtual environment, the convolution function modifies that sound for each ear in the same way that the sound would be modified as it reached the ear from a real-world sound source.

42.3.1.3 Haptic Displays

Haptics refers to the senses of force and touch. Haptic displays use various types of hardware to provide force or touch feedback when the user encounters an object in the virtual environment. At the time this chapter is written, haptic displays are highly experimental, with few commercial products available. Haptic displays are covered more thoroughly in Burdea and Coiffet (1994). The comments in this section are highly provisional and reflect an active research topic.

The primary purpose of haptic displays is to give the user the effect of “touching” objects in the virtual environment. The experience of touching an object in the real world is extremely complex, involving the texture of, temperature of, vibration (if any) of, and forces exerted by the object. Reflecting this complexity, haptic displays fall into two classes:

- *Surface displays*: including texture, vibration, and temperature displays
- *Deep displays*: including force displays such as pneumatic robotics, compressed air actuators, and “memory metal” devices

Surface displays have been very difficult to build. The most common texture displays have typically involved small pin-type actuators, which are raised or lowered to give the effect of a smooth or rough surface, much like a graphical bitmap. Small vibrators and heat elements mounted in the fingertips of gloves have been used as a substitute for texture display with marginal success.

Deep displays involve exerting some kind of force on the user, the technology for which is well developed in the field of robotics. Thus deep displays are a good deal more mature than surface displays. As a general rule, the larger the force and the volume over which that force is to be exerted, the more difficult and cumbersome the haptic technology will be. As of this writing, a commercial product is available which delivers good force feedback to the fingertip over a volume about 0.5 m on a side.

There are two dominant technologies for force displays:

- Pneumatic actuators, used for whole-arm or whole-body forces. Pneumatic actuators tend to be very powerful but very cumbersome.
- Stepper-motor-based actuators, with the motors connected either directly to the actuator’s lever arm or to a collection of strings or wires. Motor-based actuators tend to be smaller and more usable but have a smaller range of forces and a smaller working volume.

42.3.2 Position Tracking

There are two classes of tracking technologies: position and/or orientation trackers and angle trackers. Position and/or orientation trackers typically provide the position and/or orientation of an object at a single point in three-dimensional space. Angle trackers provide the angle between two different objects. Position and orientation sensors are typically used to track the user’s head and hand, while angle sensors are usually used to track the angle of bend of a body joint such as the user’s fingers.

42.3.2.1 Position Tracker Data

The data returned by position and orientation trackers fall into two classes: position and orientation. Position data are usually a three-dimensional vector relative to some known reference location. Orientation data are somewhat more complex, owing to the fact that three numbers are not sufficient to describe all orientations in three-dimensional space. Three numbers are sufficient to describe all but two orientations (which two depend on the type and coordinate system of the orientation data), while four numbers are required to describe all orientations. Another option is to use the matrix description of an orientation, which requires nine numbers. There are three common methods of describing orientations:

Euler angles use an ordered triple (roll, pitch, yaw) of numbers: *roll* = rotation around the front-facing axis; *pitch* = rotation around the (new) horizontal axis; and *yaw* = rotation around the (new) vertical axis. Note that these rotations are concatenated. Because they describe rotations

using three numbers, Euler angles do not describe all orientations: there are two orientations, characterized by pitch = $\pm 90^\circ$, which are not correctly described by Euler angles. When the tracker is placed in one of these orientations, the tracker is said to be in *gimbal lock*.

Rotation matrices are 3×3 matrices, which describe the rotation of an object. Rotation matrices are standard in conventional computer graphics and are described in (Foley et al. 1990).

Quaternions are an ordered quadruple (w, x, y, z) of numbers which describe all orientations. Physically, quaternions represent a rotation of an angle given by $\arcsin(w/2)$ around the axis specified by (x, y, z) . In actual use, quaternions are usually translated to rotation matrices using the following formulas:

$$\begin{pmatrix} 1 - 2y^2 - 2z^2 & 2xy + 2wz & 2xz - 2wy \\ 2xy - 2wz & 1 - 2x^2 - 2z^2 & 2yz + 2wx \\ 2xz + 2wy & 2yz - 2wx & 1 - 2x^2 - 2y^2 \end{pmatrix}$$

Quaternions avoid the gimbal-lock problem and require smaller amounts of data storage than rotation matrices.

42.3.2.2 Position Tracker Technologies

There are a variety of tracker technologies which return position and/or orientation in three-dimensional space. Each of these technologies has its strengths and weaknesses:

- *Electromagnetic trackers*: Electromagnetic trackers use a source containing three orthogonal coils to sequentially produce three oriented radio-frequency electromagnetic fields, each component of which is read by three orthogonal coils in a sensor. These measurements result in nine numbers providing the strength of each of the three fields in three directions, which are used to reconstruct the position and orientation of the sensor relative to the source. Electromagnetic trackers do not require a clear line of sight from the source to the sensor, making them useful for both head and hand tracking, and are readily available commercially. Electromagnetic trackers have limited range (typically 1 to 3 m as of 1996) and are susceptible to electromagnetic distortion and noise in the physical environment, particularly from display monitors.
- *Acoustic trackers*: Acoustic trackers use an ultrasonic sound pulse, which is picked up by an array of receivers. The time of flight of the sound pulse from the source to each receiver is used to reconstruct the position and orientation of the receiver array relative to the source. Acoustic trackers are inexpensive and commercially available. They require a clear line of sight from the source to each receiver, limiting their operational envelope and making them potentially inappropriate for hand tracking. They are, however, appropriate for head tracking when using a stationary desktop display, where the user is physically always looking at a desktop display monitor so that line of sight is assured. Acoustic trackers have a limited range (1 to 2 m) and are very susceptible to acoustic noise and echoes in the physical environment.
- *Mechanical linkage trackers*: Mechanical linkage trackers use a jointed physical structure for position and orientation tracking. These structures have appropriately situated joints, each of which has an angle sensor. By measuring the angle of each joint and knowing the length of each segment, the position and orientation of the end relative to the base of the jointed structure can be determined. Mechanical linkage trackers have the advantage of very high accuracy, allowing a minimum of filtering, resulting in low delays. They have the disadvantage of a usually cumbersome physical structure which can get in the way of task performance.
- *Video tracking*: Video tracking uses multiple video cameras to track objects in the physical space, usually targets placed on the user's head and hands. The location of these targets is identified on the video images, and these image locations are used to reconstruct the three-dimensional position of the targets relative to the cameras. Orientation can be inferred by using multiple targets. Video tracking has the advantage of providing a very fast, accurate signal. It has the disadvantage of

requiring a clear line of sight from camera to target, and so is more suited for head tracking than hand tracking in general circumstances. Other disadvantages include the complexity of the camera and video processing setup.

- *Inertial tracking*: Inertial tracking uses gyroscopes and accelerometers to measure the accelerations of the tracker, which are integrated to provide the position, orientation, and velocity. The primary advantage of inertial tracking is that it does not rely on the proximity of source and sensor and so can in principle track over very large volumes. The disadvantage is that errors in the acceleration measurements accumulate over time. As of 1996 practical accelerometers result in errors which become unacceptable within 30 to 60 s, so inertial tracking will not be further discussed here.
- *The global positioning system*: The global positioning system (GPS) is a system of satellites used for navigation. While the simplest civilian use of GPS results in position inaccuracies of a few meters, the use of *differential GPS*, which uses a GPS receiver in a known location to correct for errors in other, nearby moving GPS receivers, can provide accuracies of a few millimeters. This technology is experimental as of 1996 but shows great potential for many virtual reality applications.

42.3.2.3 Position Tracker Errors

There are two types of errors associated with trackers:

Static error: The difference between the actual position of the tracker and the position returned by the tracking system. Static error occurs in both position and orientation and is typically a function of the position of the tracker. A position error datum is typically a three-dimensional vector. Limits on the magnitude of this vector are usually provided by the tracker manufacturer. Orientation error data are usually expressed in terms of Euler angles, with limits on the error components provided by the tracker manufacturer. The source of static error will depend on the tracker technology.

Dynamic error: The difference between the history of the actual tracker position over time and the position data returned by the tracker system. The dominant sources of dynamic error are delays due to the time required to process the hardware tracker data and due to filtering to eliminate noise in the tracker signal. A second source of dynamic error is the suppression of high frequencies of motion due to the filtering. The hand and head, however, rarely have significant frequencies of motion above 5 Hz, and most filters do not suppress frequencies in this range.

42.3.2.4 Error Correction

Tracker errors can be corrected when a model of what the signal should be exists. The specific methods depend on whether the correction is to static or dynamic error.

- Static-error correction can be performed when the error is approximately static over time by directly measuring the error by taking tracker data at a known location and building a lookup table of error values indexed by measured position. The error at a given measured position can then be interpolated from the error table and added to the measured position.
- Dynamic-error correction requires a model of the motion of the tracker sensor. Such models are available for head tracking and are based on models of head motion supplemented by a noise factor. Such models are usually implemented via Kalman filters.

42.3.2.5 Using Head Tracker Data

Head tracker data are usually converted into a 4×4 homogeneous matrix containing both position and orientation information, inverted and multiplied onto the transformation stack of the geometry engine rendering the virtual environment. If V is a vertex to be rendered, and M_{head} is the 4×4 position and orientation matrix describing the user's head, then the transform of V is given by $M_1 M_2 M_3 \cdots M_n M_{\text{head}}^{-1} V$, where $M_1, M_2, M_3, \dots, M_n$ are the various local transformations of V .

42.3.2.6 Using Hand Tracker Data for Direct Manipulation

Hand tracker data are used for either selecting or picking up and manipulating an object. There are several methods of selecting an object using hand tracker data:

- *Pointwise collision*: The user's hand position is represented by a simple point, the location of the hand tracker. Alternatively, when finger joint angle information is available, the point may be the tip of one of the user's fingers. An object is selected when that point is within a specified distance from the object.
- *Geometrical collision*: A geometrical model of the user's hand is constructed and used to detect polygon-by-polygon collisions with objects in the virtual environment. This type of selection is more compute-intensive but can more accurately mimic real-world object grasping.
- *Raycasting*: A ray is drawn from the user's hand position in a direction determined by the orientation of the user's hand and finger joint angles (if they are measured). If this ray intersects an object in the environment, then that object is considered selected.

Once an object is selected, it may be "picked up" and moved about by the user's hand. Following Robinett and Holloway (1992), this picking-up operation is performed by constraining the object's local transformation to be held constant relative to the user's hand transformation as that hand transformation changes. Let the hand transformation relative to the world coordinate system be M_{hand} , and let M_{object} be the object transformation relative to the world coordinate system. Then the orientatin of the object relative to the hand is $M_{hand}^{-1}M_{object}$. If M_{hand}^{old} is the matrix from the last measured transformation of the hand or object, then, given a new hand transformation, the new object transformation is given by

$$M_{object} = M_{hand}M_{hand}^{old}{}^{-1}M_{object}^{old}$$

42.3.2.7 Gesture Recognition

Many virtual reality systems measure the finger joint angles of the user's hand. These finger joint angle data can be used to infer user commands based on hand gestures. There are two types of hand gestures: static and dynamic. In both cases gesture recognition is a problem of pattern recognition: recent or current measured hand data are matched against values which define a gesture.

A static gesture is defined as a particular configuration of the finger joint angles. The configuration is identified by demanding that each finger joint angle fall within a specified range. For example, the "fist" gesture may be defined as all finger joint angles greater than, say, 60° . When detected, the application may interpret the fist gesture as a "grab and move" command. The use of many static gestures implies that the matching ranges are small, which makes recognition more sensitive to errors in the joint angle data.

Dynamic gestures are defined by the recent history of the finger angles and the hand position and orientation. The pattern recognition problem for dynamic gestures is complex and subtle and is best addressed by neural network techniques.

The measurement of finger joint angles takes place via a variety of technologies, including optical fibers which have been degraded so that the transmitted light is attenuated when the fiber bends, strain sensors which provide the strain on the sensor as the sensor is bent, and direct angle measurement via optical encoders or variable resistors. All of these technologies require calibration, which will depend on the details of the technology and the way in which the sensors are mounted on the hand. The sensor mountings vary from individual to individual and vary over time as the user's hand moves, introducing errors of as much as 10° into the calibration.

Significant issues arise in the definition and interpretation of gestures. While gestures are common in the real world, they are mostly nonconventional with different individuals making the "same" gestures differently. One guiding design principle is to reserve hand gestures for manual tasks such as pick and place, implying two conventional gestures: "fist" for picking up and moving objects, and "point with index finger" for selecting objects. Such use of small numbers of gestures allows large pattern-matching ranges and relative insensitivity to joint angle measurement errors.

FIGURE 42.1 Classification of tasks.

42.4 Software Architectures

Because virtual environments are computer-generated, the software architecture used to maintain and operate the environment is of very high importance. The virtual reality performance requirements of frame rates greater than 10 frames/s and delays less than 0.1 s demand very high performance in terms of all tasks that must take place for the presentation of the virtual environment. We shall classify these tasks as shown in Figure 42.1.

First the user state is read, typically measuring head and hand position and orientation and command gesture. Then the environment state is computed. In some applications such as simple environment walkthroughs with static environment contents, very little computation may take place. Other applications may require a great deal of computation, which may include data access from mass storage or network communications. One example is a complex walkthrough with moving environment objects, which requires scene culling and other graphics optimization calculations. Another example requiring large amounts of computations is a visualization application, in which the large amounts of computation may result from the movement of an object in the environment, and may include access to large amounts of data from mass storage or a network.

After the environment is computed, it is rendered from the user's point of view as measured by the head tracking technology. In applications which contain a large amount of computation, the computation times may not satisfy the virtual reality frame-rate requirement of greater than 10 frames/s. In addition, the user's head may move, requiring a re-rendering of the virtual environment from the new point of view even if the environment contents have not changed. User data obtained at the start of the computation phase will be out of date by the time the rendering phase starts if the rendering waits for the computation. This delay may violate the virtual reality delay requirement of less than 0.1 s. The use of out-of-date head tracking data for rendering will result in a swimming image, which typically induces motion sickness.

For these reasons, it is highly desirable to decouple the computation and rendering phases of the virtual environment, allowing the rendering process to run as fast as it can using the most recent head tracker data. This is accomplished by using one process for the rendering and another for the computation. The most efficient architecture is to have these processes on a single hardware platform implemented as lightweight processes communicating via shared memory, an architecture supported by many workstation vendors. Another option is to have the processes on separate platforms communicating over a network. The rendering and computation processes may themselves be multiple processes. The user data may be read in the rendering process, communicating the user data to the compute process, or the user data may be read in an additional process. An example using shared memory and reading the user state in one process is shown in [Figure 42.2](#).

42.4.1 Polling vs. Events

There are two types of user input for the control of the virtual environment: discrete commands, and continuous motions such as those that arise when directly manipulating an object. This distinction is reflected in the choice of software architecture used to access the data from the interaction hardware. Discrete commands have the property that they must be executed in the order in which they were given by the user. Continuous commands for direct manipulation have the property that they should minimize delay, so that,

FIGURE 42.2 An example using shared memory and reading the user state in one process.

for example, the position of the user’s hand is reflected as accurately as possible (up to specified coordinate transformations) by the position of the environment object showing the position of the user’s hand.

We define the *event* interaction architecture as a queue of commands which is read by the application program. Commands may be put on this cue in response to hardware interrupts, polling by a deeper level of the software, or some other method. For our purposes the principal property of an event queue is that it preserves the history of the command sequence, ensuring that commands appear on the queue in the order in which they were given by the user. For a wide class of discrete commands, event queues are critical for the correct execution of user commands. Event queues, however, introduce delays and have no built-in sense of simultaneity.

Direct manipulation requires that the scene presented to the user reflect, as closely as possible, the state of the user at the present time, with no sense of history. Polling offers an effective method of taking a “snapshot” of the user’s current state. Sampling the user data just before they are used minimizes delays. Simultaneity in the virtual environment can be defined as a single poll of all interaction devices.

42.4.1.1 Time-Critical Structures

Meeting the virtual reality frame-rate requirement can be a challenging aspect of virtual reality application design. This challenge is made more difficult by the often unpredictable nature of the virtual environment contents and activities, particularly in application environments which allow many user options. In many cases, applications may naturally take more computation or rendering time than the virtual reality frame-rate requirements would allow. In such cases algorithms must be built into the application which determines how much time is available and perform the application task as well as possible in that time. The result is typically a “graceful degradation” of the quality of the application for the purpose of maintaining virtual reality frame rates and responsiveness. While at first sight such degradation may seem to be highly undesirable, many users have indicated a clear preference for increased responsiveness at the cost of quality, so long as the loss of quality is appropriately understood. Designing algorithms which meet a specified time budget and a software architecture which supports these algorithms is known as the problem of *time-critical structures*. Time-critical structures falls naturally into two classes: *time-critical rendering* and *time-critical computing*.

42.4.1.2 Time-Critical Rendering

The time requirements of a rendering process depend on the method of rendering used, but for most graphics architectures this time has two components: the vertex projection rate, or the time required to compute the screen coordinates of a three-dimensional vertex, and the pixel fill rate, or the time required to fill in a solid object in screen space such as a polygon. Given a particular graphics architecture, the vertex projection time is determined primarily by the number of vertices that must be rendered, which is related to the scene complexity and the way in which the vertices are rendered (an object built out of disconnected triangles will have to render more vertices than the same object built out of triangle strips). Conventional methods of reducing the number of vertices to be projected include optimization techniques such as scene culling, so that only vertices that are potentially visible to the user are sent to the graphics system, and the

use of triangle and rectangle strips. These techniques do not degrade the quality of the virtual environment and should be used regardless of the time budget, so they are not considered time-critical. The pixel fill rate is determined in part by the shading algorithm used, including the lighting conditions. Phong shading, for example, results in a slower rasterization than Gouraud shading, which is slower than flat shading.

Time-critical rendering techniques may use, for example, changes in scene complexity to limit the number of vertices and changes in lighting or in shading algorithm to affect the pixel fill rate. All of these choices can result in variations in scene quality, so they must be designed and implemented with great care. The appropriate choice of these parameters can be made through the use of cost and benefit functions for the rendering of an object (Funkhouser and Sequin 1993). The cost is roughly measured by the time required to render the object, while the benefit is related to such parameters as the object's size on the screen, whether the object appears in the center of the user's field of view is measured by head tracking, the state of motion of the object, and direct indications by the user. The benefit function measures the desirability of a certain object complexity, measured in terms of polygons, in a particular circumstance. The characterization of the benefit function is an area of ongoing research. Given cost and benefit functions, time-critical rendering becomes the problem of assigning a time budget to each object so that the ratio of total benefit to total cost for all time-critical objects in the environment is maximized. The most common way of varying the cost of an object is by reducing the number of vertices in the object, usually performed by selecting among several precomputed representations of the object at varying levels of detail.

42.4.1.3 Time-Critical Computing

Time-critical computing is the problem of designing computational algorithms which meet a specified time budget by degrading the quality of the output of the computation. As the computations that take place in an application are very application-dependent, time-critical algorithms will be very application-dependent. We will therefore confine ourselves to general comments, illustrated by a few examples.

When the results of the computation do not change very much from frame to frame, the results of a given frame's computation can be used to estimate the cost and benefit of an object in the next frame. Great care must be used, however, when determining what to do if the computation is too costly. For example, objects are of interest if they appear in the user's field of view and are not of interest if they are not. If the computation determines the motion of the object, that computation must be accurately performed in all frames to determine if the object appears in a later frame.

The cost of a computation can be controlled in a variety of ways depending on the computation algorithm: solutions of differential equations can be chosen for higher speed at the cost of accuracy; the computation of extended objects can be truncated after an allotted time; and linear approximations to more complex behavior can be implemented.

42.4.2 Navigation

At its most basic, navigation is the problem of controlling the user's point of view in the virtual environment. Head tracking is used for navigation over small distances and for controlling the orientation of the user's viewpoint. The effective envelope of head tracking is determined by the technology used to track the user's head. Many virtual environments are, however, considerably larger than the useful envelope of the head tracker. In these cases a method must be devised to allow the user to "move about" over large distances.

Movement over distances greater than those supported by head tracking is typically implemented by the addition of an additional transformation which determines the relationship of the head tracking coordinate system to the virtual environment's graphical world coordinate system. Changing this new transformation has the effect of moving the user's point of view as if the user were in a vehicle, so we call this new transformation a *vehicle transformation*. As navigation via head tracking is a well-understood problem, we define the problem of navigation as that of controlling the vehicle transformation. Several methods of controlling the vehicle transformation have appeared in various virtual reality systems:

- *Point and fly*: A three-dimensional orientation tracking device, usually a hand tracker but sometimes the head tracker, is used to indicate a direction in space. When the appropriate command is given,

usually through a hand gesture or a button press, the vehicle transformation is translated in the indicated direction, resulting in the effect of flying through the scene. Variations on this method include using a continuous parameter such as the distance from the hand to the body or the angle of bend of a finger when using a dataglove-type device to control the speed of motion. Joystick-type devices can also be used to control both the speed and direction of motion. The primary advantage of the point-and-fly navigation method is its intuitive nature. Its primary disadvantages are poor control and the time required to travel large distances.

- *Teleportation*: When the desired location is known, the vehicle transformation can simply be set to that location. This location can be accessed from a list, indicated by a direct command, or indicated using a miniature representation of the virtual environment. This method has the advantage of speed and the disadvantage of a practical limit on the number of available target locations.
- *Direct manipulation of the environment space*: Rather than creating the effect of the user moving through the environment, limited navigation can be accomplished by providing the effect of the user moving the environment itself. One implementation is to use a hand tracking device to “grab open space,” which results in the vehicle transformation being changed by the inverse of hand manipulations. This move may allow the user to control both translation and orientation of the environment. Repeated moves allow the user to manipulate the environment over moderate distances. The advantage of this method is accurate control over the destination of the navigation move and easy control over the orientation of the environment. The disadvantages include a limited operating range.
- *Variable scale*: This method solves the navigation problem by using a scale factor in the vehicle transformation to shrink the virtual environment so that everything in the environment is within the effective envelope of the head and hand trackers. The hand tracker can then be used to indicate a new desired location, which determines the origin of subsequent scale operations. When the scale is increased again, it is around the new origin at the desired destination, so the user has the experience of ending up at the desired location. Variable scaling is best suited for applications which do not have a preferred scale. This method has the advantages of rapid operation over potentially very large distance scales, and fine control at a user-selectable scale. The disadvantages include the complexity of the navigation operation (scale, select new location, scale).
- *Manipulation of miniatures*: This method uses a miniature model of the environment which contains a representation of the user. Direct manipulation of the user’s representation in the model controls the vehicle transformation, resulting in the effect of the user moving to the representation’s location in the full-scale environment. It has been found (Pausch et al. 1995) that the most effective and least disorienting way of setting the vehicle transformation using the miniature is to interpolate the vehicle transformation between its original scale, orientation, and translation and that of the representation in the model. This results in the user’s experience of the modeling expanding to become the full-scale environment seen from the desired new location and orientation (or equivalently the experience of zooming into the model). This method is appropriate for applications which have a preferred scale, such as an architectural walkthrough. Manipulation of miniatures has the advantage of an intuitive and simple control interface. The disadvantages include the requirement of the model of the environment and the limitations to effective navigation over varying scales using the limited scale of the model.

42.4.3 Virtual Objects

Careful design of the objects in the virtual environment is critical to implementation of a successful application. Such objects fall roughly into two classes:

- *Application objects*: Objects which are directly related to application tasks. These objects will have properties and behaviors directly relevant to the application task. Interaction with these objects will depend on the individual object and its task.

- *Interface objects (widgets)*: Objects which exist solely for user control of the environment. Interface objects can provide a layer of a conventional interface between applications. Extensions of conventional graphical user interfaces such as menus and sliders inserted into the virtual environment are examples of interface objects. Using raycasting to select menu items (Jacoby and Ellis 1993) has been shown to be a fruitful implementation of menus in the virtual environment.

Some interface objects will be intimately connected to the application, so the distinction between application and interface objects can become very weak.

The extensive use of direct manipulation in the virtual environment raises the issue of arm fatigue: constantly holding the hand in front of the face when performing extended tasks can be tiring. For non-see-through displays, where the user's physical hand is not visible, one solution to the fatigue problem is to offset the hand cursor from the actual hand position so that when the hand is held low by the user's side the cursor appears in front of the user's face in the virtual environment. Experience has shown that people adapt very quickly to such offsets and these offsets do not impair task performance.

Many objects in the virtual environment will be autonomous, with behavior reflecting such things as simulated physics, information displays, or (in the case of simulated humans) complex volition. The maintenance of autonomous objects and their interactions with the user and other objects can place significant computational burdens on the virtual environment. Such autonomous behaviors will be highly application-dependent and will take advantage of the behavioral modeling literature from conventional computer graphics (Foley et al. 1990).

42.5 Environment Design Concepts

The ability to tailor a virtual environment for an application combined with the lack of a conventional interface layer makes the design of the virtual environment a challenging task. The use of metaphor in the design process has proven to be a useful guide. For our purposes a *metaphor* is a mapping from an application task to a task which is well understood by the user. The design of the virtual environment should be driven by the application, with metaphors from the application domain as the guiding design principle.

Metaphors in the virtual environment can appear at several levels:

- *Overall environment metaphor*: What is the driving metaphor of the application? How does that metaphor determine the overall appearance of the environment? The overall environment metaphor may include user navigation metaphors.
- *Object interaction metaphors*: What is the metaphor for interaction with objects in the virtual environment? There may be several classes of objects, with each class having its own metaphor. For example, an environment may have application objects which are picked up and moved and fall when they are released. The same environment may also have interaction objects which can also be picked up and moved but do not fall when released.
- *Individual object metaphors*: Individual objects in the environment may have their own metaphors which determine their appearance and behavior. A data display object may have a numerical appearance, while a training simulation object may faithfully mimic a real-world object.

When considering all of these levels of metaphor, the following questions should be asked:

- *Is there a metaphor intrinsic to the application?* An example of an intrinsic overall environment metaphor is "walking about the interior of a building" for an architectural walkthrough application. An example of an intrinsic object metaphor is a bat in a virtual baseball application.
- *Is there a metaphor from the language of the target user community?* The user community for the application may have conventions which can be the basis for design metaphors. These metaphors need not be understood by people outside the target user community. A common example of such conventions is the use of menus, sliders, and buttons for user interfaces.

42.6 Distributed Virtual Reality

The implementation of a virtual reality application distributed across several hardware platforms is an important capability, allowing physically separated users to share an environment in a collaborative setting and allowing remote access to large, high-capability systems. The virtual reality performance requirements of greater than 10 frames/s and delays of less than 0.1 s put extreme demands on the network systems involved in such distribution.

Several issues arise in the design of a distributed virtual environment:

- *Network capability*: Primarily the network's bandwidth and latency characteristics. Local area networks (LANs) have typically higher capability than wide area networks (WANs), as LANs usually have a higher bandwidth and lower latency. WANs will have latencies which will generally increase as more nodes are traversed.
- *Minimizing network traffic*: The amount of traffic involved in the operation of the virtual environment should be minimized. This is usually accomplished by transmitting only changes in the environment. Further minimization can be attained when environment changes can be modeled by each system. For example, when the position and velocity of, and forces acting on, an object are known, that object's motion can be predicted so long as no other force acts on that object. In this case only changes in the forces acting on the object need to be transmitted, avoiding constant messages indicating changes in position of the object.
- *Scaling with number of participants*: Some applications are designed for only a small number of participants, while others are designed for an unlimited number of participants. Architectures such as client-server and peer-to-peer unicast that require sequential maintenance of each participant will not have good scaling behavior. Multicast network protocols alleviate this problem somewhat. The NPSNET system (Macedonia et al. 1995) takes advantage of locality information, building multicast groups out of participants which are near each other in the virtual environment. In this case participants who are not near each other are assumed to be far apart.

There are several models of distribution that can be used for virtual reality:

- *Client-server*: In a client-server architecture the environment is maintained on a single computer system (which may itself be distributed over several components), with the state of the environment sent to client workstations which display the environment to the users. As the environment is maintained by a single system, issues of consistency are easily dealt with. User interactions are transmitted to the server, where they are interpreted and change the state of the environment.
- *Peer-to-peer*: In the peer-to-peer architecture, all systems maintain a model of the environment and changes in the environment are sent to each of the other systems. The messages may be sent to the other systems individually by address or via a multicast network message.

A natural issue that arises in any distributed application is that of standards. The lack of standard user interfaces and behaviors in virtual environment design impedes the implementation of standards for distributed virtual environments. Standards have been adapted for particular applications, most notably the Distributed Interactive Simulation standard developed for military simulators. Standards for three-dimensional graphics have also been applied to virtual reality. The Virtual Reality Modeling Language (VRML)(Pesce 1995) is one notable example of a graphics standard, which at the time of this writing is being extended to include simple behaviors.

42.7 Application Evaluation and Design

Virtual reality is based on a paradigm of highly responsive, inherently three-dimensional interaction and display. While this virtual reality paradigm can be highly advantageous when appropriately used, meeting the virtual reality performance requirements can be very difficult to achieve in a real application

setting. Further, the new interaction concepts of virtual reality combined with the unusual and often flawed hardware interfaces can impede the acceptance of a virtual reality application by the target user community. Thus careful consideration must be given to the following two questions: “Is virtual reality valuable to the application?” and “Is virtual reality viable for the application?” We shall briefly consider approaches to these questions. As with all application design processes, we strongly recommend that input from the target user community be used when addressing these issues.

Is virtual reality valuable for the application? Virtual reality interfaces use inherently three-dimensional interaction and display technologies and concepts. Therefore a virtual reality interface is appropriate to an application if that application has a three- (or more-) dimensional spatial aspect. Classes of examples include: simulations of real-world activities, objects, experiences, or phenomena; abstract simulations such as scientific visualization; abstract experiences for artistic or entertainment purposes; or information displays which can be usefully mapped into a three-dimensional environment such as networking visualization. Examples of classes of applications which would probably not directly benefit from a virtual reality interface include: text-based applications; inherently two-dimensional applications such as image processing (though some image-processing techniques benefit from a three-dimensional representation); and applications which have no inherent spatial display content.

The value of a virtual reality interface for a particular application can be estimated in more detail by considering display and interaction separately:

- *Display: How would the three-dimensional display be used? What would be the role of head tracking?* These questions can be addressed by sketching out the expected appearance of the application environment as experienced by the user, including considerations of how the user would move about in the environment.
- *Interaction: How would the three-dimensional interaction capabilities be used? What is the role of direct manipulation?* These questions can be addressed by identifying representative application tasks that require three-dimensional interaction and sketching out how these tasks are performed.

If the answers to these questions are positive, then a virtual reality interface is probably useful to the application.

Is virtual reality viable for the application? Once the value of a virtual reality interface for an application has been established, it must be established that it is possible to implement that application in a way consistent with both the virtual reality performance requirements and with the current state of the art in both the computational and graphics capabilities and the virtual reality interface hardware. These issues fall into several categories:

- *Can the graphics for the application environment be rendered with a frame rate of 10 frames/s or higher?* Are there more polygons in the scene than can be rendered with available hardware in 0.1 s? Does the rendering require computationally intensive techniques such as volume rendering, raycasting, or sophisticated lighting techniques such as radiosity? While some high-end hardware platforms can perform some of these tasks with the performance required, will such platforms be available to the target user community? Failure to meet the graphics frame-rate requirement may result in a system which does not support head tracking and so does not take advantage of the virtual reality interface.
- *Can direct-manipulation-based application tasks be performed in less than 0.1 s?* Direct-manipulation-based tasks are those that occur in response to a user’s continuous motion. Examples include the movement of an object in the virtual environment, which may trigger complex collision detection computations, or a data probe in a scientific visualization environment, where motion triggers the computation of new data displays. These computations may require access to data stored on disk or information over a network. Simple estimates of the computation time required can be made by counting the number of objects required for a collision detection computation or counting floating-point operations in a data display application. If it is found that the application task probably cannot be performed in 0.1 s or less, possibilities of limiting the task, changing how data are represented, or time-critical techniques which quickly provide approximations can be examined.

- *Do the currently available virtual reality interface hardware devices provide the required accuracy or quality?* At any given time virtual reality interface devices provide only a particular level of quality. Do the available/affordable display devices provide sufficient image quality, resolution, field of view, and/or level of comfort required by this application? Do the trackers appropriate for the application provide the required accuracy over an appropriate range in the environment in which they will actually be used? Is the interface hardware convenient to use? Does the interface provide sufficient benefit to justify any inconvenience? Accuracy issues are particularly critical for augmented reality applications.

42.8 Case Studies

42.8.1 Architectural Walkthrough

An architectural walkthrough is an application which simulates walking through a building. This application is usually used to evaluate the building before it is actually built. The overall environment metaphor is that of being in a building, and there may or may not be individual interactive objects in the building. The navigation metaphor is largely determined by the available interface hardware, and is typically the point-and-fly paradigm. Collision with walls is not typically implemented. Time-critical graphics has been used in these walkthroughs to maintain a constant frame rate.

42.8.2 The Virtual Wind Tunnel

The virtual wind tunnel (Bryson et al. 1995) is an application of virtual reality to the visualization of simulated airflow. The overall environment metaphor is an aircraft body with airflow around it. Various tools are available to visualize the airflow, including streamlines, isosurfaces, and cutting planes. These tools are fully interactive, with movement by the user causing the recomputation of the visualization geometry. The recomputation and display of the visualization geometry allows real-time exploration of complex airflows, providing rapid understanding of the simulation. The virtual wind tunnel uses two asynchronous process groups, one for the computation of the visualization geometry and the other for rendering. Visualization geometry computation uses parallel processing when available. These two processes are typically in the same lightweight process group and communicate via shared memory, but they may be on separate systems communicating over a network in a client-server mode. Several users may be connected to the same server, providing the virtual wind tunnel with a shared-use mode.

Time-critical computation in the virtual wind tunnel is implemented to maintain the responsiveness of the visualization tools when they are moved and to maintain animation rates for time-varying flows. The time-critical computation at a given frame is based on the assignment of a time budget to each visualization geometry computation. The ratio of the total computation time for all visualization geometry computations from the previous frame to the allotted time then multiplies these time budgets, providing a new time budget for each visualization geometry computation. It is then up to the individual computation to decide how to meet the new time budget, either by reducing the size of the visualization computed or by reducing the accuracy of the visualization by switching to a simpler, faster algorithm.

42.9 Research Issues

Essentially all aspects of virtual reality involve research issues. Critical research issues fall into roughly the following categorizations:

- *Human factors:* What is the impact on task performance of tracker inaccuracies, frame rates, end-to-end delays, the lack of full sensory feedback, and other technological distortions of experience in virtual reality? What is the appropriate approach to three-dimensional interfaces for task

performance? What is the classification of tasks which are appropriate for virtual reality? What enhancements to the virtual environment can be inserted to aid task performance? How do we resolve the tension between application-specific and standard conventional interfaces?

- *Software:* Time-critical rendering and computation concepts, operating systems which support high-resolution scheduling and time-critical operations, and software structures for the rapid design of environments including complex behaviors need to be more fully developed.
- *Hardware:* Technologies need to be developed which deliver immersive visual displays with acceptable ergonomics, with the ideal being the form factor of sunglasses. While three-dimensional computer workstations, networks, and mass storage systems are a mature technology, they are usually developed to maximize throughput with little attention to latency. Developing hardware systems with both high throughput and low latency is a critical need for virtual reality.
- *Design:* Design methodologies for virtual environment applications are currently lacking. A classification of applications and useful approaches for virtual environments is required.

42.10 Summary

Virtual reality is an interface paradigm which relies on the effect of presenting the user with a computer-generated three-dimensional world which contains interactive objects that have three-dimensional locations independent of the user. Virtual reality is an inherently three-dimensional approach to human-computer interfaces which stresses responsive interaction with the virtual environment, which mimics real-world interaction. The three-dimensional aspects and high-performance requirements of virtual reality provide a platform for simulating real-world tasks, interactive entertainment, and exploration of complex data. These requirements also place significant stresses on the performance characteristics of the systems supporting the virtual environment.

Interface hardware for virtual reality involves several sensory modalities including visual, audio, touch, and force. The visual and audio display technologies are relatively mature, with the touch and force technologies requiring further development as of 1996. Virtual reality systems rely on tracking the user in three dimensions using technology which introduces errors and limitations. Working with these errors and limitations is one of the primary challenges of virtual reality application development.

Software systems for virtual reality are typically oriented toward specific applications or application domains. The high-performance requirements of virtual reality place unusual demands on the computation, rendering, and data management software that underlies a virtual reality application. Effective use of multiple processes and optimized, carefully written codes are critical for the success of a virtual reality application. Time-critical structures which gracefully degrade quality in order to maintain performance are important components in virtual reality software systems.

Virtual environment design raises further opportunities and challenges. The appropriate use of three-dimensional display and interface for a specific application must be approached on a task-by-task basis. The use of interface metaphors from the real world and the application domain naturally leads to the design of application-specific interfaces. The implementation and design of standard interfaces in this context is a challenging and open issue.

In spite of its difficulties, virtual reality allows the development of environments tailored to the best way for a user to perform an application task.

Defining Terms

Head-coupled display: A display which moves with the user's head, typically allowing the user to see the screen regardless of the position and orientation of the user's head.

Head-mounted display: A display which is rigidly mounted on the user's head. A subset of head-coupled displays.

- Head tracking:** The measurement of the position and orientation of the user's head, usually used for rendering the three-dimensional scene from the current point of view.
- Spatial constancy:** The property of having a spatial location when viewed from a moving point of view.
- Spatial presence:** The property of having a spatial location relative to and independent of a viewer in three-dimensional space.
- Virtual reality:** Use of computer systems and interfaces to create the effect of an interactive environment, called the virtual environment, which contains objects which have spatial presence. Also known as virtual environments or virtual worlds.

43.1 Introduction

The goal of computer vision is to extract information from images. For example, **structure from motion** methods can recover a three-dimensional model of an object from a sequence of views, for use in robot grasping, medical imaging, and graphical modeling; **model-based recognition** methods can determine the best matches of stored models to image data, for use in visual inspection and image database searches; and **visual motion analysis** can recover image motion patterns for use in vehicle guidance and processing **digital video**. Computer vision is closely related to the field of image processing. In computer vision the focus is on extracting information from image data, whereas in image processing the focus is on transforming images. For instance, extracting a three-dimensional model from two-dimensional images is more of a computer vision problem than an image processing one, whereas image enhancement is more of an image processing problem than a computer vision one.

Computer vision is an interdisciplinary area, which falls primarily within the field of computer science, but also draws heavily on a number of other areas including image processing, differential and combinatorial geometry, numerical methods, and statistics. Some research in computer vision also has ties with biology and psychophysics; however, computer vision tends to be more concerned with building artificial vision systems than with accurately modeling human or animate systems. One of the main challenges for students of computer vision is developing adequate depth across such a wide range of areas. There are a number of books that provide relatively broad coverage of the field, with more advanced treatments in Faugeras [1993], Haralick and Shapiro [1992], and Horn [1986].

Human visual perception appears to be nearly effortless, in contrast with cognition, which can require substantial conscious effort. However, visual perception tasks are arguably at least as difficult as cognitive ones. For instance, computers can now beat all but the best human chess players and computational

mathematics systems are routinely used to solve calculus problems that are too involved for people to do. Yet computational vision systems have only achieved human levels of performance in very restricted domains, such as automated parts inspection (under controlled lighting conditions). One particularly successful area of visual information processing is the development of systems for recognizing printed text. However, such optical character recognition (OCR) systems still make mistakes that a grade school student would not make, even if the child did not know the particular words being recognized. The main problem is that artificial vision systems are brittle, in the sense that small variations in the input may cause enormous changes in the output. Developing vision systems that degrade gracefully is a major challenge of computer vision.

Computer vision systems operate on **digital images**. A digital image is quantized into discrete values, both in space and in intensity. The discrete spatial locations are called **pixels**, and are generally arranged on a square grid, spaced equally apart (although the area covered by each pixel may not actually be square). Each pixel takes on a range of integer values. For a *gray-level* (or *intensity*) image these values are generally between 0 and 255 (8 b). For a *binary* image (or *bitmap*) the values are just 0 and 1. Color images can be represented in several ways; commonly three intensity images are used, one for each of three color channels (e.g., red, green, and blue). Digital images are large: a single gray-level frame from a video camera is about $\frac{1}{3}$ of a megabyte, a 24-b color image of a page scanned at 400 dots/in is about 44 megabytes, and an uncompressed 24-b color video stream is about 30 megabytes/s.

Computer vision methods are often classified into low, middle, and high levels. Although these classes are by no means universal, they still provide a useful way of categorizing computer vision problems. We will consider the following definitions:

- Low-level vision techniques are those that operate directly on images and produce outputs that are other images in the same coordinate system as the input. For example, an **edge detection** algorithm takes an intensity image as input and produces a binary image indicating where edges are present.
- Middle-level vision techniques are those that take images or the results of low-level vision algorithms as input and produce outputs that are something other than pixels in the image coordinate system. For example, a structure from motion algorithm takes as input sets of image features and produces as output the three-dimensional coordinates of those features.
- High-level vision techniques are those that take the results of low- or middle-level vision algorithms as input and produce outputs that are abstract data structures. For example, a model-based recognition system can take a set of image features as input and return the geometric transformations mapping models in its database to their locations in the image.

There are many applications of computer vision techniques. Traditionally, most computer vision systems have been designed for military and industrial applications. Common military applications include target recognition, visual guidance for autonomous vehicles, and interpretation of reconnaissance imagery. Common industrial applications include parts inspection and visual control of automated systems. Over the past few years a number of new applications have emerged in medical imaging and multimedia systems. In medical applications computer vision methods are being used to register preoperative scans with a patient in the operating room. Computer vision techniques are also being used for realistic rendering and virtual reality applications, as well as image database retrieval.

In this chapter we will discuss a few computer vision problems in enough detail to give the reader an idea of some of the issues and to illustrate the kinds of techniques that are used to solve them. The presentation is divided according to low-, middle-, and high-level vision.

43.2 Low-Level Vision

Low-level vision computations operate directly on images and produce outputs that are pixel based and in the image coordinate system. Low-level vision computations include finding intensity edges in an image, representing images at multiple scales based on smoothing the image with different filters, computing

visual motion fields, and analyzing the color information in images. In order to illustrate low-level vision methods, we will consider the problems of edge detection and image smoothing in more detail.

43.2.1 Local Edge Detectors

The primary goal of edge detection is to extract information about the geometry of an image for use in higher-level processing. There are many physical events in the world that cause intensity changes, or edges, in an image. Only some of these are geometric: object boundaries produce intensity changes due to a discontinuity in depth or difference in surface color and texture, surface boundaries produce intensity changes due to a difference in surface orientation. Other intensity changes do not directly reflect geometry (though it may be possible to derive some geometric information from them): specular reflections produce sharp intensity changes due to direct reflection of light; shadows and interreflections produce intensity changes due to other objects or parts of the same object.

We will refer to a gray-level image as $I(x, y)$, which denotes intensity as a function of the image coordinate system. Intensity edges correspond to rapid changes in the value of $I(x, y)$; thus it is common to use local differential properties such as the squared **gradient magnitude**,

$$\|\nabla I\|^2 = \left(\frac{\partial I}{\partial x}\right)^2 + \left(\frac{\partial I}{\partial y}\right)^2$$

Simplistically speaking, where the squared gradient magnitude is large, there is an edge. Another local differential operator that is used in edge detection is the Laplacian (see Horn [1986, Ch. 8]),

$$\nabla^2 I = \frac{\partial^2 I}{\partial x^2} + \frac{\partial^2 I}{\partial y^2}$$

This second derivative operator preserves information about which side of an edge is brighter. The zero crossings (sign changes) of $\nabla^2 I$ correspond to intensity edges in the image, and the sign on each side of a zero crossing indicates which side is brighter.

The images used in computer vision systems are digitized both in space and in intensity, producing an array $I[j, k]$ of discrete intensity values. Thus, in order to compute local differential operators, finite difference approximations are used to estimate the derivatives. For a discrete one-dimensional sampled function, represented as a vector of values $F[j]$, the derivative dF/dx can be approximated as $F[j + 1] - F[j]$, and the second derivative d^2F/dx^2 can be approximated as $F[j - 1] - 2F[j] + F[j + 1]$. The squared gradient magnitude, $\|\nabla I\|^2 = (\partial I/\partial x)^2 + (\partial I/\partial y)^2$, can be approximated (at the center of a 2×2 grid of pixels) as

$$\left(\frac{\partial I}{\partial x}\right)^2 + \left(\frac{\partial I}{\partial y}\right)^2 \approx (I[j + 1, k + 1] - I[j, k])^2 + (I[j, k + 1] - I[j + 1, k])^2 \quad (43.1)$$

The Laplacian, $\nabla^2 I$, can be computed in a similar manner using the approximation to the second derivative (see Horn [1986, Ch. 8]).

In practice edges cannot be computed reliably using these kinds of local operators, which consider just a 2×2 or 3×3 window of pixel values. The high degree of variability in images causes such operators to both report edge points where there are none and to miss edge points. For example, Figure 43.1b shows the result of running a local gradient magnitude edge detector on the image shown in Figure 43.1a. This detector simply finds local maxima in the gradient magnitude which are larger than some threshold. Note the broken edges and large number of isolated edge points. In contrast, Figure 43.1c shows the edges detected using a nonlocal (or less local) gradient magnitude computation, which is described later in the section on the **Canny edge operator**.

A number of local edge operators have been developed, which can mainly be understood in terms of directional first and second derivatives. A more detailed discussion of some of these operators can be found

FIGURE 43.1 An example of edge detection: (a) an image, (b) a local gradient magnitude edge operator, (c) the Canny edge operator.

in Haralick and Shapiro [1992]. For example, the Sobel operator is a directional first derivative, based on the approximation $F[j + 1] - F[j - 1]$ (as opposed to $F[j + 1] - F[j]$ as used earlier). The Sobel operator also uses a simple form of local smoothing. These local edge operators (which use 4×4 or 5×5 windows of pixel values) work slightly better in practice than the local gradient magnitude or Laplacian operators. The main reason is that they do local averaging (or weighted smoothing) of the image as part of the processing. We now turn to a discussion of local smoothing operations, and then put these operations together with the Laplacian and gradient magnitude to obtain edge detectors that work better than local methods such as Sobel.

43.2.2 Image Smoothing and Filtering

The basic operation used to smooth images in computer vision (and to filter images in general) is convolution. Consider the following function $g(x, y)$, defined in terms of $f(x, y)$ and $h(x, y)$,

$$g(x, y) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f(x - \xi, y - \eta)h(\xi, \eta) d\xi d\eta$$

We say that g is the convolution of f and h , which is written as $g = f \otimes h$. This function can be difficult to understand at first, because the value of g at a given point (x, y) depends on the values of f and h at all points. Convolution is commutative and associative, which allows computations to be rearranged in whatever fashion is most convenient (or efficient).

In the discrete approximation to the convolution, the sum of products can be expressed as four nested loops over two arrays that represent the (sampled) functions f and h . Let $h[i, j]$ be an $m \times m$ array and $f[x, y]$ be an $n \times n$ array, where $n > m$ and both arrays are indexed from 0. Then the code fragment in Table 43.1 computes the discrete convolution of the sampled functions f and h . The notation $[x]$ denotes the integer portion of x . Note that the iteration variables x and y cannot simply range between 0 and $n - 1$ as this would cause array references outside of f . These boundary cases can be handled in several ways and are important in any implementation.

Convolution can be used to smooth, or low-pass filter, an image in order to handle the problem of high-frequency variation (differences from one pixel to the next). In computer vision, the **Gaussian** is the most commonly used function for low-pass filtering. In one dimension, the Gaussian is given by

$$G_{\sigma}(x) = \frac{1}{\sqrt{2\pi}\sigma} e^{-\frac{x^2}{2\sigma^2}}$$

This is the canonical bell-shaped or normal distribution as used in statistics. The maximum value is attained at $G_{\sigma}(0)$, the function is symmetric about 0, and the area of the function is 1. The parameter σ controls the width of the curve: the larger the value of σ , the wider the bell. In two dimensions, the Gaussian can be defined as

$$G_{\sigma}(x, y) = \frac{1}{2\pi\sigma^2} e^{-\frac{(x^2+y^2)}{2\sigma^2}}$$

In the discrete case the values at integral steps over some range (generally $\pm 4\sigma$) are used as approximations. These values are normalized so that they sum to 1 (just as in the continuous case where the integral is 1).

TABLE 43.1 Four Nested Loops Which Compute the Discrete Convolution of f and h

```

for  $x \leftarrow x \text{ min to } x \text{ max}$ 
  do for  $y \leftarrow y \text{ min to } y \text{ max}$ 
    do  $sum = 0$ 
      for  $i \leftarrow 0 \text{ to } m - 1$ 
        do for  $j \leftarrow 0 \text{ to } m - 1$ 
          do  $sum \leftarrow sum + h[i, j]f[x - [m/2] + i, y - [m/2] + j]$ 
         $g[x, y] = sum$ 

```

A direct implementation of discrete convolution as in [Table 43.1](#) requires $O(m^2n^2)$ operations for an $m \times m$ mask representing the Gaussian and an $n \times n$ image. In the case of Gaussians, the operator is *separable* into the product of two one-dimensional Gaussians, and we can use this fact to speed up the convolution to $O(mn^2)$. The underlying idea is to do a one-dimensional convolution in the x -direction followed by a one-dimensional convolution in the y -dimension. The reason that this works is beyond the scope of this chapter. This is a significant savings, both theoretically and in practice, over the direct implementation. Any smoothing method (or edge detector) that uses separable filtering operators should be implemented in this manner. Gaussian smoothing can be made even faster using an approximation which is nearly independent of σ and thus the size of the mask, m . These methods are $O(n^2 + m)$, and use a form of the central limit theorem to approximate a Gaussian by several repeated convolutions with functions of constant height. Such convolutions can be performed in a constant number of operations for each image pixel (see Wells [1986]). In practice for Gaussian smoothing with σ of more than about 1 the repeated convolution approximation method is the fastest. For smaller values of σ the two one-dimensional convolutions are faster.

43.2.3 The Canny Edge Operator

The Canny [1986] edge detector is based on computing the squared gradient magnitude of the Gaussian smoothed image. Local maxima of the gradient are identified using a process known as *non-maximum suppression* (NMS). The NMS operation enables thin, connected chains of edge pixels to be identified. Conceptually, it is much like following the ridge lines in a mountain range, rather than just finding the (isolated) peaks. This is done by defining local maxima with respect to the gradient direction (the direction of steepest change) rather than in all directions. The NMS operation still leaves many local maxima that are not very large. These are then thresholded based on the gradient magnitude (or strength of the edge) to remove the small maxima. The maxima that pass this threshold are classified as edge pixels. Canny uses a thresholding operation with two thresholds, lo and hi . Any local maximum for which the gradient magnitude $m(x, y)$ is larger than hi is kept as an edge pixel. Moreover, any local maximum for which $m(x, y) > lo$ and some neighbor is an edge pixel is also kept as an edge pixel. Note that this is a recursive definition: any pixel that is above the low threshold and adjacent to an *edge* pixel is itself an *edge* pixel.

The steps of the Canny method are as follows:

1. Gaussian smooth the image, $I_s = G_\sigma \otimes I$.
2. Compute the gradient ∇I_s and the squared magnitude $\|\nabla I_s\|^2$ as in Equation 43.1.
3. Perform NMS. Let $(\delta x, \delta y)$ be the unit vector in the gradient direction, ∇I_s . Compare $\|\nabla I_s(x, y)\|^2$ with $\|\nabla I_s(x + \delta x, y + \delta y)\|^2$ and $\|\nabla I_s(x - \delta x, y - \delta y)\|^2$ to see if it is a local maximum.
4. Threshold strong local maxima using $\|\nabla I_s\|^2$ as measure of edge strength, with two thresholds on edge strength, lo and hi , as previously described.

The edges in [Figure 43.1\(c\)](#) are from the Canny edge detector. In practice, this edge operator or variants of it (see Faugeras [1993, Ch. 4]) are the most useful and widely used.

43.2.4 Multiscale Processing

One problem with image filtering is choosing the *scale* of smoothing (e.g., the value of σ to use for the Gaussian). As the scale increases less of the detailed information in an image is preserved (and spatial localization gets worse). It is often desirable to be able to process an image at multiple scales; for instance, in order to determine the significance of edges by finding the range of scales over which they occur. Witkin [1983] developed the idea of multiscale signals resulting from smoothing with a Gaussian at different scales, which he called the **scale space** representation. For example, given an image $I(x, y)$, the corresponding scale-space function is

$$\mathcal{I}(\$, \dagger, \sigma) = \mathcal{I}(\$, \dagger) \otimes \mathcal{G}_\sigma(\$, \dagger)$$

where the scale parameter σ ranges from 0 to ∞ [at $\sigma = 0$ the scale-space function is the original function $I(x, y)$].

The use of multiscale representations and the characterization of signals from their edges at multiple scales can be viewed in terms of **wavelet** theory (cf. Mallat and Zhong [1992]). A wavelet function is a function whose integral is zero,

$$\int_{-\infty}^{\infty} h(x) = 0$$

and which has a scaling property

$$h_s(x) = \frac{1}{s} h\left(\frac{x}{s}\right)$$

The wavelet transform of a function f at scale s is then defined as $W_s^h f(x) = f(x) \otimes h_s(x)$, where h is a wavelet function (has integral zero and the scaling property). The derivative of a Gaussian has both the zero integral and scaling properties and thus is a wavelet function. Therefore, the multiscale edge representation of an image can be viewed as a wavelet transform. Wavelets have been used for a number of applications in image processing and analysis, such as image compression.

Multiscale representations using oriented filters are also common in computer vision [Perona 1992]. The gradient magnitude of the Gaussian smoothed image is not sensitive to orientation; it responds equally to edges in all directions. It is possible to design filters that are sensitive primarily to edges at a particular orientation, such as vertical or horizontal edges. The visual systems of many animals perform such orientation-sensitive filtering. For example, in many environments large horizontal edges are of considerable interest (especially moving ones, which could be predators).

43.2.5 Visual Motion and Optical Flow

Given a sequence of images taken over time (e.g., a digitized video stream at 30 frames/s), the goal of visual motion analysis is to recover information about the motion of objects in the image. The true motion of points in the world is not directly observable in an image sequence, only the changes in image intensity or the **optical flow**. For example, consider a rotating uniform sphere; in this case there is no optical flow (no change in brightness patterns in the image) but there is motion of the object. On the other hand, consider a shadow moving across a static scene. In this case there is optical flow, but there is no motion of the objects in the scene.

The optical flow is the vector field that tells us where each point in the image at time t “moved to” at time $t + \delta t$. Let $\mathbf{u}(x, y)$ and $\mathbf{v}(x, y)$ denote the components of this vector field; in other words the vector $(\mathbf{u}(x, y), \mathbf{v}(x, y))$ denotes the instantaneous motion of each point (x, y) . One class of methods for computing the optical flow are based on measuring local intensity changes in the image with respect to time (see Horn [1986, Ch. 12]). The *optical flow constraint equation*

$$\frac{\partial I}{\partial x} \mathbf{u} + \frac{\partial I}{\partial y} \mathbf{v} + \frac{\partial I}{\partial t} = 0$$

shows how the components of the optical flow, \mathbf{u} and \mathbf{v} , can be computed from local derivatives of the image with respect to space and time $(x, y, \text{ and } t)$. This equation also illustrates a fundamental problem with measuring motion from local intensity change. The equation can be rewritten in vector form as $(\partial I / \partial x, \partial I / \partial y) \cdot (\mathbf{u}, \mathbf{v}) = -\partial I / \partial t$. In other words, only the component of the optical flow in the direction of the brightness gradient $(\partial I / \partial x, \partial I / \partial y)$ is recoverable. This problem is known as the *aperture problem*; intuitively if a line segment is viewed through a small local window it is possible to tell what the motion of the segment is only in the direction normal to the segment.

There are a number of ways to provide additional constraints so that the flow problem can be solved. One approach is to assume that there is a single body moving rigidly [Horn 1986, Ch. 12]. This is powerful

but generally overly restrictive. A second approach is to assume that the motion field varies smoothly in most parts of the image, which allows for nonrigid deformations and multiple objects, but has the drawback of performing poorly at motion boundaries because it blurs together multiple motions. A third approach is to use robust statistical techniques to combine local motion estimates [Black and Anandan 1993]. Another approach is to determine the motion of edge contours, rather than using local intensity differences with respect to time (see Horn [1986, Ch. 9]). As long as the contour is not a line segment, it is possible to extract the complete two-dimensional motion (because there are at least two distinct normals to the edge, which thus span the plane).

In practice, the best techniques for computing the optical flow are **area-based** methods, rather than computing the flow from discrete approximations to partial derivatives. Area-based methods operate by considering a small area, or *window*, around each pixel of an image. For each location (x, y) in the image at one time, I_t , a window of the image is matched against a set of windows in a local neighborhood of the next image I_{t+1} . The best matching window of I_{t+1} , using some match criterion, specifies the motion of the point (x, y) . For example, if the best match for the window at (x, y) in I_t is the window at (w, z) in I_{t+1} , then the motion is $\mathbf{u}(x, y) = w - x$ and $\mathbf{v}(x, y) = z - y$. Area-based techniques generally use a simple matching measure for comparing windows, such as the **sum-squared difference (SSD)** of the corresponding pixels in the two windows. There is no ideal choice of window size for computing the optical flow. As the window gets smaller the flow estimate becomes noisy because the windows are not distinctive enough. As the window gets larger the motion boundaries become inaccurate because there are multiple motions in a window.

The pseudocode fragment in Table 43.2 illustrates the area-based computation of \mathbf{u} and \mathbf{v} for two images **img1** and **img2**, where the match window is of width m (size $(2m + 1) \times (2m + 1)$) and the search neighborhood is of width n (size $(2n + 1) \times (2n + 1)$). The window of **img1** centered at each (x, y) location is compared against the windows in the search neighborhood of **img2**, to find the best match for each window using the function **ssd**. The function **ssd** computes the sum-squared difference (or L_2 norm) of two images. The estimates of the optical flow resulting from a simple computation like this must generally be processed further in order to be useful.

As with local differential methods, the motions computed with area-based methods are generally processed by smoothing or aggregating the motion over local regions. Preprocessing of the images can also be used to improve the performance of area-based methods, particularly at motion boundaries where there are different motions in the same window. One such preprocessing method is based on transforming

TABLE 43.2 Area-Based Computation of the Optical Flow

      for  $i \leftarrow -n \text{ to } n$ 
        do for  $j \leftarrow -n \text{ to } n$ 
          do  $\text{diff} \leftarrow \text{SSD}(\text{img1}, x, y, \text{img2}, x + i, y + j, m)$ 
            if  $\text{diff} < \text{min}$ 
              then  $\text{min} \leftarrow \text{diff}$ 
                  $u \text{ min} \leftarrow i$ 
                  $v \text{ min} \leftarrow j$ 
           $u(x, y) = u \text{ min}$ 
           $v(x, y) = v \text{ min}$ 

SSD( $\text{img1}, x1, y1, \text{img2}, x2, y2, w$ )
   $\text{sum} \leftarrow 0$ 
  for  $i \leftarrow -w \text{ to } w$ 
    do for  $j \leftarrow -w \text{ to } w$ 
      do  $\text{sum} \leftarrow \text{sum} + (\text{img1}(x1 + i, y1 + i) - \text{img2}(x2 + i, y2 + i))^2$ 
  return  $\text{sum}$ 

```

the images using local nonparametric measures [Zabih and Woodfill 1994]. Two of these transforms are known as the *rank* and *census* transforms. The idea of both transforms is to replace the image intensities with measures based on order statistics in a local neighborhood. These measures are relatively insensitive to overall changes in intensity and thus are more reliable for use in area-based matching. In the rank transform, each pixel is replaced with the rank of its intensity over a local neighborhood. For example, when the neighborhood is size 15×15 , if the point at the center of the neighborhood is brighter than any of the others its rank is 1, if it is darker than any of its neighbors its rank is 225, and if it is the median intensity its rank is 113. In the census transform a bit vector is used to encode information about which of the neighboring pixels are brighter or darker than the center pixel in the window.

43.3 Middle-Level Vision

Recall that we consider middle-level vision techniques to be those that take images or the results of low-level vision algorithms as inputs and produce some output other than pixels in the image coordinate system. One of the goals of middle-level vision is to extract three-dimensional geometric information from images. Extracting three-dimensional geometry from images is often referred to as *shape-from-x*, because there are a number of different sources of information that can be used to recover the three-dimensional structure, or shape, of a scene from two-dimensional images. Shading in an image reveals information about three-dimensional shapes (see Horn [1986, Ch. 11]). For instance, much of the way that the shape of a sphere in a photograph is perceived as being a solid rather than a disk is due to the uniform change in brightness away from the light source. Specular reflections can also provide information about the three-dimensional shapes of objects [Blake and Brelstaff 1988]. Another source of three-dimensional shape information is provided by the change in location of an object from one image to another in a set of two or more images. The main techniques for extracting image shape from multiple images are **stereopsis** and structure from motion.

Another goal of middle level vision is to extract structural descriptions of images. Active contour models or **snakes** are often used to fit models to data [Amini et al. 1990, Kass et al. 1988]. Relations between image structures can be identified using *perceptual grouping* methods. Grouping methods are generally concerned with recovering nonaccidental alignments of image primitives, such as colinear line segments or cocircular arcs [Lowe 1985]. We will not discuss grouping methods further in this chapter. First we will consider the shape-recovery methods of stereopsis and structure from motion, and then the fitting of contours using snakes.

43.3.1 Stereopsis

In the basic stereo vision paradigm, there are two cameras observing a scene. The central idea is that objects that are closer to the cameras will move more between the two views than will objects that are farther away. This phenomenon is readily observable by alternately blinking the two eyes. For a given point in the scene, the magnitude of its motion between the two views is referred to as the *disparity*. If the camera system is calibrated in world coordinates then the actual distance to a point can be determined from its disparity. The disparity between two images is often displayed as an intensity image with brighter points corresponding to larger intensities (things that are closer to the cameras). [Figure 43.2](#) shows two intensity images and the resulting disparities from an area-based stereo matcher (discussed further subsequently).

A simple *pinhole* camera model consists of a focal point (or optical center), o , through which all rays of light pass, and an image plane I onto which these rays are projected. The *optical axis* of the camera is the line perpendicular to the image plane I and through the focal point o . The *focal length* f is the distance from the optical center o to the image plane I . For stereo vision there are two cameras at fixed relative positions. We will consider a simple stereo camera geometry in which the optical axes of the two cameras are parallel to one another and are perpendicular to the *baseline* that connects the two camera centers (which are denoted by o_l and o_r). We will also assume that the focal length f of the two cameras is the same. Denote the length of the baseline (distance between the camera centers) by b , and place the origin

FIGURE 43.2 An example of stereo matching: (a) the left image, (b) the right image, (c) a disparity map with brighter points being larger disparity (closer to the cameras).

FIGURE 43.3 A simple stereo camera geometry.

of the world coordinate frame along the baseline, at the point equidistant between the two camera centers (at distance $b/2$ from each o_l and o_r). Let the origin of the coordinate system for the left image plane L be the projection of its optic axis o'_l (and similarly the origin of the right image plane R is at o'_r). This simple camera model is illustrated in Figure 43.3.

Consider a point $p = (x, y, z)$ in the world which is projected into L at location $p'_l = (x'_l, y'_l)$ and into R at location $p'_r = (x'_r, y'_r)$. From the geometry of the two cameras, it can be seen that

$$\begin{aligned}\frac{x'_l}{f} &= \frac{x + b/2}{z} \\ \frac{x'_r}{f} &= \frac{x - b/2}{z} \\ \frac{y'_l}{f} &= \frac{y'_r}{f} = \frac{y}{z}\end{aligned}$$

Note that in this simple camera geometry, only the x location of a projected point differs between the left and right images. The y location of a given point in space is the same for both images.

The disparity is defined as the distance between $p'_l = (x'_l, y'_l)$ and $p'_r = (x'_r, y'_r)$, which in this case is just $x'_l - x'_r$. From the preceding equations, we see that

$$\frac{x'_l - x'_r}{f} = \frac{b}{z}$$

Thus, if b and f are known, the depth z of the point p can be computed from the disparity. If b and f are unknown then the *relative* depths of points can be computed, but not their absolute distance from the camera.

The basic computation in stereopsis is that of finding corresponding pairs of points, p'_l in L and p'_r in R , which are images of the same point p in the world. Note that a given point p need not have an image in both L and R ; there may be some other point in the scene that hides p from view in the left or right image, causing there to be no correspondence. This search for corresponding pairs is simplified by the fact that corresponding pairs of points must lie along certain lines in the two images, known as **epipolar lines**, rather than anywhere in the image. For the simple camera geometry illustrated in Figure 43.3, the corresponding epipolar lines are those with the same y -coordinates in the two images. Thus, given $p'_l = (x'_l, y'_l)$, it is necessary only to search for points p'_r in R that have $y'_r = y'_l$. In general, the corresponding epipolar lines are not parallel to one another but the search is still one dimensional. The epipolar lines in general form a pencil of lines in each image plane (a pencil is the set of lines through a given point). The point common to all of the epipolar lines in each image is the intersection of the image with the baseline connecting the two camera centers (for the simple camera geometry this point is at infinity so the epipolar lines are parallel).

The correspondence of epipolar lines in the left and right images can be determined through an iterative process that identifies sparse corresponding points in the two images [Deriche et al. 1994].

In practice the recovery of corresponding points in two images L and R is usually accomplished using area-based matching techniques like those described in the section on visual motion. Multiple cameras can be used for more accuracy (which is called multibaseline stereo). Using special hardware, these methods can compute depth maps at video rates. The matching process in stereo is made particularly difficult by the fact that the two images were taken by different cameras, with different gain and bias. However, the matching process is also simplified by the fact that in stereo the search region is one dimensional (along an epipolar line). A useful postprocess in stereo matching is *cross checking* [Hannah 1989], which ensures that if p_r in R is the best match for p_l in L , then the converse is also true. At locations where this is not the case, the match is probably incorrect. There have also been a number of matching techniques developed specifically for stereo, which directly implement constraints such as the fact that the disparity should in general not change quickly, except at object boundaries where there may be depth discontinuities (see Horn [1986, Ch. 6]).

In order to derive surface models from the depth (or disparity) information recovered from stereo, a surface interpolation process is often applied to the data (cf. Grimson [1983] and Terzopoulos [1988]). Such interpolation methods have broad applicability beyond computer vision.

43.3.2 Structure from Motion

Determining the three-dimensional structure, or shape, of an object in the world from a sequence of two-dimensional views is a problem that has been studied extensively (starting with Ullman [1979]). It is generally assumed that some feature points have been extracted and *tracked* through successive frames, so that the correspondence between points in each frame is known. The task is to recover the three-dimensional structure of the feature points in the world and the trajectory of the camera. Much of the early work on structure from motion was concerned with identifying the minimum number of points and frames that are needed to determine the three-dimensional structure of the points. We will not discuss these results here, because in practice it is necessary to have many more than the theoretical minimum number of observations in order to obtain a reliable solution.

To illustrate structure from motion techniques we will consider the case of orthographic projection (where all of the light rays are perpendicular to the image plane rather than going through a single focal point) and all of the points are visible in all of the frames. We will also limit the problem to a static scene and a moving camera, so that the goal is to recover the locations of P points in space and the positions of the camera at each of F time frames. The data provides $2PF$ observations (the x and y coordinates of the image points in each frame). The key issue is to use the redundancy of the observations to cancel out any (unbiased) noise in the locations of the image points and thereby recover the true structure and motion. There are a number of possible techniques for doing this; the approach of Tomasi and Kanade [1992] has been particularly effective.

Let (u_{fp}, v_{fp}) be the image coordinates of the p th point in the f th frame, $1 \leq p \leq P$, $1 \leq f \leq F$, where the origin of each frame is the centroid of the P points in that frame. Given the assumption that all of the points are visible in each frame, using the centroid as the origin of each frame omits the need to consider translations of the points. Let $W = [UV]^T$ be a matrix containing the data points, where U and V are the $F \times P$ matrices of the u and v coordinates of each observed point. If there were no error in the observed image data, then the measurement matrix W could be expressed as the matrix product $W = MS$, where $M = [\mathbf{i}_1 \dots \mathbf{i}_F \mathbf{j}_1 \dots \mathbf{j}_F]^T$ represents the camera motion [each $(\mathbf{i}_f, \mathbf{j}_f)$ is a pair of orthogonal unit vectors specifying the orientation of the image plane at frame f] and $S = [s_1 \dots s_P]$ is the shape matrix (the locations of the points in space, with their centroid as the origin). In other words the observed image data, as represented by W , is the product of two parts, the camera motion and the three-dimensional positions of the points.

As M is a $2F \times 3$ matrix and S is a $3 \times P$ matrix, if the measurements were exact $W = MS$ would be of rank at most 3. In reality, the problem is to recover M and S given W despite the fact that there is some

error in the observed data. Of course, in the case of even small errors in the locations of the image points, the rank of W will not be 3. However, the singular value decomposition (SVD) can be used to determine the approximate rank of W , which we expect to be 3 (see a numerical methods book such as Press et al. [1988] for a description of the SVD).

The SVD of the measurement matrix is $W = L \Sigma R$ where L is a $2F \times P$ matrix, Σ is a $P \times P$ diagonal matrix of singular values and R is a $P \times P$ matrix. The information of interest corresponds to the three greatest singular values, so the best approximation is

$$\hat{W} = L' \Sigma' R' = (L' \Sigma'^{\frac{1}{2}}) (\Sigma'^{\frac{1}{2}} R') = \hat{M} \hat{S}$$

where L' is the $2F \times 3$ matrix corresponding to the first three columns of L , Σ' is the 3×3 diagonal matrix corresponding to the upper left part of Σ , and R' is the $3 \times P$ matrix corresponding to the first three rows of R . One problem is that this is not a unique factorization as any linear transformation of $\hat{M} = L' \Sigma'^{\frac{1}{2}}$ and $\hat{S} = \Sigma'^{\frac{1}{2}} R'$ yields a valid result. It is possible to solve for the correct motion and shape transformations by noting that the true motion matrix M is composed of unit vectors, and the first F rows are orthogonal to the remaining rows (because each pair of rows \mathbf{i} and $\mathbf{i} + F$ correspond to the two orthogonal unit vectors defining the image plane at frame \mathbf{i}). This specifies a unique solution up to a rotational ambiguity, which corresponds to the initial position of the camera with respect to the world. In other words, the overall orientation of the points in the world can be recovered only relative to the initial orientation of the camera.

A number of structures from motion methods have considered the problem of reconstructing the shape of objects up to certain transformations of space (such as affine or projective transformations). A nice book on the subject of solid shape is Koenderink [1990].

43.3.3 Snakes: Active Contour Models

Active contours, or *snakes*, are useful for applications that involve fitting models to image data. An active contour model is a curve that seeks to minimize both internal and external forces which control its shape. The internal forces are generally related to the smoothness of the curve, as reflected by measures such as first and second derivatives of the contour. The external forces are generally based on image measurements, but may also be due to user inputs in interactive curve-fitting applications. The image forces are often based on the gradient magnitude, so that the contour is attracted to edges. In most applications a contour is initially placed near some image structure, and then the constraint forces act on the snake to make it fit the image structure. An iterative update procedure is used to find the position of the snake which (locally) minimizes the forces.

The active contour model was defined in Kass et al. [1988] as a curve $\mathbf{v}(s) = (x(s), y(s))$ with an associated energy functional,

$$\int_0^1 E_{\text{int}}(s) + E_{\text{ext}}(s) ds \quad (43.2)$$

The internal energy is composed of first- and second-order terms that measure the smoothness of the curve, and which make the contour act like a membrane or a thin plate,

$$E_{\text{int}}(s) = (\alpha(s)|\mathbf{v}_s(s)|^2 + \beta(s)|\mathbf{v}_{ss}(s)|^2)/2$$

where the subscripts denote the first and second derivatives of the curve with respect to arclength, and the functions α and β are weights (in practice these functions are often constant). The external energy is related to some image measure such as the gradient magnitude $E_{\text{ext}}(s) = -|\nabla I(x, y)|^2$. The curve that minimizes Equation 43.2 can be found using variational methods, by deriving a pair of Euler equations in x and y , discretizing them and then solving the discrete equations iteratively until they converge. This technique was developed in Kass et al. [1988]. Related methods have been developed for fitting three-dimensional energy-minimizing models to two- or three-dimensional data.

There are several difficulties with the variational approach to minimizing the energy of an active contour model. First, there is no constraint for the distance between points on the contour, so that many points of the contour can cluster near or on top of one another. More generally it is not possible to specify hard constraints, such as a minimum distance between points on the contour, because the energy functional must be differentiable. It is also difficult to choose the parameters of the minimization, and to determine to what degree the external energy term must be smoothed in order to produce a stable solution.

A different approach to the energy minimization is taken in Amini et al. [1990] where a discrete dynamic programming method is used. One of the main advantages of this method is that it allows the incorporation of hard constraints such as a minimum distance between points on the contour. One of the main disadvantages is that it is fairly computationally intensive. In this approach, the internal energy terms are discretized, $E_{\text{int}}(i) = (\alpha_i |\mathbf{v}_i - \mathbf{v}_{i-1}|^2 + \beta_i |\mathbf{v}_{i+1} - 2\mathbf{v}_i + \mathbf{v}_{i-1}|^2)/2$ and $E_{\text{ext}}(i) = -|\nabla I(x_i, y_i)|$. The energy over all of the contour points $(\mathbf{v}_0, \dots, \mathbf{v}_{n-1})$, $\mathbf{v}_i = (x_i, y_i)$ is then

$$\sum_{i=0}^{n-1} E_{\text{int}}(i) + E_{\text{ext}}(i)$$

The minimization of this sum can be performed using $O(n)$ separate stages, where each stage considers only a local neighborhood around each of three successive contour points, because only the variables indexed by i , $i - 1$, and $i + 1$ must be considered simultaneously. This is used to develop a dynamic programming solution that runs in time $O(m^3 n)$ where m is the size of the local neighborhood around each point. In practice, the dynamic programming methods are easier to implement and more numerically stable than the variational ones.

43.4 High-Level Vision

High-level vision methods are those that make abstract decisions or categorizations based on visual data (generally using the outputs of low- or middle-level vision algorithms). For instance, *object recognition* systems can be used to determine whether or not particular objects are present in a scene, as well as to recover the locations of objects with respect to the camera. *Object tracking* systems can be used to follow a moving object in a video sequence and thus to guide a mobile robot or an autonomous vehicle (cf. Dickmanns and Graefe [1988] and Thorpe et al. [1988]). In this section we will discuss some approaches to object recognition.

43.4.1 Object Recognition

Object recognition systems generally operate by comparing an unknown image to stored object models in order to determine whether any of the models are present in the image. Many systems perform both recognition and localization, identifying an object and recovering its location in the image or in the world. The location of an object is often referred to as its **pose**, and it is generally specified by a transformation mapping the model coordinate system to the image or world coordinate system. One way of categorizing object recognition systems is in terms of the kind of problems they solve. The simplest recognition problems involve identifying two-dimensional objects which are completely unoccluded (i.e., none of the object is hidden from view), appear against a uniform background, and where the lighting conditions are controlled (e.g., there are no shadows or reflections). Many industrial inspection problems fall into this category and can be handled quite accurately with commercially available systems. Recognition problems become more difficult when there are many objects in a scene, when objects may be touching and occluding one another, when the background is highly textured, and when the lighting conditions are unknown. Recognition problems also become more difficult as the number of object models increases. Finally, recognizing three-dimensional objects in a two-dimensional image is more difficult than recognizing two-dimensional objects.

We will primarily consider approaches that can handle images with multiple objects, partly occluded objects, and some amount of background clutter. Most methods that address these kinds of recognition problems are based on extracting geometric information such as intensity edges from an image. This two-dimensional image geometry can then be compared with three-dimensional geometric models. For instance, Kriegman and Ponce [1990] use silhouettes for recognizing objects from intensity edges. A different approach is to compute invariant representations of the image geometry, which remain unchanged under changes in viewpoint [Mundy and Zisserman 1992]. These representations can be used to index into a library of object models. One of the central issues in geometric recognition systems is that of determining which portions of an image correspond to a given object. The recognition problem is often framed as that of recovering a correspondence between local features of an image and an object model. Three major classes of methods can be identified based on how they search for possible matches between model and image features: (1) *correspondence methods* consider the space of possible corresponding features, (2) *transformation space methods* consider the space of possible transformations mapping the model to the image, and (3) *hypothesize and test* methods consider k -tuples of model and data features. A more detailed treatment of geometric search methods can be found in Grimson [1990].

43.4.2 Correspondence Search: Interpretation Tree

Given a set of image features $S = \{s_1, \dots, s_n\}$ and a set of model features $M = \{m_1, \dots, m_r\}$, an *interpretation* of the image is a set of pairs $N = \{(m_i, s_j), \dots\}$ specifying which model features correspond to which image features. If model features may be occluded and there may be extraneous image features, then in principle the set N can be any subset of the set of all pairs of model and image features. The **interpretation tree** approach (see Grimson [1990, Ch. 3]) is a pruned search of this exponential-sized space of possible interpretations (pairings of model and image features). The main idea is to use pairwise relations between features to prune a tree of possible model and image feature pairs, where paths in the tree correspond to interpretations. For concreteness, we consider the case where the features are points in the plane, and the transformation mapping a model to an image is a rigid motion (translation and rotation) plus some allowable error tolerance. As distances are preserved under rigid motion, the distance between pairs of points can be used as a constraint for pruning the search. In order for an interpretation to contain the pairs (m_i, s_j) and (m_p, s_q) , the distances $\|m_p - m_i\|$ and $\|s_q - s_j\|$ must be equal (up to the allowable error tolerance).

The search for interpretations is structured as a pruned tree search, in the following manner. Each level of the tree (other than the root) corresponds to a given image feature. Each branch at a given node corresponds to a given model feature or to a special branch called the *null face*. Thus each node of the tree specifies a pair of an image feature (the one at that level of the tree) and a model feature or the null feature (the branch that was taken from the previous level). The search is depth first from the root, and at each node the null face branch is expanded last in the search. A given node is expanded only if it is pairwise consistent with all of the nodes along the path from the current node back to the root of the tree. That is, a given node is paired with each node along the path back to the root, and for each such pair the distance constraint is checked. Only when all of these pairs satisfy the constraint is the node expanded. (The null face branch is always consistent.)

A path from the root to a leaf node of the tree is an interpretation that accounts for zero or more model features (any of the branches may be null branches that do not account for a model feature). A path that accounts for k model features is called a k -interpretation. A threshold k_0 is used to filter out any hypotheses that do not account for enough model features (i.e., the matcher should report only those interpretations for which $k > k_0$). Note that a k -interpretation is guaranteed only to be *pairwise* consistent. Thus an additional step of model verification is performed, which estimates the best transformation for each k -interpretation and checks that this transformation brings each model feature within some error range ϵ of each corresponding image feature.

The HYPER and LFF systems (see Grimson [1990, Ch. 7]) similarly structure recognition as a search for consistent sets of model and image features, using pairwise constraints to prune the search. HYPER starts by matching a privileged model feature against compatible image features. A privileged feature is one that is believed a priori to be more reliable (e.g., for line segment features, longer segments might be considered more reliable). LFF searches for maximal cliques in a graph structure formed from pairwise consistent features.

43.4.3 Transformation Space Search

Transformation space (or pose space) methods are based on searching the space of possible transformations mapping a model to the image or world coordinate system. The idea underlying these methods is to accumulate independent pieces of evidence for a match. Pairs of model and image features, which are part of the same correct match, will specify approximately the same transformation, whereas random pairs of model and image features will tend to result in randomly distributed transformations. Therefore, pairs of features which result in a cluster of similar transformations are assumed to correspond to a match of the model to the data. The validity of this assumption, however, depends on there being a low likelihood that random clusters will be as large as those clusters resulting from correct matches (see Grimson [1990, Ch. 11]). Transformation space search methods compute the transformations that are consistent with each pair of model and image features (or in general each k -tuple of feature pairs). Then the space of possible transformations is searched to find clusters of similar transformations. The exact means of searching the space and identifying clusters depends on the particular transformation space search method.

The generalized **Hough transform** (see Grimson [1990, Ch. 11]) is a transformation search method that operates by voting for buckets in a discrete transformation space. For example, a rigid motion of the plane can be represented using three parameters x , y , and θ corresponding to two translations and a rotation. Each of these parameters is broken into discrete ranges, forming a three-dimensional array of buckets, which tile the space of transformations. Every pair of model and image features then votes for those buckets containing transformations that map the given model feature to the given image feature, up to the allowable sensing error. A bucket that gets many votes corresponds to a possible transformation of the model to the image. There are a number of practical issues with the generalized Hough transform, such as what parameterization of the transformations to use, how to break the space up into a reasonable number of buckets (hierarchical schemes are often used rather than forming an explicit array of buckets), what kind of weighting scheme to use when a given feature pair votes for multiple buckets, and what to do about clusters that occur near bucket boundaries (because then votes may be spread over neighboring buckets instead of all occurring in the same bucket, possibly causing matches to be missed).

Another class of transformation search methods is based on precisely characterizing the regions of transformation space that are specified by each k -tuple of model and image feature pairs. The arrangement of these regions is then searched to find those cells where a large number of regions overlap. For example, consider the case of matching two point sets under translation, where a positional uncertainty of ϵ is allowed for each point. For each pair of model and image points there is a circle of translations of radius ϵ , which places the model point within ϵ of the image point. Translations at which many of these circles overlap are good potential matches of the model and image. Recognition methods that search the arrangement of these transformation space regions (e.g., Cass [1992]) make heavy use of techniques from computational geometry.

43.4.4 k -Tuple Search: Alignment and Linear Combinations

In the absence of sensor uncertainty, k pairs of model and image features exactly determine the transformation mapping a model to an image (where k depends on the kind of feature and the kind of transformation). For example, under translation a single pair of model and image points specifies the transformation. The idea underlying k -tuple search methods is to use the transformations specified by each k -tuple as an hypothesis about the pose of a model in an image (see Grimson [1990, Ch. 7]). If the transformation specified

by k pairs of model and image features corresponds to a correct hypothesis, then it will map the other model features onto image features. In this case we say that the transformation *aligns* the model with the image. If the transformation is incorrect then other model features will in general not be mapped onto image features. When there is sensor uncertainty, it is necessary to account for the fact that the transformations computed from k -tuples will not in general bring other model features precisely into correspondence with image features.

Many applications of k -tuple search have considered the case of affine transformations of the plane. An affine transformation of the plane can be represented as $A(x) = Lx + b$, where L is a nonsingular 2×2 matrix, and b is a two-dimensional translation. Three pairs of corresponding points uniquely define such a transformation (which maps any triangle to any other triangle). Thus under an affine transformation each triple of model and image features defines a possible alignment of a model with an image. An affine transformation mapping three model points to three image points also constrains the three-dimensional location of an object. Under an orthographic projection camera model (where all of the light rays are parallel rather than going through an optical center), the three-dimensional position and orientation can be recovered up to a reflective ambiguity [Huttenlocher and Ullman 1990].

The most basic k -tuple search method is called the *alignment* technique, because it simply considers k -tuples of model and image feature pairs, checking the resulting transformations to find those that align a large number of model features with image features. In order to find all possible matches of a model to an image each ordered k -tuple of model and image features must be considered, although in some methods the search may terminate after one or more matches are found. For affine transformations of the plane, each ordered triple of model points and ordered triple of image points defines a basis set which specifies a possible transformation (or two transformations for a three-dimensional object). For each such basis set the transformation mapping the model into the image is computed, and the transformation is evaluated by using it to map the remaining model features into the image. The quality of a transformation is measured by the number of transformed model features for which there are nearby image features. The size of the region to search for each transformed model feature depends on the degree of error in sensing the image points, the spatial configuration of the basis triples, and the location of the given point with respect to the basis points.

An interesting extension of alignment techniques is the linear combinations method [Ullman and Basri 1991], which is based on the idea of forming two-dimensional images of a three-dimensional model as combinations of two-dimensional views of the object. That is, an object is modeled as a set of two-dimensional views, with known correspondence between the points in different views. A new view is recognized by determining whether it is a linear combination of a small number of stored two-dimensional views. This method assumes an orthographic projection camera model and is developed both for point sets and for objects with smooth bounding contours.

43.4.5 Invariants, Indexing, and Geometric Hashing

The central idea underlying the use of **geometric invariants** in model-based recognition is to develop representations of objects that remain unchanged as the viewpoint changes. Such invariants can be found in classical geometry and can also be derived using algebraic techniques (cf. Mundy and Zisserman [1992]). The invariant representations of objects can be used as keys to index into a table of stored objects. In principle it is then possible to look up an object in a large library of stored models in time that is essentially independent of the number of models. One of the key issues that separates such model indexing from hashing in general is the fact that different instances of the same object in various images will not generate exactly the same key or invariant signature, due to sensing uncertainty. Thus in practice exact numerical values cannot be used to hash into a data structure.

A number of methods have been developed for using invariants in recognition, based on geometric, differential, photometric, and even thermal properties of images (see Mundy and Zisserman [1992]). Structural indexing methods use combinations of simple features such as points and segments. Other geometric techniques use invariant properties of curves such as coplanar conics. The main advantage

of using curve features is lower combinatorial complexity, and the main disadvantage is the need to extract these features from noisy, cluttered images. Photometric (intensity) information provides a richer description of an image than do geometric features such as points and line segments. The use of photometric invariants in recognition has been investigated in Nayar and Bolle [1993]. In order to illustrate the use of invariants in recognition we consider the **geometric hashing** approach [Lamdan and Wolfson 1988]. As in the previous section we examine the case of two-dimensional affine transformations. The fundamental observation underlying affine-invariant geometric hashing is the fact that three points define a coordinate system or basis with respect to which other points can be encoded in an invariant manner.

The geometric hashing method consists of two basic stages: (1) the construction of a model hash table and (2) the matching of the models to an image. The hash table is used to store a redundant, transformation-invariant representation of each object. Each model is entered into a hash table prior to recognition. For a given model, each ordered triple of model points m_1, m_2, m_3 forms an affine basis with origin $o = m_1$ and axes $u = m_2 - m_1, v = m_3 - m_1$. For each such basis every additional model point m_i is rewritten as (α_i, β_i) such that $m_i - o = \alpha_i u + \beta_i v$. The basis triple (o, u, v) and the point m_i are then stored in the hash table using the affine invariant indices (α_i, β_i) . This results in a table with $O(r^4)$ entries for r model points. The table is generally formed using buckets rather than using a hashing scheme, as in practice the sensing uncertainty in real data makes it impossible to use exact values for retrieval. The issue of how to determine appropriate bucket sizes is somewhat complicated.

At recognition time, the hash table is used to determine which models are present in the image. The idea is that when the image points are rewritten in terms of an *image basis* that corresponds to an instance of the model, then the same *model basis* will be retrieved from the table many times. Each ordered triple of image points s_1, s_2, s_3 is used to form a basis, with origin $O = s_1$ and axes $U = s_2 - s_1, V = s_3 - s_1$. For a given image basis, each additional image point s_i is rewritten as (α'_i, β'_i) such that $s_i - O = \alpha'_i U + \beta'_i V$. The indices (α'_i, β'_i) are used to retrieve the corresponding entries from the hash table. For each model basis retrieved from the table, a corresponding counter is incremented in a histogram. Once all of the image points have been considered for a given image basis, the histogram contains votes for those model bases that could correspond to the current image basis, (O, U, V) . If the peak in the histogram for a given model basis, (o, u, v) , is sufficiently high, then this basis is selected as a possible match. When a new image basis is chosen the histogram counts are cleared.

This basic method often does not work well in practice due to the effects of sensing uncertainty on the locations of image features. Several weighted schemes have been developed which work well in practice. These methods enter each basis triple into multiple buckets in the table based on the sensing uncertainty [Rigoutsos and Hummel 1992].

43.4.6 Dense Feature Matching: Hausdorff Distances

The methods considered so far are primarily useful when there are relatively small numbers of model and image features, because they are based on considering subsets of features. A different approach is taken in Huttenlocher et al. [1993], which is based on computing distances between point sets rather than finding correspondences of points in two sets. These methods can be used for large sets of points, such as entire edge maps. The methods are similar to the template matching techniques used in some commercial recognition systems, but they use a new measure of image similarity based on the **Hausdorff** distance, and provide efficient algorithms for searching cluttered images.

Given two point sets \mathcal{P} and \mathcal{Q} , with m and n points, respectively, and a fraction, $0 \leq f \leq 1$, the generalized Hausdorff measure is defined in Huttenlocher et al. [1993] and Rucklidge [1995] as

$$h_f(\mathcal{P}, \mathcal{Q}) = \left\{ \sqrt[\text{th}]{\min_{p \in \mathcal{P}} \prod_{q \in \mathcal{Q}} \|p - q\|} \right\}$$

where $f^{\text{th}}_{p \in \mathcal{P}} g(p)$ denotes the f th quantile of $g(p)$ over the set \mathcal{P} . For example, the 1st quantile is the maximum (the largest element), and the $\frac{1}{2}$ th quantile is the median. This generalizes the classical Hausdorff distance, which *maximizes* over $p \in \mathcal{P}$. Hausdorff-based measures are asymmetric; for example, $h_f(\mathcal{P}, \mathcal{Q})$

and $h_f(Q, \mathcal{P})$ can attain very different values as there may be points of \mathcal{P} that are not near any points of Q , or vice versa. This asymmetry is useful in recognition problems, where a hypothesize-and-test paradigm is often employed.

The generalized Hausdorff measure has been used for a number of matching and recognition problems. There are two complementary ways in which the measure has been employed. The first approach is to specify a fixed fraction f , and then determine the distance $d = h_f(\mathcal{P}, Q)$. In other words, find the smallest distance d , such that $k = \lceil fm \rceil$ of the points of \mathcal{P} are within d of points of Q . This has been termed finding the distance for a given fraction. Intuitively, it measures how well the best subset of size $k = \lceil fm \rceil$ of \mathcal{P} matches Q , with smaller distances being better matches. The second approach is to specify a fixed distance d , and then determine the resulting fraction of points that are within that distance. In other words, find the largest f such that $h_f(\mathcal{P}, Q) \leq d$. Intuitively, this measures what portion of \mathcal{P} is near Q for some fixed neighborhood size d . This has been termed “finding the fraction for a given distance.” It measures how well two sets match, with larger fractions being better matches.

Most applications of the measure are based on the second of the approaches, computing the *Hausdorff fraction*, because in most visual matching problems there is a reasonable prior estimate of the uncertainty in the positional location of image features. For example, a positional error of one pixel is generally introduced by the digitization process. If the feature points are edge features, then there is an uncertainty based on the degree of smoothing of the image. Efficient methods for finding the transformations of one point set such that the Hausdorff fraction is above some threshold (and the distance below some threshold) have been developed for affine transformations of the plane [Huttenlocher et al. 1993, Rucklidge 1995]. When the transformations are restricted to translations the fastest methods use dilation and correlation, whereas for full affine transformations the fastest methods use a hierarchical decomposition of the parameter space. The initial methods for computing Hausdorff distances were combinatorial algorithms using techniques from computational geometry, but current practice does not use these combinatorial techniques.

43.4.7 Appearance-Based Matching: Subspace Methods

Appearance-based recognition methods using **subspace techniques** have proven successful in a number of visual matching and recognition systems (e.g., Murase and Nayar [1995]). Appearance-based methods differ from those that we have already considered in that they operate by directly comparing images or image regions rather than by matching sets of local geometric features. The main advantage of appearance-based methods is that they are useful for tasks in which there is a large database of objects to be searched. The main disadvantage is that, in general, they do not work well with occlusion or with complex scenes and cluttered backgrounds. The most effective applications have been to problems such as the recognition of faces from mug shots, where the faces are generally about the same size and location in each image, and the background is a fixed color [Pentland et al. 1994].

The central idea underlying subspace methods is to represent images in terms of their projection into a relatively low-dimensional space, which captures the important characteristics of the set of objects to be recognized. This low-dimensional space is generally formed using the predominant eigenvectors (or principal components) of a set of known model images, where the k largest eigenvectors serve as the coordinate axes of the space (see Press et al. [1988] for more on eigendecomposition). Each model image is represented in terms of the k coefficients that result from projecting the image into the space. An unknown image is recognized by projecting it into the subspace and finding the closest model(s). The projection of an image can be thought of as a summary, which represents the image using just k numbers.

Subspace methods are attractive for problems in which there is a relatively large database of known objects, because the set of model images can be represented using just k coefficients in each, rather than the thousands of pixels in each image. This both saves storage and speeds the process of finding the closest matching images in the database. Moreover, to the extent that a subspace captures the important characteristics of a given set of images while omitting the unimportant characteristics, it can be used to generalize from a set of models. The main limitation of subspace methods is that when extraneous

information from the background of an unknown image is projected into the subspace, it tends to cause incorrect recognition results. This is analogous to the problem that occurs when using the SSD to compare two image windows in motion or stereo, where background pixels included in a matching window can significantly alter the value of the SSD and cause incorrect matches.

Let I denote a two-dimensional image with N pixels, and let \mathbf{x} be its representation as a (column) vector in scan line order. Given a set of training or model images, $\{I_m\}$, $1 \leq m \leq M$, define the matrix $X = [\mathbf{x}_1 - c, \dots, \mathbf{x}_M - c]$, where \mathbf{x}_m denotes the representation of I_m as a vector, and c is the average of the \mathbf{x}_m . The average image is subtracted from each \mathbf{x}_m so that the predominant eigenvectors of XX^T will capture the maximal variation of the original set of images. Generally the \mathbf{x}_m are also normalized prior to forming X , such as making $\|\mathbf{x}_m\| = 1$, to prevent the overall brightness of the images from affecting the results.

The eigenvectors of XX^T are an orthogonal basis in terms of which the \mathbf{x}_m can be rewritten (and other, unknown, images as well). Let λ_i , $1 \leq i \leq N$, denote the ordered (from largest to smallest) eigenvalues of XX^T and let \mathbf{e}_i denote each corresponding eigenvector. Define E to be the matrix of eigenvectors $[\mathbf{e}_1, \dots, \mathbf{e}_N]$. Then $g_m = E^T(\mathbf{x}_m - c)$ is the rewriting of $\mathbf{x}_m - c$ in terms of the orthogonal basis defined by the eigenvectors of XX^T . It is straightforward to show that $\|\mathbf{x}_m - \mathbf{x}_n\|^2 = \|g_m - g_n\|^2$ [Murase and Nayar 1995], because distances are preserved under an orthonormal change of basis. That is, the SSD can be computed using the squared distance between the eigenspace representations of the two images.

The central idea underlying the use of subspace methods is to *approximate* the \mathbf{x}_m , and thus the SSD, using just those eigenvectors corresponding to the few largest eigenvalues. That is, $\mathbf{x}_m \approx \sum_{i=1}^k g_{mi} \mathbf{e}_i + c$, where $k \ll N$. This low-dimensional representation is intended to capture the important characteristics of the set of training images. As this representation uses just the k predominant eigenvectors, it is not necessary to compute all N eigenvalues and eigenvectors of XX^T (which would be quite impractical as N is usually many thousands). Each model I_m is just represented by the k coefficients $(g_{m_1}, \dots, g_{m_k})$, so comparing it with an unknown image requires only k rather than N comparisons. Generally k is considerably smaller than the number of models M , which is in turn much smaller than the number of pixels N .

Defining Terms

Appearance-based recognition: Recognizing objects based on views, generally using properties such as surface reflectance patterns; often used in contrast with model-based recognition.

Area-based matching: A means of identifying corresponding points in two images, for motion or stereo, by comparing small areas or windows of the two images.

Canny edge operator: An edge detector based on finding local maxima (peaks and ridges) of the gradient magnitude.

Correlation: The product of one function and shifted versions of another function; the maximum of the correlation can be used to find the best relative shift of two functions.

Digital image: Sampling of an image into discrete units in both space and intensity (or color) for processing with a digital computer; an array of pixels.

Digital video: A sequence of digital images representing a sampled video signal.

Edge detection: Locating significant changes in an intensity (gray-level) image, generally using local differential image properties.

Epipolar geometry: The constraint that the locations of points in one image must lie along a particular line in order to correspond to the same scene point as a given point in another image.

Gaussian smoothing: Convolution of a signal (an image) with a Gaussian function in order to remove high spatial frequency changes from the image (a type of low pass filtering).

Geometric hashing: A model-based recognition technique using a highly redundant representation that is invariant to certain geometric transformations.

Geometric invariants: Properties of a geometric model (e.g., a set of points) that remain unchanged under specified types of geometric transformations (e.g., distances between points under rigid motion).

Gradient magnitude: The magnitude of the gradient vector, or equivalently the square root of the sums of the squares of the local directional derivatives.

Hausdorff matching: A geometric technique for comparing binary images based on computing a variant of the classical Hausdorff distance from point set topology.

Hough transform: A technique used in model-based recognition to accumulate independent pieces of evidence for a match, using local features to vote for possible transformations mapping a model to an image.

Interpretation tree: A model-based recognition technique that uses a pruned exponential tree search to find corresponding sets of model and image features.

Model-based recognition: Approaches to recognizing objects in images that are based on comparing sets of stored model features against features extracted from an unknown image (generally geometric features).

Motion analysis: The recovery of information about how objects are moving in the image or in the world, or about the shape of objects, based on changes in brightness patterns over time.

Optical flow: The local change in image brightness as a function of time.

Pixels: The discrete spatial units of a digital image, generally obtained by conversion of an analog image signal from a camera or scanner; each pixel can generally take on a range of integer values (e.g., 0–255).

Pose recovery: Determining the position and orientation of an object in the world with respect to the camera coordinate system.

Scale space: Representation of a signal (an image) at multiple scales of smoothing.

Snakes: Energy-minimizing contours that combine internal constraints on their shape, such as smoothness of the contour, and external constraints from the image, such as brightness or gradient magnitude.

Stereopsis: The recovery of depth (or relative depth) by finding corresponding points in two or more images of the same scene.

Structure from motion: The recovery of the three-dimensional structure of an object based on a sequence of views as the camera moves with respect to the object.

Subspace methods: Reducing the dimensionality of image matching or recognition problems by representing the images in terms of their projection into a lower-dimensional space.

Sum-squared difference (SSD): A measure used to find the best relative shift of two images (or functions) based on the squared L_2 distance; similar to correlation, but based on minimizing a distance rather than maximizing a product.

Wavelets: Functions with a scaling and zero-sum property that are used to form a multiscale representation of an image (or function).

Further Information

Much of the material in computer vision is in the form of original research articles, a few of which are cited in the References. In-depth coverage of the field can be found in the books by Faugeras [1993] and Haralick and Shapiro [1992], and good coverage of low-level vision is provided by Horn [1986]. The area of model-based object recognition is covered in Grimson [1990], and the geometric invariants approach to recognition is in Mundy and Zisserman [1992].

Human–Computer Interaction

The subject area of Human–Computer Interaction is concerned with improving the quality and effectiveness of technology, its development, and its interactions with people. This includes the analysis, design, implementation, and evaluation of computing systems with a keen interest in user interfaces and user performance. With the recent global deployment of computers and software, both organizational and cultural issues have become critical factors in the design of interfaces that people can use in increasingly diverse professional and personal settings.

44.1 Introduction

Human–computer interaction has focused on individual users and their relationships to systems. Much of the progress in the field has come about by looking for commonalities across the increasing number and diversity of computer-supported tasks. The personal computer (PC) of the 1980s was the perfect laboratory for this effort, and the initial difficulty in networking PCs together only helped shield PC users from group and organizational influences.

The large, expensive systems that preceded the PC had few resources to devote to usability and less reason to worry about it. The users of these systems were people who used the output, typically paper reports. They did not interact directly with computers: that task was left to programmers and computer operators, who acquired the necessary technical competence. With spreadsheets and word processors on PCs, however, to a much greater extent user and operator were synonymous. These users did not see themselves as computer professionals. They had less desire to master technical aspects of systems, and the emerging shrinkwrap software market allowed them to seek out more usable software.

Today, PCs and workstations are networked, intranetworked, and internetworked; once again, all computer use is being carried out in organizational contexts. The implications of this move — from the three key elements of human–computer interaction: user, system, and use, to larger contexts — are described

in other chapters. In this chapter, we examine what has always been a fundamental unit: organization. Organizations affect human–computer interaction in two important ways. First, systems and applications are developed in organizations, and the context of development influences the development process. Second, interactive systems and applications are used in organizations, and successful use is often affected by a range of organizational factors, which has implications for those developing, introducing, and using systems.

44.2 The Need for Organizational Analysis in Human–Computer Interface Design

A case study by Markus and Keil [1994] illustrates the benefit of a careful organizational analysis by demonstrating that a well-executed interface design project can produce a highly usable system that is not useful, and not used. The setting is “CompuSys,” a major computer company and employer of leading interface designers. The project was initiated to redesign the interface to a system developed for internal use by the sales organization, an expert system of the sort that achieved prominence in the mid-1980s through the success of Digital’s XCON [Barker and O’Connor 1989]. Sales representatives frequently made errors working out details of complex customer system configurations, such as omitting minor but necessary components. CompuSys swallowed the cost of repairing these errors. An expert system for product configuration was built; it was accurate, but was only used with a fraction of orders.

Costly errors continued. Why wasn’t the system used? The sales force complained about its usability. A project employing many advanced interface design techniques, including iterative design and user feedback, led to a major redesign of the clearly awkward interface. Users from five pilot sites were trained on the new system. Millions of dollars later, a new system with a much improved interface was introduced. But the new system was not used much more than the one it replaced.

Why? The system design was based on the following model of a typical sales process: (1) a customer identifies system requirements, (2) the sales representative works out a system configuration to meet the requirements, (3) the price is calculated. This seemed logical to the designers, but it was wrong. More often, customers had a fuzzy sense of their problem and a concrete budget for the system. They indicated how much they had to spend and the sales representative would try to identify an adequate system that could be acquired for that amount. The expert system did not support reasoning back from price to configuration — it reasoned only in one direction, from configuration to price. The new interface made it much easier to work from configuration to the price, but it missed the point. The system was usable but not useful. At the end of the project, the developers did not understand why the usable system was neglected. An organizational analysis — actually an interorganizational analysis — uncovered the *counterintuitive* work process.

To avoid such costly mistakes requires greater analysis or awareness of the organizational context and actual work processes than these designers had, even after direct interviews with the sales force. The awareness might be obtained in different ways: through a more sophisticated survey, ethnographic observation, contextual inquiry, or more extensive participation by users. Intuitions could be enhanced through familiarity with the literature on organizational theory and practice. The next section of this chapter summarizes some of the insights from this literature, drawing from Grudin and Markus [in press].

44.3 Organizations and Their Components

Organizations are often defined as collections of people with a common purpose or task. How does this differ from groups? Is it only a matter of size and structure — are organizations (usually) groups of groups?

Organizations arguably have a longer lifespan than groups. Loss or change in one or two members often changes a group completely, and it would seem odd to consider a group the same following entire replacement of its personnel, but organizations (such as Ford Motor Company or the University of California) can continue despite extensive internal reorganization or change. A group may be more than its members, but an organization is much more so.

Organizations also differ from groups in that they often have distinct public and legal identities and engage in a range of activities as a result, whereas groups are more likely to have a single focus. Although rock groups may be anomalous in some ways, we could argue that the Rolling Stones as a group play music; the Rolling Stones as an organization plans concert tours, handles arrangements, invests money, and so forth. People invest in organizations, the annual reports of many organizations are scrutinized, organizations often engage in more competitive activities than we associate with groups. And for these reasons, organizations have possibly been studied more intensely than groups (except for rock groups!).

If we are trying to understand a human–computer dialogue, we would first move one level up and learn what the purpose and context of that interaction was. Only then would we consider the components: an individual with a display, keyboard, and mouse. Similarly, to understand an organization, we first examine the whole of which it is a part — the role that the organization plays in networks of organizations. Then we examine its component parts: groups and individuals with structured relationships and dynamic interactions.

44.3.1 Organizations in Context

Organizations operate in a larger societal context or environment than can usefully be considered a network of organizations. Consider the Boeing Airplane Company. We think of Boeing as making airplanes, but in fact Boeing manufactures very little of the aircraft apart from the wings. Boeing designs the plane, it assembles the plane, and the components are made by scores of organizations around the world. Much of Boeing's work consists of managing this network of organizations, which includes vendors in most countries to which Boeing sells planes. This of course helps ingratiate Boeing to their governments.

Governments are another kind of organization with which the company interacts, as are airlines, financial institutions, unions, passengers, competitors, and so forth. Each organization in this network of interacting organizations performs a different role. Each organization has its own goals or interests that are sometimes mutually compatible and sometimes in conflict. Some organizations are more powerful than the others, controlling more resources, and thus are more likely to win when there are conflicts of interests. If the Chinese government decides to make a foreign policy point by canceling plans for a large order, there is little Boeing can do.

Similarly, the software industry is a network of organizations with different roles involved in the production, sale, support, and use of various products and services. The 1980s saw a proliferation of organizations mediating between developers and users. These include consulting companies, standards organizations, value-added resellers, third-party developers, subcontractors, advertising agencies, professional organizations, magazine companies, and others.

There are opportunities for conflict as well as cooperation in these relationships. Some organizations both cooperate and compete, as in well-known joint ventures between Apple and IBM, for example. Organizations define success differently: for some it is the bottom line, the annual return to stockholders; for other organizations, such as universities, hospitals, governments, social-service agencies, and voluntary organizations, success may mean knowledge creation and transfer, health, social welfare, or member satisfaction. The interaction of organizations with different goals and interests leads to complex, rich dynamics.

44.3.2 Organizational Components

Apart perhaps from quite small organizations, an organization consists of people deployed in various work groups, which may be organized into departments, divisions, or other structural units. A computer manufacturer can be organized by product category (PCs, workstations, minicomputers) or by function (hardware, systems software, applications software, support); they can have sales organized by region or by product line, and so on.

There is no general agreement on optimal organizational structure. Although in some industries, virtually all organizations in the same size class have a similar organizational structure, others are marked by a

great deal of local variation. Large organizations often shift from one structure to another, based perhaps on shifts in the external environment, or as a result of the personnel at hand, or perhaps even as a way of releasing adrenaline and enhancing vitality. Choices may not be fixed, but they can determine what the organization can do easily and well. For instance, a computer manufacturer organized by function may have a harder time delivering new PC models to market than a similar company with a product organization, but may have an easier time establishing consistency and interoperability across all product lines.

A specific example of particular interest to many in the human–computer interaction field is the deployment of usability specialists or human factors engineers in a very large research and development division. Should they be grouped together in a central usability laboratory, where they have the benefits of pooled resources and management that understands their roles? One drawback is possible isolation in a usability ghetto. Or should each specialist become a member of a product team, gaining the benefit of close interaction throughout the product cycle and a team that comes to understand and trust them? One drawback is that a usability specialist, managed as a member of a software team by someone with little understanding of usability, may become a software engineer. Both approaches and others are tried.

An ambitious analysis of organizational components has been developed by Mintzberg [1984, 1989]. Mintzberg identifies five basic organizational components or groups: the strategic apex (executives), the middle line (management), the operating core (production workers, whether surgeons in a hospital or assembly line workers), the technostructure (those who define the work processes in an organization), and the support staff (technical support, custodial, kitchen, and so on). Mintzberg argues that these functions will to some degree compete for control, and that five organizational forms can be found, each marking the dominance of one of these groups, along with some hybrids. Mintzberg extends his analysis to look at a wealth of accompanying and interacting factors, such as the approach to measuring output, the organizational environment, and so on. One of us once worked for a 500-person organization that was created with only a loose mission, and it was fascinating to see the correspondence of behavior to Mintzberg's model as each of the five groups jockeyed for control in this uniquely undefined setting.

Thus even when an organization as a whole has a clear set of goals and interests, individuals, groups, and subunits within the organization may not share them fully. Newspaper reporters and newspaper editors may differ, hardware and software engineers may engage in rivalry that is friendly or not so friendly — and both groups may have less than full respect for their colleagues in marketing or upper management. In many user organizations, the information systems staff differs in age and outlook from other groups, which can lead to breakdowns in communication or cooperation.

Employees may be subject to different performance measures and rewards. For example, a software unit may be evaluated on development schedules and budgets, whereas a hardware group may be evaluated largely on manufacturing cost. If so, it may be hard for the units to cooperate to achieve the total organization's goals. In the case of CompuSys, errors in computer system configuration originated with the sales department, which was rewarded for sales volume, but the manufacturing unit bore the costs associated with fixing incorrect orders. Given these incentives and rewards, the sales department devoted little time and energy to ensuring that orders were correct at the outset.

Good management, good communication of organizational purpose, an appropriate set of measures, rewards, and punishments might keep everyone singing the same tune. However, the complexity of large organizations makes it difficult to design efficient and effective management structures. Generally speaking, in organizations of any size and structural complexity, subunits exhibit a fair degree of goal displacement, pursuing goals and values that make sense to the subunit, but that do not necessarily advance the overall interests of the organization. And there is not agreement as to the appropriate level of conflict within an organization; one ideal would be to eliminate internal conflict and competition, but others endorse a management style that fosters a level of internal jockeying for resources.

Groups within organizations can develop distinct cultures (assumptions, beliefs, and language systems) that render clear communication with members of other groups and units more difficult. The same terms are often used in very different ways in different parts of an organization, creating problems for efforts to create a common database. Mark and Mambrey [1996] describe an example in which typists wanted

documents categorized by author and completion date, whereas authors wanted categorization by topic. An example noted by Grudin and Markus [in press]: It is a sale to sales when a customer verbally commits to an order, but it is not a sale to legal until a contract is signed; it is not a sale to manufacturing until a purchase order is entered into the manufacturing control system, and the accounting department only acknowledges a sale when an invoice has been prepared. Language differences contribute to widely differing points of view on key organizational decisions. Conflict as well as cooperation occurs in organizational decision making, producing behavioral dynamics inside organizations that are as rich as those observable when organizations interact.

44.3.3 Ways in Which Organizations Differ

It is useful to think of at least three levels of reality operating simultaneously in organizations. The first can be called rational, technical, or economic reality. It takes a stated goal as given and looks for an efficient and effective means of achieving it. The second level of reality can be called socioemotional task reality. People have social needs and organizations are one place in which they attempt to meet them. In addition, people habituate to particular ways of thinking and behaving due in part to their membership in organizational groups and subunits. These ways of thinking and acting may differ dramatically from what an outside observer would see as the rational optimum. The third level of reality is structural/political, focusing on goals and interests created by resources and positions in units and task chains (often called business processes) or interorganizational networks. Keeping all three realities in mind helps in seeing and understanding the complex dynamics of organizational behavior.

This has been a highly simplified overview of organizational behavior. Next, we show how these organizational issues can have enormous implications for the adoption, deployment, use, and consequences of information technology in organizations. However, first we will review some major categories of differences between organizations and their component work groups and subunits that can significantly shape the use of information technology:

- Headcount
- Economic resources, particularly *slack* (uncommitted resources)
- Geography (scope of operations) and space (e.g., in buildings)
- Age of organization, demographic profile, experience including experience working together
- Stated or implicit goals (e.g., least cost producer vs. product innovator)
- Structure/basis of organization (product, geographic, function, technology, time)
- Culture (beliefs, assumptions, language systems, characteristic behavior patterns)
- Management style (measures, rewards, promotion patterns, etc.)
- Information technology infrastructure (prior investments, commitments, governance)

With so many variable factors, it is not surprising that organizations and subunits react quite differently to a given technology.

44.4 Organizational Modeling, Formal and Informal

When a system or application is developed for use within a single organization, the software is likely to better mesh with the behavior of the organization if pertinent aspects of the organization can be formally modeled; that is, represented in a form the computer can manipulate. Formal modeling of organizational processes and data have been a major concern in the development of large systems.

Before addressing this history, though, it is useful to contrast the development of a system for a single organization with other development situations. In particular, when developing a shrinkwrap software product, intended for use in a range of organizations, the initial developers have less motivation for organizational modeling. Rather, those tailoring a system for a given customer might consider organizational

modeling. This is significant because commercial software has been the focus of most work in human-computer interaction (HCI). Most in HCI have no familiarity with organizational modeling; many have little experience with databases.

In the area of groupware and computer-supported cooperative work, formal modeling is appearing. Some is at the level of group behavior rather than organizational behavior, but workflow management systems (e.g., Abbott and Sarin [1994] and Marshak [1994]) involve a broad enough context to be considered organizational. The workflow tool developers do not model organizations; it is assumed the customer (or a consultant) will carry out the modeling.

Workflow management systems are often considered in the context of business process re-engineering (BPR). Both are predicated on the idea of creating detailed models of organizational processes. BPR looks to rationalize such processes; workflow management systems look to incorporate them in software and support them. Workflow management systems appear to be useful for high-volume, relatively routine business activities; whether current systems have the flexibility to support other activity is unclear. Bowers et al. [1995] is a nice study of a workflow system.

When we consider *user* organizations and the design and development of interactive software, formal modeling and its limitations arise. In considering the effects of *development* organizations on the design and development of interactive software, formal modeling does not arise, because our examination there deals with the need for people — designers and developers — to contend with the organizational environment, not a program. Fostering *awareness* of organizational influences is the objective, not modeling it formally. Awareness is a kind of informal modeling, of course, a point that arises in contexts of system use as well.

44.5 Organizational Contexts of Development

Developers are well aware that organizations constrain them through time pressures, approval processes, formal specifications, and other practices. What is often less evident is that these constraints differ markedly, and systematically, across organizations. To quote Mahoney [1988], “we speak of the computer industry as if it were a monolith rather than a network of interdependent industries with separate interests and concerns.” An organization’s structure and practices can have effects on the human-computer interfaces that it produces, and these may be major effects or subtle effects. Differences across segments of the industry affect what techniques can or should be applied, and what tools will or will not be useful. The history of segmentation within the field left traces in systems development practices, and the history differs in North America and Europe. (The following account draws on Grudin [1991a], Grudin and Poltrock [1995], and Grudin and Markus [in press], as well as the sources cited in the text.)

To illustrate the effects of organizational context, consider a key relationship in the design of interactive systems: the relationship between the developers and the users. Adapted from Grudin [1991a], [Figure 44.1](#) shows, for three development contexts, the times at which development teams are identified and the actual users are identified for a new application. From the top, an organization putting out a project for competitive bidding must produce a preliminary design to give possible contractors a specification to bid on. The users are identified well before the development team is known, and to prevent any favoritism toward a particular contractor, interaction between user and development organization may be curtailed or prohibited. For in-house development of a system by the information systems group within a user organization, both parties are often identifiable from the outset. The developers of a novel commercial product work under still different conditions: After marketing or management has done some analysis and high-level specification, the development team is formed. But the users are not truly known until the product is marketed. As we will see, these and other differences in conditions can greatly affect the process of developing interactive systems.

44.5.1 The Emergence of Distinct Development Contexts in the U.S.

An examination of the historical emergence of development contexts illuminates their differences and explains aspects of systems development practices that can adversely affect human-computer interfaces.

FIGURE 44.1 Identification of users and developers in different development contexts.

Most major early systems were contracted by the U.S. government. The government defined the requirements, and geographically distant organizations bid and were awarded contracts. Different contracts might be awarded for design, development, and maintenance. Legal restrictions governed their communication. This created tremendous organizational barriers to direct contact among developers and users. However, this was of less import because little software was interactive. Most computers were batch processors: a program and data were loaded and the computer computed, and perhaps produced a printed output.

Stage models of systems development evolved naturally in this environment. In the U.S., the waterfall model of Royce [1970], appearing at the dawn of the discipline of software engineering, was enormously influential. This design-it-first, specification-based approach, with little provision for feedback or iteration, became the dominant development methodology.

The design of usable human-computer dialogues requires abandoning the design-it-first approach. Boehm [1988] introduced spiral models explicitly to incorporate prototyping and iterative design for interactive software development. Nevertheless, the separation of developers and users remains a major organizational obstacle to interface design in contract development contexts. Winkler and Buie [1995] provide a good summary of the challenges and possible approaches, such as developing standards that can be included in requests for proposals (RFPs). The primary focus, however, is on raising awareness in user and developer organizations. Perhaps more important than trying to specify the interface in detail is to specify an interface development *process*. Winkler and Buie identify the primary interface development problems in government contracting to be organizational, not technical, in nature.

As business use of computers expanded, in-house development of software in large user organizations became the principal focus of system development. (In Europe, in-house development has always predominated.) Most processing remained batch rather than interactive, with end users primarily engaged in data entry and system operator tasks, but the waterfall development method approach was challenged from the outset in this organizational context, more effectively in Europe, where the stage models did not have the same prominence [Friedman 1989, Hirschheim et al. 1995].

Barriers to interaction among users and developers are less compelling for internal development. Organizational and cultural barriers still hinder user involvement in development — young, highly paid

information systems staff may clash culturally with other workers. But developers and users have the same employer and often work in greater proximity.

Methodologies developed to increase user involvement in in-house projects include the sociotechnical approach [Mumford 1983, 1993] and Scandinavian participatory design approaches [Bjerknes et al. 1987, Greenbaum and Kyng 1991]. These stress the need for developers to obtain a detailed understanding of actual work processes and worker preferences. Participatory design also emphasizes educating prospective users about technical possibilities. Early work focused on workplace democracy; when interactive systems arrived, the focus shifted to developing better software tools for workers.

With the arrival of PCs, commercial, off-the-shelf product development focused attention on highly interactive systems and applications. Product development organizations present a different set of constraints on developers. As with contract development, users and developers are in different organizations. Unlike contract development, the development organization is responsible for defining the requirements. Competitive markets mean more emphasis on human–computer interfaces and greater time pressures.

Inadequacies of the waterfall development methodology were clear in this context. Rapid prototyping and iterative design, with heavy user involvement, were promoted from the outset. These principles were widely accepted, but not widely practiced, due to organizational constraints detailed in Grudin [1991b] and Poltrock and Grudin [1994]. When motivated to seek user involvement, which is not always the case, developers can have difficulty identifying appropriate users, obtaining access to them, and motivating users who after all work in other organizations and may never use the product that emerges. If these barriers are overcome, there are often obstacles to using the information that is received. Development schedules rarely provide time for iteration, and changes in the interface can be visible and unsettling to management, as well as to those working on product documentation and training, which are tied closely to the interface.

To overcome these obstacles, product developers have sought to adapt and extend participatory design and related techniques. A notable example is contextual inquiry and modeling [Holtzblatt and Beyer 1993, Holtzblatt and Jones 1993, Beyer and Holtzblatt 1995].

A fourth organizational context for development, custom development, blends characteristics of each of the three previously discussed. The development organization is distinct from the user organization and works under contract. The contract is not necessarily competitively bid and the development organization may be selected based on geographic proximity. Rather than prohibited, long-term, close involvement can serve to mutual advantage, infusing some aspects of internal development into the process. The development organization often focuses on a market niche, where similar custom jobs will amortize their investment. The more successful they are at finding customers with the same needs, the closer their situation comes to resemble product development; in fact, their software may evolve into a commercial product.

Custom development seems likely to thrive as demands for software become increasingly diverse and specialized. Grudin [1996] argues that custom development could be particularly promising for HCI tools that focus on documenting upstream design process for subsequent use in redesign or maintenance, because, for example, it is a context in which design, redesign, and maintenance are likely to be done by the same people.

Figure 44.2 summarizes responses to stage or waterfall models arising in contract development (software engineering), in-house development (information systems), and product or package development (human–computer interaction). For a richer view of the history, see Hirschheim et al. [1995].

This only suggests differences among development contexts and the effects of organizations. There exist organizations to mediate between a developer and a user organization. This activity takes place in economic, cultural, political, and societal conditions to which organizations contribute. Other organizational factors influence how technology is developed and used: structures and processes, size, intended market, geographical placement, age, application novelty, function, culture, environment. In a small startup company, all employees may see one another regularly; in a large organization, the software, documentation, and training developers may work in different states or countries. In the U.S., court decisions regarding *look and feel* copyrights or patents can affect the process and product of development; in Europe, codetermination laws can affect the development process by requiring user involvement.

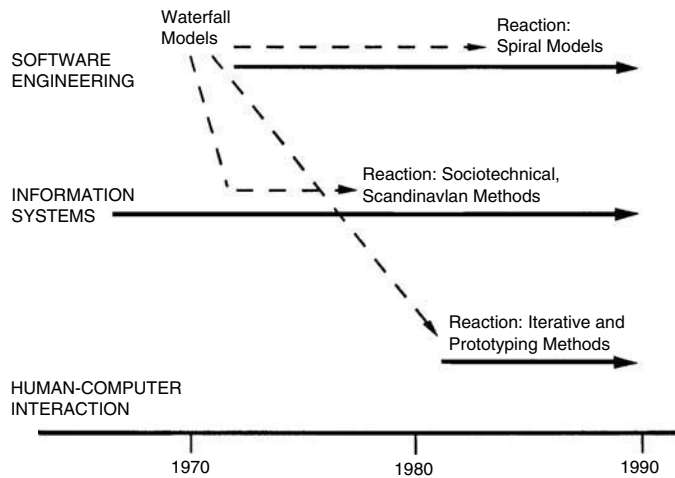

FIGURE 44.2 Approaches to systems development in different development contexts.

This list is not exhaustive, but it serves as an indicator that organizational factors within a development environment have a strong bearing on systems development, and thoughtful developers will consider those factors carefully. Knowledge of organizational influences can alert developers to obstacles and biases that can result in painful mistakes. It can also guide them to techniques that are suited to their context. Keil and Carmel [1995] have closely analyzed successful projects in two contexts, corresponding to what we have called in-house and product development. They report, for example, on 11 different approaches to establishing links among customers and developers and find that the methods used and their levels of effectiveness vary across contexts.

44.6 Organizational Contexts of Use

We now examine efforts to model, understand, or use intermediaries to represent user organizations. The emergence of different contexts of system use and development is relevant here as well. A very good treatment of this topic is found in Hirschheim et al. [1995]. This work to some degree builds on Friedman [1989] which is equally absorbing.

Both of these works focus virtually exclusively on internal or in-house systems development, with perhaps some attention to custom development. This is understandable: in-house development dominated systems development for decades, and this has been even more true in Europe. In the U.S., competitive contract development was more influential in the early days and commercial off-the-shelf software has attracted considerable attention recently.

It is important to keep in mind that close attention to human–computer interaction bloomed in commercial software development, not in in-house systems development. In the latter context, it makes intuitive sense to try to model aspects of the organization, but the focus has not been on improving human–computer interaction.

Hirschheim et al. [1995] note that those applications were growing more complex over time, but do not note the dramatic shifts in the user populations, the specific new demands that highly interactive systems introduce, or strong ties between the features of certain systems development methodologies and the development contexts in which they originate.

For example, they note that at one time user requirements elicitation was considered a largely noncontroversial task of asking users what they needed in their jobs. This may always have been a questionable assumption, but it was less so for batch processing than for interactive systems. Elsewhere, they note that software engineering focused on development steps “under the assumption that systems requirements are

given” without noting that in government contracting that was often the situation, however problematic it might be. And so forth.

Nevertheless, Hirschheim et al. [1995] is an excellent introduction to organizational and data modeling, as long as one keeps in mind that the history and context of these modeling and development approaches placed less weight on human–computer interaction concerns than the reader might. The distinctions that are introduced include the following:

- Information systems (IS) can be limited to the technical aspects or defined to include humans. IS design can be viewed as designing technical systems that have social consequences or as primarily addressing organizational and social complexity.
- IS development involves changing object systems that are defined differently by different individuals; the choice of a systems development methodology is a major factor among the many that affect a person’s definition of the object system.
- Rather than say that a problem exists, it may be better to say that one is constructed among stakeholders with different perceptions.
- Information systems development can be marked by uncertainty regarding the means employed, the effects that will result, or whether the right problem was attacked. Systems development methodologies can be categorized as process oriented or data oriented. Object systems can be perceived and modeled as static, dynamic, or hybrid.
- User participation in system design can be seen as expedient in collecting needed information or overcoming resistance to change, as a prerequisite for creating shared meanings necessary for design, or as a moral right.
- Most methodologies focus on one application; only a few embrace organization-wide planning.

The authors use these and other distinctions to provide alternative views of a range of methodologies. These include structured analysis and design methodologies, which focus on modeling organizational processes and data flows, and data-oriented analysis and design approaches, which represent organizations as a structured collection of facts and associations among them. Object-oriented analysis and design define software units that encapsulate methods and data. In parallel with the evolution of IS development, the authors consider the evolution of data modeling approaches emerging from the techniques that led to the development of database technologies.

The authors identify seven generations of information system design methodologies that replaced unstructured, ad hoc approaches to design. The sequencing is not strictly chronological or convincing, but it is a useful exercise. They are: (1) formal life cycle approaches (from mid-1960s); (2) structured approaches (mid-1970s), emphasizing user requirements; (3) prototyping and evolutionary approaches (late 1970s), tied here to greater competition but not especially to greater prominence of the human–computer interface; (4) sociotechnical and participative approaches (late 1970s, early 1980s) in which users take at least some control and redesign work situations; (5) sense making and problem formulation approaches (early 1980s), involving users and developers from very early in a project; (6) trade union led approaches (mid-1970s through mid-1980s), to support democratic planning and later to design tools to augment workers’ skills; and (7) emancipatory approaches (future), a rather vaguely defined approach devised by the authors.

What emerges from this examination of modeling, interpreted through a sense of the contexts in which these approaches have been introduced, is a sense of the trajectory of change and the pressures driving it. When information systems consist largely of entering, organizing, storing, and transforming data, and when the data contain records such as employee names with their ages, salaries, managers, departments, and so forth, then data-centered IS design might flourish in ways that are less likely when the system focuses on real-time computer-mediated communication. A system designed to compute projectile trajectories might give rise to wide agreement on the definition of terms and relevant concepts, whereas a workflow system that must model a group of people and objects that have not previously been considered together will inevitably confront conflicting views of work, conflicting terminology, and other issues. Of particular

relevance here, software applications in which over 50% of the program code is devoted to the human-computer interface inevitably introduce a range of considerations and challenges that did not exist for methodologies that often consciously ignored or relegated to a single process substep the establishment of the interface.

Although one does not leave the survey of current practice with a prescription for organizational modeling, one does leave it with a sense of the richness and importance of the problem, and an awareness of the steps taken in the direction of solutions. The growing focus on sense making, on recognizing the multitude of perspectives, and the constant shift in the sense of the target suggests that formal modeling of groups and organizations will encounter limits. And yet as people strive to build systems to support organizations through contact with most or all members, the effort to flexibly model the organizations will inevitably continue.

44.7 What Are the Organizational Issues in Interactive System Use?

This discussion is organized along broad system life cycle phases used by Grudin and Markus [in press]: initiation (idea origination, project funding), acquisition (system acquired or built), implementation and use (internal deployment, use or rejection), and impacts and consequences (system effects experienced; steps taken to augment, mitigate, or otherwise manage them).

44.7.1 Initiation Phase

The source of a technology investment idea can have important influences on downstream events. The source can be external or internal; if internal, it can be from high-ranking line management* (possibly responding to advertising or business fads) or lower, perhaps from the technical staff. Approval may require consent of one line manager or an internal technology approval board. Justification can serve a positive purpose of building shared understanding, but the understanding may be inaccurate if distortion is needed to meet preset criteria. See Dean [1987] for a discussion of the technology justification process and Cohen et al. [1972] for a classic paper on decision making in organizations. Suboptimal outcome possibilities include underutilized systems as well as systems rejected because they benefited few users (e.g., only the decision maker [Grudin 1994]). Kling [1978] describes a welfare case tracking system that was adopted despite its lack of operational benefits because the system made the agency look good to potential funders. This was considered a success.

During the initiation phase, the project schedule, funding level, and allocation of funds to different project activities are usually set. Often these decisions have lasting and not entirely positive downstream influences. For instance, an organizational decision to limit access to Lotus Notes to one particular work unit can create difficulties later for activities that cross the boundaries between work units. Or the decision makers may allocate enough resources to acquire or develop a technology but significantly underfund training and support for users, creating predictably negative consequences when the technology is up and running (see Walton [1989]).

In short, the initiation phase of the life cycle can involve political negotiations between people and groups who propose new technologies and people and groups who control essential resources (both technical and financial). These negotiations can result in the selection of inappropriate solutions to organizational problems, or they can result in perceptions and decisions that subsequently have negative effects on system features, use, and impacts.

**Line* refers to managers in the core businesses or functions of the organization, as opposed to those in staff functions. In most organizations, IS is viewed as a staff function. This is frequently true even in software development firms, where the IS people who provide support for the internal operations of the business are organizationally separate from line software developers who work on the products the company sells.

44.7.2 Acquisition

A project leader is usually appointed to oversee acquisition of a software product. Several difficulties can arise in this phase.

As noted earlier, the project team may define the capabilities required by the interactive system in purely technical terms [Stinchcombe 1990]. The project team may focus on software features, hardware, and networking requirements, but neglect to provide for the training and support of users and necessary changes in organizational aspects such as their job descriptions, their performance evaluations, and their rewards. Likely result: limited user acceptance and poor quality use [Walton 1989].

The project team is often subjected to influence attempts by interested parties: some may desire to build the technology in-house, even with perfectly acceptable packages available. Some may wish to customize a package to unique organizational needs rather than to change the way the organization works. Project team members may have different personal preferences for a technology vendor, a software package, or a platform, or demand that the solution incorporate certain features. To meet schedule and budgets, certain aspects of the project included in the original proposal may be postponed or dropped altogether. In the acquisition phase the innovation becomes more real and more resistant to change. Errors made in initiation can be fixed, or a well-reasoned decision steered astray [Markus and Soh 1993, Soh and Markus 1995].

Finally, another outcome of the acquisition phase is a new set of social relations among various groups inside and outside the organization who will work with or support the technology during the *use* phase: linkages among technology vendors, third-party developers, in-house developers, in-house computer operations and support personnel, or an outsourcing firm, and users and their managers. Thorny support issues may remain unresolved due to the incentives built into outsourcer's service level agreements as negotiated during the acquisition phase. User skills may stagnate or decline, because a one-shot training program did not address the need for advanced training or for initial training for new hires. In short, what results from the acquisition phase may or may not be adequate for the organization's future needs.

44.7.3 Implementation (Introduction) and Use

Activities occurring during the implementation and use phase can quite substantially alter (for better or worse) the capabilities previously acquired. Technology that is made or bought and thrown "over the wall" to users and their managers usually results in a failure of the technology to yield appropriate organizational benefits. Sometimes line managers and users see some potential in the technologies tossed at them and adopt (and support) these technologies as their own.

There is no guarantee that technology will be used in ways consistent with either the initiator's or the project team's vision. The average user of even a modestly complex information technology like the digital telephone system uses only a small fraction of the technology's features [Manross and Rice 1986]. Once they acquire some level of proficiency, users often stop learning new features unless a new release, a conversion, or a major change in work requirements demands new learning [Tyre and Orlikowski 1994]. Often users will enact time consuming and inefficient workarounds [Gasser 1986], rather than invest the time, energy, and pain required to learn a more efficient procedure.

Sometimes users take simple information technologies and *overuse* them, getting more out of them than designers ever intended. Use unanticipated when the technology was first acquired, rather than the initially planned uses, often results in what are subsequently called organizational *transformations*: radical improvements in business processes, first-in-the-world new products and services, and so forth.

The technical term for the process we have been describing, in which users take a technology and redefine it, using it differently than developers, initiators, and implementors intended, is *reinvention* [Rogers 1995] or *emergence* [Markus and Robey 1988]. Reinvention is significant because it means that the use and hence the impacts of a technology can never fully be determined during the acquisition phase. Even when the project team involves users in design and fashions a careful technology implementation plan, both users and developers may fail to see the organizational implications of a technology until the technology itself is

real, installed, and running in an organization.* What happens when users get their hands on a technology can never be fully predicted or controlled. Sometimes what emerges during use is much less than vendors, initiators, and implementors had hoped; sometimes it is much more.

44.7.4 Impacts and Performance

Some experts estimate that most benefits obtained from an innovation come from subsequent modifications and enhancements, rather than from the initial change itself [Stinchcombe 1990]. Thus, for example, Frito-Lay did not reap full advantages from its hand-held computer project until it developed analytic tools to improve product promotion decision making and changed the organizational level at which promotion decisions were made [Harvard 1993].

On the other hand, a major reason for the failure of information technology (IT) investments to pay off in terms of improved organizational performance is a tendency for organizations to make nonvalue added improvements in their IT environments [Baily 1986, Baily and Gordon 1988].** The people at VeriFone note, "If you're just using e-mail, there's no reason to have a Pentium. You don't need a Ferrari to drive to the supermarket" [Harvard 1994].

Positive organizational impacts from information technology are said to fall into four categories: new products and services enabled by IT, improved business processes, better organizational decision making attributable to databases and analytic tools, and increased organizational flexibility attributable to communication, collaboration, and coordination technologies [Sambamurthy and Zmud 1992]. However, two issues regarding the impacts of technology must be borne in mind.

First, positive organizational impacts due to technology investments do not always result in improved organizational performance, measured in terms important to various organizational stakeholders [Soh and Markus 1995]. Lack of performance improvement despite positive impacts can occur if the innovation is quickly duplicated by competitors or if the improvements only bring company performance up to existing customer expectations [Arthur 1990, Clemons 1991].

Second, positive organizational impacts are almost invariably accompanied by negative impacts on some dimensions of organizational life [Pool 1983, Rogers 1995]. For instance, the improved organizational efficiency and flexibility attributed to electronic communications technologies such as e-mail may be accompanied by depersonalization, stress, overload, and accountability politics [Sproull and Kiesler 1991, Markus 1994b]. And no matter how much people in an organization value the improvements in organizational functioning, they may still mourn the passing of traditional ways that gave meaning and quality to their working lives.

44.8 Conclusions

Human-computer interaction could postpone reckoning with organizational issues when PCs were computational islands. Today we are networked and on the Internet: The day of reckoning has arrived. Designers, developers, acquirers, users, and researchers must all be cognizant of group and organizational issues to a degree previously unnecessary. The HCI and IS fields are quickly merging. Organizational issues will affect many of us working on human-computer interaction, through the organizational contexts of system introduction and adoption, and the organizational contexts of system development. With this knowledge, frustration often gives away to challenge, and challenge evolves into adventure.

*Social scientists repeatedly warn that user participation in design does not ensure success, since participation can lead to incrementalism or recreation of the status quo [Walton 1989, Leonard-Barton 1988, 1990, Markus and Keil 1994].

**This issue and its relationship to usability is explored in detail by Landauer [1995].

45.1 Introduction

Usability engineering [Nielsen 1994b] is not a one-shot event where the user interface is fixed up before the release of a product. Rather, usability engineering is a set of activities that ideally take place throughout the lifecycle of the product, with significant activities happening at the early stages before the user interface has even been designed. The need to have multiple usability engineering stages supplement each other was recognized early in the field, though not always followed by development projects [Gould and Lewis 1985].

Usability cannot be seen in isolation from the broader corporate product development context where one-shot projects are fairly rare. Indeed, usability applies to the development of entire product families and extended projects where products are released in several versions over time. In fact, this broader context only strengthens the arguments for allocating substantial usability engineering resources as early as possible, since design decisions made for any given product have ripple effects due to the need for subsequent products and versions to be backward compatible. Consequently, some usability engineering specialists [Grudin et al. 1987] believe that “human factors involvement with a particular product may ultimately have its greatest impact on future product releases.” Of course, having to plan for future versions is also a primary reason to follow up the release of a product with field studies of its actual use.

Table 45.1 shows a summary of the lifecycle stages discussed in this chapter. It is important to note that a usability engineering effort can still be successful even if it does not include every possible refinement at all of the stages.

The lifecycle model emphasizes that one should not rush straight into design. The least expensive way for usability activities to influence a product is to do as much as possible before design is started, since it will

then not be necessary to change the design to comply with the usability recommendations. Also, usability work done before the system is designed may make it possible to avoid developing unnecessary features. Several of the predesign usability activities might be considered part of a market research or product planning process as well, and may sometimes be performed by marketing groups. However, traditional market research does not usually employ all of the methods needed to properly inform usability design, and the results are often poorly communicated to developers. But there should be no need for duplicate efforts if management successfully integrates usability and marketing activities [Wichansky et al. 1988]. One outcome of such integration could be the consideration of product usability attributes as features to be used by marketing to differentiate the product. Also, marketing efforts based on usability studies can sell the product on the basis of its benefits as perceived by users (*what* it can do that they want) rather than its features as perceived by developers (*how* does it do it).

45.2 Know the User

The first step in the usability process is to study the intended users and use of the product. At a minimum, developers should visit a customer site so that they have a feel for how the product will be used. Individual user characteristics and variability in tasks are the two factors with the largest impact on usability, so they need to be studied carefully. When considering users, one should keep in mind that they often include installers, maintainers, system administrators, and other support staff in addition to the people who sit at the keyboard. The concept of *user* should be defined to include everybody whose work is affected by the production in some way, including the users of the system's end product or output even if they never see a single screen.

Even though "know the user" is the most basic of all usability guidelines, it is often difficult for developers to get access to users. Grudin [1990, 1991a, 1991b] analyzes the obstacles to such access, including:

- The need for the development company to protect its developers from being known to customers, since customers may bypass established technical support organizations and call developers directly, sidetracking them from their main job
- The reluctance of sales representatives to let anybody else from the company talk to their customers, fearing that the developers or usability people may offend the customer or create dissatisfaction with the current generation of products
- User organizations only making users available for a short time, either because they are highly paid executives or because they are unionized and dislike being studied

All of these issues are real and need to be addressed when trying to get to know the user. No universal solutions are available, except to recommend an explicit effort to get direct access to representative users

and not be satisfied with indirect access and hearsay. It is amazing how much time is wasted on certain development projects by arguing over what users *might* be like or what they *may* want to do. Instead of discussing such issues in a vacuum, it is much better (and actually less time consuming) to get hard facts from the users themselves.

45.2.1 Individual User Characteristics

It is necessary to know the class of people who will be using the system. In some situations this is easy since it is possible to identify these users as concrete individuals. This is the case when the product is going to be used in a specific department in a particular company. For other products, users may be more widely scattered such that it is possible to visit only a few, representative customers. Alternatively, the products might be aimed toward the entire population or a very large subset.

By knowing the users' work experience, educational levels, ages, previous computer experience, and so on, it is possible to anticipate their learning difficulties to some extent and to better set appropriate limits for the complexity of the user interface. Certainly one also needs to know the reading and language skills of the users. For example, very young children have no reading ability, so an entirely nontextual interface is required. Also, one needs to know the amount of time users will have available for learning and whether they will have the opportunity for attending training courses: The interface must be made much simpler if users are expected to use it within minimum training.

The users' work environment and social context also need to be known. As a simple example, the use of audible alarms, beeps, or more elaborate sound effects may not be appropriate for users in open office environments. In a field interview I once did, a secretary complained strongly that she wanted the ability to shut off the beep because she did not want others to think that she was stupid because her computer beeped at her all the time.

A great deal of the information needed to characterize individual users may come from market analysis or as a side benefit of the observational studies one may conduct as part of the task analysis. One may also collect such information directly through questionnaires or interviews. In many cases, it is best not to rely totally on written information since new insights are almost always achieved by observing and talking to actual users in their own working environment.

45.2.2 Task Analysis

A task analysis [Diaper 1989, Fath and Bias 1992, Johnson 1992] is extremely important as early input to the system design. The users' overall goals should be studied as well as how they currently approach the task, what their information needs are, and how they deal with exceptional circumstances or emergencies. For example, systematic observation of users talking to their clients may reveal input and output needs for a transactions-processing system. Sometimes, interviewing or observing the users' clients or others who interact with them can also provide additional task analysis insights [Garber and Grunes 1992].

The users' model of the task should also be identified, since it can be used as a source for metaphors for the user interface. Also, seek out and observe especially effective users and user strategies and *workarounds* as hints of what a new system could support. Such lead users are often a major source of innovations [von Hippel 1988]. Finally, one should try to identify the weaknesses of the current situation: points where users fail to achieve goals, spend excessive time, or are made uncomfortable. These weaknesses present opportunities for improvements in the product being developed.

A typical outcome of a task analysis is a list of all of the things users want to accomplish with the system (the goals), all of the information they will need to achieve these goals (the preconditions), the steps that need to be performed and the interdependencies between these steps, all of the various outcomes and reports that need to be produced, the criteria used to determine the quality and acceptability of these results, and finally the communication needs of the users as they exchange information with others while performing the task or preparing to do so.

When interviewing users for the purpose of collecting task information, it is always a good idea to ask them to show concrete examples of their work products rather than keeping the discussion on an abstract level. Also, it is preferable to supplement such interviews with observations of some users working on real problems, since users will often rationalize their actions or forget about important details or exceptions when they are interviewed.

Often, a task analysis can be decomposed in a hierarchical fashion [Greif 1991], starting with the larger tasks and goals of the organization and breaking each of them down into smaller subtasks, that can again be further subdivided. Typically, each time a user says, “then I do this,” an interviewer could ask two questions: “*Why* do you do it?” (to relate the activity to larger goals) and “*How* do you do it?” (to decompose the activity into subtasks that can be further studied). Other good questions to ask include, “Why do you not do this in such and such a manner?” (mentioning some alternative approach you can think of), “Do errors ever occur when doing this?,” and “How do you discover and correct these errors?” [Nielsen et al. 1986].

Finally, users should be asked to describe exceptions from their normal work flow. Even though users cannot be expected to remember *all* of the exceptions that have ever occurred, and even though it will be impossible to predict all of the future exceptions, there is considerable value to having a list indicating the *range* of exceptions that must be accommodated. Users should also be asked for remarkable instances of notable successes and failures, problems, what they liked best and least, what changes they would like, what ideas they have for improvements, and what currently annoys them. Even though not all such suggestions may be followed in the final design, they are a rich source of inspiration.

45.2.3 Functional Analysis

A new computer system should not be designed simply to propagate suboptimal ways of doing things that may have been instituted because of limitations in previous technologies. Therefore, one should not analyze just the way users currently do the task, but also the underlying functional reason for the task: What is it that really needs to be done, and what are merely surface procedures which can, and perhaps should, be changed.

As a simple example, initial observations of people reading printed manuals could show them frequently turning pages to move through the document. A naive implementation of on-line documentation might take this observation to indicate the need for really good and fast paging or scrolling mechanisms. A functional analysis would show that manual users really turn pages this much because they want to find specific information, but they have a hard time locating the correct page. Based on this analysis, one could design an on-line documentation interface that first allowed users to specify their search needs, then used an outline of the document to show locations with high search scores, and finally allowed users to jump directly to these locations, highlighting their search terms to make it easier to judge the relevance of the information [Egan et al. 1989]. Of course, there is a limit to how drastically one can change the way users currently approach their task, so the functional analysis should be coordinated with a task analysis.

45.2.4 International Use

A final point related to knowing the users is to plan for any international use of the product from the very beginning of the usability engineering lifecycle [del Galdo and Nielsen 1996]. Some products are only intended for use in a single country, but many development projects need to consider foreign users. Traditionally, internationalization and localization was done after shipping the domestic version of the product, but true international usability requires that international users are considered throughout the lifecycle. Consider, for example, the design of the addressing feature in an e-mail program. If the program is going to be used in a country with an extremely strong sense of hierarchy in the workplace, then customers may require that the addressing feature sort the message recipients by rank, so fitting the program to that culture cannot be done simply by translating the menu items.

45.3 Competitive Analysis

Much of what you need to learn about user interface design for a new product can be gleaned from studies of your competitors' products [Nielsen 1995]. The best prototype of your next product is your own old product since you will presumably want to repeat everything that was good about it and avoid everything that was bad about it. The second-best prototypes are the competing products. Your competitors have invested significant resources in designing and implementing what they believe to be good user interfaces. You should take advantage of those investments.

Please note that I am not suggesting that you violate copyright by cloning your competitors' interface designs. What I *do* suggest is that you can learn a lot by analyzing other products that are designed to solve the same (or related) problems as your own future product. You can see what works and what does not work in these other designs, and you can learn how users approach the tasks by seeing how they work with the competing products. Competitive usability analysis should be performed very early in the usability engineering lifecycle. I would recommend performing competitive usability analysis after the first stages of customer visits, requirements gathering, and defining the product vision, but before you move on to actually designing and prototyping your own user interface.

For competitive usability analysis, I normally recommend acquiring the three or four leading competing products. Often, these products can be bought at a nominal price on the open market, especially in the case of PC software. Even if you are developing for high-end workstations or mainframes, much can still be learned from the design of lower end software even if there is some difference in the supported feature set. To design and develop a prototype yourself will normally take at least a week of engineering time, even for quite low-fidelity prototypes, so a home-grown prototype will cost a minimum of \$4000 if the loaded cost of an engineer (whether usability engineer or development engineer) is \$100 per hour. Normally one can buy at least 10 commercial software packages for the same money, and these packages will be very high-fidelity prototypes since they are fully functional (even if the features are not exactly the same as the ones you want in your product).

Some classes of products are substantially more expensive than PC software, but it is still often possible to buy evaluation copies, single-user licenses, or other cheap versions of high-end systems. Considering that a competitive usability analysis normally consists of having three or four users use the system for 1 or 2 h each, there is no need to buy the most elaborate version of the competing systems.

If even the cheapest versions of the competing systems are too expensive, you can rely on paper prototyping. Briefly, this method consists of showing users paper printouts of some of the screens from a user interface and asking them to describe what they would do with each screen. A selection of screendumps can usually be acquired from your competitors' sales brochures and so a few hours at a good trade show should suffice to collect more than enough material for an informative usability test.

Often you will have too many competitors to perform a usability study of them all. I usually find that one learns the most from studying four or five competing user interfaces. Three criteria should be used to select the systems that will be subjected to a competitive usability analysis:

- What products have an especially good reputation for good user interface design?
- What products show examples of interesting features or design ideas that you want for your own product?
- Who is the market leader?

Furthermore, you can consider pragmatic issues such as the price of a product and the difficulty of installing and running it on the equipment in your competitive analysis laboratory. If you do not have a competitive analysis laboratory, I highly recommend getting one: buy a computer from each of the major platform families, making sure that it is a high-end model with plenty of memory, a large hard disk, and a compact disc-read-only memory (CD-ROM) drive. You do not want to save on equipment purchases for the competitive analysis laboratory because you will not have the expertise to make each model run optimally: just buy nice big models in vendor-supported configurations. Also buy a good screendump

utility for each machine because you will want to include shots of the competing user interfaces in your internal reports and presentations.

The first steps of a competitive usability analysis simply consist of familiarizing yourself with the products and checking how they have designed the features you are contemplating for your product. You can also make lists of user interface elements (commands, features, and attributes) to make sure that you do not overlook something important when designing your own interface.

The next step in competitive usability analysis is a brief usability test where a small number of users are exposed to the various products and asked to perform a few sample tasks. As always with user testing it is important to recruit test users who are representative of the intended user population (that is, the actual end users and not their managers or information systems (IS) support staff — unless, of course, the product is *intended* to have IS personnel as its main users). The tasks should also be chosen to represent the intended usage of the product. For competitive usability analysis, you should select users and tasks that are representative for your future product and not users and tasks that are representative for the other products. After all, the goal is not to evaluate whether the other companies have done a good job designing for *their* customer base but to see what you can learn from their efforts when applied to *your* customer base.

45.4 Goal Setting

Usability is not a one-dimensional attribute of a system. Usability comprises several components, including learnability, efficiency of use, user error rates, and subjective satisfaction, that can sometimes conflict. Normally, not all usability aspects can be given equal weight in a given design project, and so you will have to make your priorities clear on the basis of your analysis of the users and their tasks. For example, learnability would be especially important if new employees were constantly being brought in on a temporary basis, and the ability of infrequent users to return to the system would be especially important for a reconfiguration utility that was used once every three or four months.

The different usability parameters can be operationalized and expressed in measurable ways. Before starting the design of a new interface, it is important to discuss the usability metrics of interest to the project and to specify the goals of the user interface in terms of measured usability [Chapanis and Budurka 1990]. One may not always have the resources available to collect statistically reliable measures of the usability metrics specified as goals, but it is still better to have some idea of the level of usability to strive for.

For each usability attribute of interest, several different levels of performance can be specified as part of a goal-setting process [Whiteside et al. 1988]. One would at least specify the minimum level which would be acceptable for release of the product, but a more detailed goal specification can also include the planned level one is aiming for as well as the current level of performance. Additionally, it can help to list the current value of the usability attribute as measured for existing or competing interfaces, and one can also list the theoretically best possible value, even though this value will typically not be attained. Figure 45.1 shows one possible notation, called a *usability goal line*, for representing the range of specification levels for one usability goal.

In the example in Figure 45.1, the number of user errors per hour is counted. When using the current system, users make an average of 4.5 errors/h and the planned number of user errors is 2.0/h. Furthermore,

FIGURE 45.1 An example of a usability goal line in a notation similar to that used by Rideout [1991].

the theoretical optimum is obviously to have no errors at all. If the new interface is measured at anything between 1.0 and 3.0 user errors/h, it will be considered on target with respect to this usability goal. A performance in the interval of 3–5 would be a danger signal that the usability goal was not met, even though the new interface could still be released on a temporary basis since a minimal level of usability had been achieved. It would then be necessary to develop a plan to reduce user errors in future releases. Finally, more than 5.0 user errors/h would make this particular product sufficiently unusable to make a release unacceptable.

Usability goals are reasonably easy to set for new versions of existing systems or for systems that have a clearly defined competitor on the market. The minimum acceptable usability would normally be equal to the current usability level, and the target usability could be derived as an improvement that was sufficiently large to induce users to change systems. For completely new systems without any competition, usability goals are much harder to set. One approach is to define a set of sample tasks and ask several usability specialists how long it ought to take users to perform them. One can also get an idea of the minimum acceptable level by asking the users, but unfortunately users are notoriously fickle in this respect; countless projects have failed because developers believed users' claims about what they wanted, only to find that the resulting product was not satisfactory in real use.

45.4.1 Parallel Design

It is often a good idea to start the design with a parallel design process, in which several different designers work out preliminary designs [Nielsen et al. 1993, 1994, Nielsen and Faber 1996]. The goal of parallel design is to explore different design alternatives before one settles on a single approach that can then be developed in further detail and subjected to more detailed usability activities. Figure 45.2 is a conceptual illustration of the relation between parallel and iterative design.

Typically, one can have three or four designers involved in parallel design. For critical products, some large computer companies have been known to devote entire teams to developing multiple alternative designs almost to the final product stage, before upper management decided on which version to release. In general, though, it may not be necessary for the designers to spend more than a few hours or at the most one or two days on developing their initial designs. Also, it is normally better to have designers work individually rather than in teams, since parallel design only aims at generating rough drafts of the basic design ideas.

In parallel design, it is important to have the designers (or the design teams) work independently, since the goal is to generate as much diversity as possible. Therefore, the designers should not discuss their designs with each other until after they have produced their draft interface designs.

FIGURE 45.2 Conceptual illustration of the relation between parallel and iterative design. Normally, the first prototype would be based on ideas from several of the parallel design sketches.

When the designers have completed the draft designs, one will often find that they have approached the problem in at least two drastically different ways that would give rise to fundamentally different user interface models. Even those designers who are basing their designs on the same basic approach almost always have different details in their designs. Usually, it is possible to generate new combined designs after having compared the set of initial designs, taking advantage of the best ideas from each design. If several fundamentally different designs are available, it is preferable to pursue each of the main lines of design a little further in order to arrive at a small number of prototypes that can be subjected to usability evaluation before the final approach is chosen.

A variant of parallel design is called *diversified parallel design* and is based on asking the different designers to concentrate on different aspects of the design problem. For example, one designer could design an interface that was optimized for novice users, at the same time as another designer designed an interface optimized for expert users and a third designer explored the possibilities of producing an entirely nonverbal interface. By explicitly directing the design approach of each designer, diversified parallel design drives each of these approaches to their limit, leading to design ideas that might never have emerged in a unified design. Of course, some of these diversified design ideas may have to be modified to work in a single, integrated design.

It is especially important to employ parallel design for novel systems where little guidance is available for what interface approaches work the best. For more traditional systems, where competitive products are available, the competitive analysis previously discussed can serve as initial parallel designs, but it might still be advantageous to have a few designers create additional parallel designs to explore further possibilities.

The parallel design method might at first seem to run counter to the principle of cost-effective usability engineering, since most of the design ideas will have to be thrown away without even being implemented. In reality, though, parallel design is a very cheap way of exploring the design space, exactly *because* most of the ideas will not need to be implemented, the way they might be if some of them were not tried until later as part of the iterative design. The main financial benefit of parallel design is its parallel nature, which allows several design approaches to be explored at the same time, thus compressing the development schedule for the product and bringing it to market more rapidly. Studies have shown that about a third of the profits are lost when products ship as little as half a year late [House and Price 1991], and so anything that can speed up the development process should be worth the small additional cost of designing in parallel rather than in sequence.

45.4.2 Participatory Design

Participatory design is discussed further in [Chapter 66](#) and elsewhere and will not be covered here.

45.5 Coordinating the Total Interface

Consistency is one of the most important usability characteristics. Consistency should apply across the different media which form the total user interface, including not just the application screens but also the documentation, the on-line help system, and any on-line or videotaped tutorials [Perlman 1989] as well as traditional training classes. For example, in one case studied by Poltrock [1996], training materials described an obsolete way of using an interface because the training department had not been informed about the introduction of a redesigned, and presumably better, interface.

Consistency is not just measured at a single point in time but should apply over successive releases of a product so that new releases are consistent with their predecessors. Also, since very few companies produce only a single product, efforts should be made to promote consistency across entire product families. Corporate user interface standards are one common way of promoting that goal. In spite of the general desirability of consistency, it is obviously not the only desirable usability characteristic, and consistency may sometimes conflict with other interface desiderata [Grudin 1989]. It is necessary to maintain some flexibility so that bad design is not forced upon users for the sake of consistency alone.

To achieve consistency of the total interface it is necessary to have some centralized authority for each development project to coordinate the various aspects of the interface. Typically, this coordination can be

done by a single person, but on very large projects or to achieve corporatwide consistency, a committee structure may be more appropriate. Also, interface standards are an important approach to achieving consistency. In addition to such general standards, a project can develop its own ad hoc standard with elements such as a dictionary of the appropriate terminology to be used in all screen designs as well as in the other parts of the total interface.

In addition to formal coordination activities, it is helpful to have a shared culture in the development groups with common understanding of what the user interface should be like. Many aspects of user interface design (especially the dynamics) are hard to specify in written documents but can be fairly easily understood from looking at existing products following a given interface style. Actually, prototyping also helps achieve consistency, since the prototype is an early statement of the kind of interface toward which the project is aiming. Having an explicit instance of parts of the design makes the details of the design more salient for developers and encourages them to follow similar principles in subsequent design activities [Bellantone and Lanzetta 1991].

Furthermore, consistency can be increased through technological means such as code sharing or a constraining development environment. When several products use the same code for parts of their user interface, then those parts of the interface automatically will be consistent. Even if identical code cannot be used, it is possible to constrain developers by providing development tools and libraries that encourage user interface consistency by making it easier to implement interfaces that follow given guidelines [Tognazzini 1989, Wiecha et al. 1989].

45.6 Heuristic Evaluation

Guidelines list well-known principles for user interface design which should be followed in the development project. In any given project, several different levels of guidelines should be used: *general guidelines* applicable to all user interfaces, *category-specific guidelines* for the kind of system being developed (e.g., guidelines for window-based administrative data processing or for voice interfaces accessed through telephone keypads), and *product-specific guidelines* for the individual product. All of these guidelines can be used as background for heuristic evaluation.

Heuristic evaluation [Nielsen and Molich 1990, Nielsen 1994a] is the most popular of the usability inspection methods [Nielsen and Mack 1994]. Heuristic evaluation is done by looking at an interface and trying to come up with an opinion about what is good and bad about the interface. Heuristic evaluation should be done as a systematic inspection of a user interface design for usability. The goal of heuristic evaluation is to find the usability problems in a user interface design so that they can be attended to as part of an iterative design process. Heuristic evaluation involves having a small set of evaluators examine the interface and judge its compliance with recognized usability principles (the heuristics). A recommended set of heuristics is listed in [Table 45.2](#).

In principle, individual evaluators can perform a heuristic evaluation of a user interface on their own, but the experience from several projects indicates that any single evaluator will miss most of the usability problems in an interface. Averaged over six projects, single evaluators found only 35% of the usability problems in the interfaces. However, since different evaluators tend to find different problems, it is possible to achieve substantially better performance by aggregating the evaluations from several evaluators. There is a nice payoff from using more than one evaluator, and it is recommended to use about five evaluators, and certainly at least three. The exact number of evaluators to use would depend on a cost-benefit analysis, and more evaluators should obviously be used in cases where usability is critical or when large payoffs can be expected due to extensive or mission-critical use of a system.

Heuristic evaluation is performed by having each individual evaluator inspect the interface alone. Only after all evaluations have been completed are the evaluators allowed to communicate and have their findings aggregated. This procedure is important in order to ensure independent and unbiased evaluations from each evaluator. The results of the evaluation can be recorded either as written reports from each evaluator or by having an observer present during the evaluation sessions and having the evaluators vocalize their comments as they go through the interface. Written reports have the advantage of presenting a formal

TABLE 45.2 List of 10 Heuristics for Good User Interface Design

<i>Visibility of system status:</i> The system should always keep users informed about what is going on, through appropriate feedback within reasonable time.
<i>Match between system and the real world:</i> The system should speak the users' language, with words, phrases, and concepts familiar to the user, rather than system-oriented terms. Follow real-world conventions, making information appear in a natural and logical order.
<i>User control and freedom:</i> Users often choose system functions by mistake and will need a clearly marked emergency exit to leave the unwanted state without having to go through an extended dialogue. Support undo and redo.
<i>Consistency and standards:</i> Users should not have to wonder whether different words, situations, or actions mean the same thing. Follow platform conventions.
<i>Error prevention:</i> Even better than good error messages is a careful design which prevents a problem from occurring in the first place.
<i>Recognition rather than recall:</i> Make objects, actions, and options visible. The user should not have to remember information from one part of the dialogue to another. Instructions for use of the system should be visible or easily retrievable whenever appropriate.
<i>Flexibility and efficiency of use:</i> Accelerators — unseen by the novice user — may often speed up the interaction for the expert user such that the system can cater to both inexperienced and experienced users. Allow users to tailor frequent actions.
<i>Aesthetic and minimalist design:</i> Dialogues should not contain information which is irrelevant or rarely needed. Every extra unit of information in a dialogue competes with the relevant units of information and diminishes their relative visibility.
<i>Help users recognize, diagnose, and recover from errors:</i> Error messages should be expressed in plain language (no codes), precisely indicate the problem, and constructively suggest a solution.
<i>Help and documentation:</i> Even though it is better if the system can be used without documentation, it may be necessary to provide help and documentation. Any such information should be easy to search, focused on the users' tasks, list concrete steps to be carried out, and not be too large.

record of the evaluation, but require an additional effort from the evaluators and also need to be read and aggregated by an evaluation manager. Using an observer adds to be overhead of each evaluation session but reduces the workload on the evaluators and provides the opportunity for having the result of the evaluation available fairly soon after the last evaluation session since the observer only needs to understand and organize his or her own notes and not a set of reports written by others. Furthermore, the observer can assist the evaluators in operating the interface in case of problems with, e.g., an unstable prototype, and help if the evaluators have limited domain expertise and need to have certain aspects of the interface explained.

Typically, a heuristic evaluation session for an individual evaluator lasts one or two hours. Longer evaluation sessions might be necessary for larger or very complicated interfaces with a substantial number of dialogue elements, but it is likely that it would be better to split up the evaluation in several smaller sessions, each concentrating on a part of the interface.

During the evaluation session, the evaluator goes through the interface several times and inspects the various dialogue elements and compares them with a list of recognized usability principles. These heuristics are general rules that seem to describe common properties of usable interfaces and it is possible to apply lists of heuristics that are more specialized for the particular application domain than the general list given in Table 45.2. In addition to the checklist of heuristics to be considered for all dialogue elements, the evaluator obviously is also allowed to consider any additional usability principles or results that come to mind that may be relevant for any specific dialogue element.

In principle, the evaluators decide on their own how they want to proceed with evaluating the interface. A general recommendation would be that they go through the interface at least twice, however. The first pass would be intended to get a feel for the flow of the interaction and the general scope of the system. The second pass then allows the evaluator to focus on specific interface elements while knowing how they fit the larger whole.

Since the evaluators are not *using* the system as such (to perform a real task), it is possible to perform heuristic evaluation of user interfaces that exist on paper only and have not yet been implemented [Nielsen 1990]. This makes heuristic evaluation suitable for use early in the usability engineering lifecycle.

45.7 Prototyping

One should not start full-scale implementation efforts based on early user interface designs. Instead, early usability evaluation can be based on prototypes of the final systems that can be developed much faster and much more cheaply, and which can thus be changed many times until a better understanding of the user interface design has been achieved.

In traditional models of software engineering most of the development time is devoted to the refinement of various intermediate work products, and executable programs are produced at the last possible moment. A problem with this *waterfall* approach is that there will then be no user interface to test with real users until this last possible moment, since the intermediate work products do not explicitly separate out the user interface in a prototype with which users can interact. Experience also shows that it is not possible to involve the users in the design process by showing them abstract specifications documents, since they will not understand them nearly as well as concrete prototypes.

The entire idea behind prototyping is to save on the time and cost to develop something that can be tested with real users. These savings can only be achieved by somehow reducing the prototype compared with the full system: either cutting down on the number of features in the prototype or reducing the level of functionality of the features such that they *seem* to work but do not actually *do* anything.

Reducing the number of features is called *vertical prototyping* since the result is a narrow system that does include in-depth functionality, but only for a few selected features. A vertical prototype can thus only test a limited part of the full system, but it will be tested in depth under realistic circumstances with real user tasks. For example, for a test of a website, in-depth functionality would mean that a user would actually access a set of documents with real content from the information providers.

Reducing the level of functionality is called *horizontal prototyping* since the result is a surface layer that includes the entire user interface to a full-featured system but with no underlying functionality. A horizontal prototype is a simulation [Life et al. 1990] of the interface where no real work can be performed. In the Web example, this would mean that users should be able to execute all navigation and search commands but without retrieving any real documents as a result of these commands. Horizontal prototyping makes it possible to test the entire user interface, even though the test is of course somewhat less realistic, since users cannot perform any real tasks on a system with no functionality. The main advantages of horizontal prototypes are that they can often be implemented fast with the use of various prototyping and screen design tools and that they can be used to assess how well the entire interface hangs together and feels as a whole.

Finally, one can reduce both the number of features and the level of functionality to arrive at a scenario that is only able to simulate the user interface as long as the test user follows a previously planned path. Scenarios are extremely easy and cheap to build, while at the same time not being particularly realistic. Scenarios are discussed further in other chapters.

In addition to reducing the proportion of the system that is implemented, prototypes can be produced faster by the following.

- Placing less emphasis on the efficiency of the implementation. For example, it will not matter how much disk space the prototype uses since it will only be used for a short time. Similarly, test users may be able to cope with slow response times that would never be acceptable in the final product. Note, however, that response times are an important aspect of usability and that test users may get very frustrated and make errors if the prototype is *too* slow. Of course, efficiency measures of the users' performance will be invalid if the prototype slows them down too much, so inefficient prototypes are better suited for early evaluation of interface concepts than for measurement studies.
- Accepting less reliable or poorer quality code. Even though bugs and crashes do distract users during testing, they can often be compensated for by the experimenter.
- Using simplified algorithms that cannot handle all of the special cases (such as leap years) that normally require a disproportionately large programming effort to get right.

- Using a human expert operating behind the scenes to take over certain computer operations that would be too difficult to program. This approach is often referred to as the *Wizard of Oz technique* after the “pay no attention to that man behind the curtain” scene in this story. Basically, the user interacts normally with the computer, but the users’ input is not relayed directly to the program. Instead, the input is transmitted to the wizard who, using another computer, transforms the users’ input into an appropriate format. A famous early Wizard of Oz study was the listening typewriter [Gould et al. 1983] simulation of a speech recognition interface where the users’ spoken input was typed into a word processor by a human typist located in another room. When setting up a Wizard of Oz simulation, experience with previously implemented systems is helpful in order to place realistic bounds on the wizard’s abilities [Maulsby et al. 1993].
- Using a different computer system than the eventual target platform. Often, one will have a computer available that is faster or otherwise more advanced than the final system and which can therefore support more flexible prototyping tools and require less programming tricks to achieve the necessary response times.
- Using low-fidelity media [Virzi 1989] that are not as elaborate as the final interface but still represent the essential nature of the interaction. For example, a prototype hypermedia system could use scanned still images instead of live video for illustrations.
- Using fake data and other content. For example, a prototype of a hypermedia system that was intended to include heavy use of video could use existing video material, even though it did not exactly match the topic of the text, in order to get a feel for the interaction techniques needed to deal with live images. A similar technique is used in the advertising industry, where so-called ripomatics are used as rudimentary television commercials with existing shots from earlier commercials to demonstrate concepts to clients before they commit to pay for the shooting of new footage.
- Using paper mockups instead of a running computer system. Such mockups are usually based on printouts of screen designs, dialogue boxes, pop-up menus, etc., that have been drawn up in some standard graphics or desktop publishing package. They are made into functioning prototypes by having a human play computer and find the next screen or dialogue element from a big pile of paper whenever the user indicates some action. This human needs to be an expert in the way the program is intended to work since it is otherwise difficult to keep track of the state of the simulated computer system and find the appropriate piece of paper to respond to the users’ stated input.
- Paper mockups have the further advantage that they can be shown to larger groups on overhead projectors [Rowley and Rhoades 1992] and used in conditions where computers may not be available, such as customer conference rooms. Portable computers with screen projection attachments confer some of the same advantages to computerized prototypes, but also increase the risk of something going wrong.
- Relying on a completely imaginary prototype where the experimenter describes a possible interface to the user orally, posing a series of “what if (the interface did this or that) . . .” questions as the user steps through an example task. This verbal prototyping technique has been called *forward scenario simulation* [Cordingley 1989] and is more akin to interviews or brainstorming than a true prototyping technique.

A prototype is a form of design specification, and the final implementation of a user interface is often performed with the prototype as a major way of communicating the design to developers. Unfortunately, the prototype can be *over* specified in some aspects that are not really intended to be part of the design. Whenever something is made concrete, there is a need to instantiate a multitude of representational details that might not have been explicitly designed by anybody. For example, a screen design will have to use certain colors and fonts, even though the designer’s focus may have been on the wording and positioning of the dialogue elements. Basically, one needs to be aware that not every aspect of the prototype should be replicated in the final system, and the designers should inform developers about which aspects of the prototype are intentional and which are arbitrary.

45.8 User Testing

The most basic advice with respect to interface evaluation is simply to *do it*, and especially to conduct some user testing. The benefits of employing some reasonable usability engineering methods to evaluate a user interface rather than releasing it without evaluation are much larger than the incremental benefits of using exactly the right methods for a given project.

User testing with real users is the most fundamental usability method and is in some sense irreplaceable, since it provides direct information about how people use computers and what their exact problems are with the concrete interface being tested. Even so, other usability engineering methods [Nielsen 1994b] can serve as good supplements to gather additional information or to gain usability insights at a lower cost. In particular, user testing can often be combined with heuristic evaluation (discussed previously) or other usability inspection methods for greater efficiency: the heuristic evaluation will find many usability problems that should be cleaned up before presenting the design to real users.

The three main rules of user testing are:

- Get real users
- Have them do real tasks
- Shut up while they are trying

45.8.1 The Test Users

Your test users should accurately represent the system's intended users. You cannot simply test with the engineer in the neighboring office, despite his or her suspicious resemblance to a real person. Actually, much can be learned from testing with other engineers and it is also possible to gain substantial insight into potential usability problems by having other experts inspect a design, but a user test should always involve real users who have no special software skills.

Sometimes, during development, the specific individuals who will use the completed system can be identified. This is typically the case when a company is developing a system internally for use by a given department. This makes representative users easy to find, although it may be difficult to have them spend time on user testing instead of their primary job. Internal test users are often recruited through the users' management, who agree to provide a certain number of people. Unfortunately, managers often tend to select their most able staff members for such tests, either to make their department look good or because these staff members have the most interest in new technology. Thus, you should explicitly ask managers to choose a broad test sample based on characteristics such as experience and seniority.

In other cases, the system is designed for a certain user type, such as lawyers, secretaries in a dental clinic, or warehouse managers in small manufacturing companies. These groups can be more or less homogeneous, although it still may be desirable to involve test users from several different locations. Sometimes, existing customers will help with the test because doing so gives them an early look at new software and improves the quality of the resulting product, which they will be using.

But sometimes, no existing customers will be available, making it difficult to gain access to representative users. Test users can then be recruited from temporary employment agencies, or students in the application domain may be attending a local university or trade school. You may also recruit users who are currently unemployed by placing a classified advertisement under job openings. Of course, it will be necessary to pay all users thus recruited.

45.8.2 Test Tasks

Your users should perform specific tasks and not just try out the system. The experience of doing real work is different from that of simply dabbling with the software. For example, a user who plays around and discovers a menu with lots of obscure choices may try one or two commands and will then sound pleasantly surprised if something nice happens. The same user will be completely baffled when viewing

that menu in the context of having to perform a specific task that does not map to the menu structure presented.

Test tasks should closely represent the uses to which the installed system will be put. Also, the tasks should provide reasonable coverage of the most important parts of the interface. You can design the test tasks based on a task analysis or on a product-identity statement that lists the product's intended uses. Information that helps you learn how users actually use systems — such as logging the frequency of use for specific commands in existing, similar systems, or direct field observation — can also help construct more representative test task sets for user testing.

The tasks must be small enough to be completed within the time limits of your user test, but they should not be so small they become trivial. For example, a good test task for a spreadsheet might be to enter sales figures for six regions through each of four quarters, using the sample numbers given in the task description. A second test task could be to obtain totals and percentages from the data entered, and a third might be to construct a bar chart showing trends across the six regions.

You should give all test users written task descriptions. This ensures they all receive identical information and also lets them refer to the description during the experiment. After the user receives the task descriptions and has a chance to read them, the tester should allow questions. Normally, task descriptions are distributed in printed form, but they can also be shown on line in a help window. The latter approach works best in computer-paced tests that require users to perform many tasks.

45.8.3 Role of Observers

During testing, the tester should not interface with users, but should let them discover the solutions to problems on their own. Not only does this lead to more valid and interesting test results, it also prevents users from feeling that they are so stupid the tester must solve the problems for them. On the other hand, the tester should not let users struggle endlessly with a task if they are clearly frustrated. In such cases, the tester can gently provide a hint or two to keep the test moving.

Mainly, though, observers should follow one simple rule during a user test: shut up and let the user do the talking. It is common for observers to offer help too quickly. It is human to want to assist a person who is struggling with a system (especially if you designed it), but doing so ruins the study.

45.8.4 Test Stages

A usability test typically has four stages:

1. Preparation
2. Introduction
3. The test itself
4. Debriefing

In preparation for the test, the tester should make sure the test room is prepared, the computer system is in the start specified in the test plan, and that all test materials, instructions, and questionnaires are available. For example, all files needed for the test tasks should be restored to their original content, and any files created during earlier tests should be moved to another computer or at least to another directory. To minimize users' discomfort and confusion, this preparation should be completed before their arrival. Also, any screen savers should be switched off, as should any other system components — such as e-mail notifiers — that might otherwise interrupt the test.

During the introduction, the tester welcomes the test users, gives a brief explanation of the test's purpose, explains the computer setup if it is unfamiliar to the users, and introduces the test procedure. After the introduction, the tester distributes any written instructions for the test, including the first test task, then asks before the start of the test if there are any questions regarding the test procedure, the instructions, or tasks.

Normally, to obtain the most feedback, the tester asks users to think aloud continuously during the test itself. By verbalizing their thoughts, test users help us understand how they view the computer system,

which makes it easy to identify their major misconceptions. You get a very direct understanding of what parts of the dialogue cause the most problems, because the thinking-aloud method shows how users interpret each interface item. Thinking aloud should not be used if the test aims at gathering performance data, however, because users may be slowed by having to verbalize.

Thinking aloud feels unnatural to most people, and some test users find it difficult to make a steady stream of comments as they use a system. The tester may need to continuously prompt the user to think aloud by asking questions like, “What are you thinking now?” or, when a user spends more than a second or two on a particular window or dialogue box, “What do you think that message means?”

If the user asks a question like, “Can I do such-and-such?” the tester should not answer, but should instead keep the user talking with a counter-question like, “What do you think will happen if you do so?” If the user acts surprised after a system action but does not otherwise say anything, the tester may prompt the user with a question like, “Is that what you expected would happen?” Of course, following the general principle of not interfering in the users’ use of the system, the tester should not use prompts like, “What do you think the message on the bottom of the screen means?” if the user has not appeared to notice that message yet.

After the test, the tester debriefs users and asks them to fill out any user-satisfaction questionnaires. To eliminate tester comments influencing the results, the questionnaires should be distributed before any further discussion of the system. During debriefing, ask users for comments about the system and suggested improvements. Such suggestions may not always lead to specific design changes; you will often find that different users make completely contradictory suggestions, but overall, this type of user suggestion can serve as a rich source of additional ideas to consider in the redesign.

45.8.5 Ethical Issues

Although usability test subjects normally escape actual bodily harm — even from irate developers resenting the users’ mistreatment of their beloved software — test participation can still be quite distressing. Users feel a tremendous pressure to perform, even when told the study’s purpose is to test the system and not the user. Also, users inevitably make errors and are slow to learn the system, especially when testing early designs that may be burdened with severe usability problems. Users can easily feel inadequate or stupid as they experience these difficulties. Knowing they are being observed, and possibly recorded, makes the feeling of performing inadequately even more unpleasant. On rare occasions, users have been known to cry during usability testing.

The tester is responsible for making the users feel as comfortable as possible during and after the test. Specifically, the tester must never laugh at the users or in any way indicate they are slow at discovering how to operate the system. During the test introduction, the tester should stress that the system is being tested, not the user. To reinforce this, test users should never be referred to as subjects, guinea pigs, or similar terms. More appropriate terms include participant and test user.

45.8.6 Severity Ratings

From whatever evaluation methods are used, a major result will be a list of the usability problems in the interface as well as hints for features to support successful user strategies. It is normally not feasible to solve all of the problems, and so one will need to prioritize them. Priorities are best based on experimental data about the impact of the problems on user performance (e.g., how many people will experience the problem and how much time each of them will waste because of it), but sometimes it is necessary to rely on intuitions only.

Severity ratings are usually gathered by sending a group of usability specialists a list of the usability problems discovered in the interface and asking them to rate the severity of each problem. Sometimes, the severity raters are given access to use the system while making their estimates, and sometimes they are asked to judge the problems based only on written description. Note that the latter approach is possible because the severity raters are supposed to be usability specialists. They should therefore be able to visualize the

TABLE 45.3 Table to Estimate the Severity of Usability Problems Based on the Frequency with Which the Problem Is Encountered by Users and the Impact of the Problems on Those Users Who Do Encounter It

Impact of problem on the users who experience it	Proportion of users experiencing the problem	
	<i>Few</i>	<i>Many</i>
<i>Small</i>	Low severity	Medium severity
<i>Large</i>	Medium severity	High severity

interface based on the written description (and possibly some screendumps) in a way that regular users would normally not be able to do. Typically, evaluators need only spend about 30 min to provide their severity ratings, though more time may of course be needed if the list of usability problems is extremely long. It is important to note that each usability specialist should provide the individual severity ratings independently of the other evaluators.

Two common approaches to severity ratings are either to have a single scale or to use a combination of several orthogonal scales. A single rating scale for the severity of usability problems might be:

- 0 = This is not a usability problem at all.
- 1 = Cosmetic problem only; need not be fixed unless extra time is available on project.
- 2 = Minor usability problem; fixing this should be given low priority.
- 3 = Major usability problem; important to fix, so should be given high priority.
- 4 = Usability catastrophe; imperative to fix this before product can be released.

Alternatively, severity can be judged as a combination of the two most important dimensions of a usability problem: how many users can be expected to have the problem and what is the extent to which those users who do have the problem are hurt by it. A simple example of such a rating scheme is given in Table 45.3. Of course, both dimensions in the table can be estimated at a finer resolution, using more categories than the two shown here for each dimension. Both the proportion of users experiencing a problem and the impact of the problem can be measured directly in user testing. A fairly large number of test users would be needed to measure reliably the frequency and impact of rare usability problems, but from a practical perspective, these problems are less important than more commonly occurring usability problems, so it is normally acceptable to have lower measurement quality for rare problems.

If no user test data is available, the frequency and impact of each problem can be estimated heuristically by usability specialists, but such estimates are probably best when made on the basis of at least a small number of user observations.

One can add a further severity dimension by judging whether a given usability problem will be a problem only the first time it is encountered or whether it will persistently bother users. For example, consider a set of pulldown menus where all of the menus are indicated by single words in the menubar except for a single menu that is indicated by a small icon (as, for example, the Apple menu on the Macintosh). Novice users of such systems can often be observed not even trying to pull down this last menu, simply because they do not realize that the icon is a menu heading. As soon as somebody shows the users that there is a menu under the icon (or if they read the manual), they immediately learn to overcome this small inconsistency and have no problems finding the last menu in future use of the system. This problem is thus not a persistent usability problem and would normally be considered less severe than a problem that also reduced the usability of the system for experienced users.

45.8.7 Usability Laboratories

Many user tests and other usability engineering activities take place in specially equipped usability laboratories [Nielsen 1994c]. Figure 45.3 shows one of Sun Microsystem's usability laboratories: the participant room and the control room. I should stress from the beginning that special laboratories are a convenience

FIGURE 45.3 View of the control room in a usability laboratory. The participant room is visible through the one-way mirror.

but not an absolute necessity for usability testing. It is possible to convert a regular office temporarily into a usability laboratory, and it is possible to perform usability testing with no more equipment than a notepad.

In September 1993, I surveyed 13 usability laboratories from a variety of companies [Nielsen 1994c]. The median floor space of the laboratories was 63 m² (678 ft²), and the median size of the test rooms was 13 m² (144 ft²). The smallest laboratory was 35 m² (377 ft²) with only 9 m² (97 ft²) for the test user. The largest laboratory was 237 m² and had 7 rooms, allowing a variety of tests to take place simultaneously [Lund 1994]. The largest single test room was 40 m² (430 ft²) and was found in a telephone company with a need to test groupware interfaces with many users. Even though the survey was conducted in the end of 1993, it seems that more recently built usability laboratories have about the same characteristics as the ones in the survey.

Having a permanent usability laboratory decreases the overhead of usability testing (once it is set up, that is!) and may thus encourage increased usability testing in an organization. Having a special room and special equipment dedicated to usability testing means that there will be fewer scheduling problems associated with each test and also makes it possible to run tests without disturbing other groups.

Usability laboratories typically have soundproof, one-way mirrors separating the observation room from the test room to allow the experimenters, other usability specialists, and the developers to discuss user actions without disturbing the user. Users are not so stupid that they do not know that there are observers behind a wall with a large mirror in a test room, so one might as well briefly show the users the observation room before the start of the test. Knowing who and what are behind the mirror is much less stressful for the users than having to imagine it. People usually come to ignore unseen observers during the test, even though they know they are there.

Having an executive observation area in the back of the main observation area allows a third group of observers (e.g., the development team) to discuss the test without disturbing the primary experimenters and the usability specialists.

Typically, a usability laboratory is equipped with several video cameras under remote control from the observation room: the average number of cameras in each test room was 2.2 in my survey, with 2 cameras being the typical number and a few labs using 1 or 3. These cameras can be used to show an overview of the test situation and to focus in on the users' face, the keyboard, the manual and the documentation, and the screen. A producer in the observation room then typically mixes the signal from these cameras to a single video stream that is recorded, and possibly time stamped for later synchronization with an observation log entered into a computer during the experiment. Such synchronization makes it possible to later find the video segment corresponding to a certain interesting user event without having to review the entire videotape.

In many ways, the most important equipment in a usability laboratory is the "do not enter" sign on the door since it makes it possible to conduct the usability test without interruptions. As long as one has a room with a do-not-disturb sign, one can conduct usability tests without any further equipment (you won't even need a computer if you are doing paper prototyping!). The second most important piece of equipment may be high-quality microphones: since there is normally a good deal of background noise from the computer, it will be impossible to hear what the user is saying unless professional microphones are used and unless the user is actually wearing the microphone.

45.9 Iterative Design

Based on the usability problems and opportunities disclosed by the empirical testing, one can produce a new version of the interface. Some testing methods such as thinking aloud provide sufficient insight into the nature of the problems to suggest specific changes to the interface in many cases. Log files of user interaction sequences often help by showing where the user paused or otherwise wasted time, and what errors were encountered most frequently. It often also helps if one is able to understand the underlying cause of the usability problem by relating it to established usability principles such as those listed in [Table 45.2](#). In other cases alternative potential solutions need to be designed based solely on knowledge of usability guidelines, and it may be necessary to test several possible solutions before making a decision. Familiarity with the design options, insight gained from watching users, creativity, and luck are all needed at this point.

Some of the changes made to solve certain usability problems may fail to solve the problems. A revised design may even introduce new usability problems [Bailey 1993]. This is yet another reason for combining iterative design and evaluation. In fact, it is quite common for a redesign to focus on improving one of the usability parameters (for example, reducing the users' error rate), only to find that some of the changes have adversely impacted other usability parameters (for example, transaction speed).

In some cases, solving a problem may make the interface worse for those users who do not experience the problem. Then a tradeoff analysis is necessary as to whether to keep or change the interface, based on a frequency analysis of how many users will have the problem compared to how many will suffer because of the proposed solution. The time and expense needed to fix a particular problem is obviously also a factor in determining priorities. Often, usability problems can be fixed by changing the wording of a menu item or an error message. Other design fixes may involve fundamental changes to the software (which is why they should be discovered as early as possible) and will only be implemented if they are judged to impact usability significantly.

Furthermore, it is likely that additional usability problems appear in repeated tests after the most blatant problems have been corrected. There is no need to test initial designs comprehensively since they will be changed anyway. The user interface should be changed and retested as soon as a usability problem has been detected and understood, so that those remaining problems that have been masked by the initial glaring problems can be found.

I surveyed four projects that had used iterative design and had tested at least three user interface versions [Nielsen 1993]. The median improvement in usability per iteration was 38%, though with extremely high

variability. In fact, in 5 of the 12 iterations studied, there was at least one usability metric that had gotten *worse* rather than better. This result certainly indicates the need to keep iterating past such negative results and to plan for at least three versions, since version two may not be any good. Also, the study showed that considerable additional improvements could be achieved after the first iteration, again indicating the benefits of planning for multiple iterations.

During the iterative design process it may not be feasible to test each successive version with actual users. The iterations can be considered a good way to evaluate design ideas simply by trying them out in a concrete design. The design can then be subjected to heuristic analysis and shown to usability experts and consultants or discussed with expert users (or teachers in the case of learning systems). One should not waste users by performing elaborate tests of every single design idea, since test subjects are normally hard to come by and should therefore be conserved for the testing of major iterations. Also, users get worn out as appropriate test subjects as they get more experience with the system and stop being representative of novice users seeing the design for the first time. Users who have been involved in participatory design are especially inappropriate as test subjects, since they will be biased.

45.10 Follow-Up Studies of Installed Systems

The main objective of usability work after the release of a product is to gather usability data for the next version and for new, future products. In the same way that existing and competing products were the best prototypes for the product in the initial competitive analysis phase, a newly released product can be viewed as a prototype of future products. Studies of the use of the product in the field assess how real users use the interface for naturally occurring tasks in their real-world working environment and can therefore provide much insight that would not be easily available from laboratory studies.

Sometimes, field feedback can be gathered as part of standard marketing studies on an ongoing basis. As an example, an Australian telephone company collected customer satisfaction data on a routine basis and found that overall satisfaction with the billing service had gone up from 67% to 84% after the introduction of a redesigned bill printout format developed according to usability engineering principles [Sless 1991]. If the trend in customer satisfaction had been the opposite, there would have been reason to doubt the true usability of the new bill outside the laboratory, but the customer satisfaction survey confirmed the laboratory results.

Alternatively, one may have to conduct specific studies to gather follow-up information about the use of released products. Basically, the same methods can be used for this kind of field study as for other field studies and task analysis, especially including interviews, questionnaires, and observational studies. Furthermore, since follow-up studies are addressing the usability of an existing system, logging data from instrumented versions of the software becomes especially valuable for its ability to indicate how the software is being used across a variety of tasks.

In addition to field studies where the development organization actively seeks out the users, information can also be gained from the more passive technique of analyzing user complaints, modification requests, and calls to help lines. Even when a user complaint at first sight might seem to indicate a programming error (for example, data lost), it can sometimes have its real roots in a usability problem, causing users to operate the system in dangerous or erroneous ways. Defect-tracking procedures are already in place in many software organizations and may only need small changes to be useful for usability engineering purposes [Rideout 1991]. Furthermore, information about common learnability problems can be gathered from instructors who teach courses in the use of the system.

Finally, economic data on the impact of the system on the quality and cost of the users' work product and work life are very important and can be gathered through surveys, supervisors' opinions, and statistics for absenteeism, etc. These data should be compared with similar data collected before the introduction of the system.

46.1 Introduction

Task analysis is the process of understanding the user’s task thoroughly enough to help design a computer system that will effectively support users in doing the task. By **task** is meant the user’s job or work activities, what the user is attempting to accomplish. By *analysis* is meant a relatively systematic approach to understanding the user’s task that goes beyond unaided intuitions or speculations, and attempts to document and describe exactly what the task involves. The design of **functionality** is a stage of the design of computer systems in which the user-accessible functions of the computer system are chosen and specified. The basic thesis of this chapter is that the successful design of functionality requires a task analysis early enough in the system design to enable the developers to create a system that effectively supports the user’s task. Thus, the proper goal of the design of functionality is to choose functions that are *useful* in the user’s task, and which, together with a good **user interface**, result in a system that is *usable*, that is, easy to learn and easy to use.

The user’s task is not just to interact with the computer, but to get a job done. Thus, understanding the user’s task involves understanding the user’s **task domain** and the user’s larger job goals. Many systems are designed for ordinary people, who presumably lack specialized knowledge, so the designers might believe

that they understand the user's task adequately well without any further consideration. This belief is often incorrect; the tasks of even ordinary people are often complex and poorly understood by developers. In contrast, many economically significant systems are intended for expert users, and understanding their tasks is absolutely critical. For example, a system to assist a petroleum geologist must be based on an understanding of the knowledge and goals of the petroleum geologist. To be useful, such a system will require functions that produce information useful to the geologist; to be usable, the system must provide these functions in a way that the frequent and most important activities of the geologist are well supported. Thus, for success, the developer must design not just the user interface, but also the functionality behind the interface.

The purpose of this chapter is to provide some background and beginning how-to information about conducting a task analysis and approaching the design of functionality. The next section of this chapter discusses why task analysis and the design of functionality are critical stages in software development, and how typical development processes interfere with these stages. Then will be presented some background on methods for human-machine system design that have developed in the field of **human factors** over the last few decades, including newer methods that attempt to identify the more cognitive components of tasks. The final section provides a summary of existing methods and a newly developing method that is especially suitable for computer system design. A general overview of the user interface design process, usability, and other specific aspects is provided in other chapters.

46.2 Principles

46.2.1 The Critical Role of Task Analysis and Design of Functionality

In many software development organizations, some group, such as a marketing department or government procurement agents, prepares a list of requirements for the system to be developed. Such requirements specify the system functions, at least in part. The designers and developers then further specify the functions, possibly adding or deleting functions from the list, and then begin to design an implementation for them. Typically, only at this point or later is the user interface design begun. Ideally, the design of the user interface will use appropriate techniques to arrive at a usable design, but these techniques normally are based on whatever conception of the user and the user's tasks have already been determined, and the interface is designed in terms of the functions that have already been specified. Thus, even following a usability process might well arrive at only a local optimum defined by an inadequate characterization of the user's needs and the corresponding functions.

In other words, the focus of usability methods tends to be on relatively low-level questions (such as menu structure) and on how to conduct usability tests to identify usability problems; the problem is posed as developing a usable interface to functions which have already been chosen. Typically, the system requirements have been prepared by a group who "throws them over the wall" to a development group, who arrives at the overall design and functional implementation, and then throws that over the wall to a usability group to "put a good interface on it."

If the initial requirements and system functions are poorly chosen, the rest of the development will probably fail to produce a usable product. It is a truism in human-computer interaction (HCI) that if customers need the functionality, they will buy and use even a clumsy, hard-to-use product; if the functionality is poorly chosen, no amount of effort spent on user interface design will result in a usable system — and it might not even be useful at all. This is by no means a rare occurrence; it is easy to find cases of poorly chosen functionality that undermine whatever usability properties the system otherwise possesses. Some examples follow.

The interface is often not the problem. An important article with this title by Goransson et al. [1987] presents several brief case studies that involve failures of functionality design masquerading as usability problems. The most painful is a business organization's database system that was considered too difficult to use. The interface was improved to make the system reasonably easy to use, but then it became clear that nobody in the organization needed the data provided by the system! Apparently, the original system

development did not include an analysis of the needs of the organization or the system users. The best way to improve the usability of the system would have been simply to remove it.

Half a loaf is worse than none. The second major version of an otherwise easy-to-use basic word processing application included a multiple-column feature; however, it was not possible to mix the number of columns on a page. Documents having a uniform layout of two or three columns throughout do not exist in the real world; rather, real multicolumn documents always mix the number of columns on at least one page. For example, a common pattern is a title page with a single column for the title that spans the page, followed by the body of the document in two-column format. The application could produce such a document only if two separate documents were prepared, printed, and then physically cut and pasted together! In other words, the multiple-column feature of this second version was essentially useless for preparing real documents. A proper task analysis would have determined the kinds and structures of multiple-column documents that users would be likely to prepare. Using this information during product development would have led either to more useful functionality (like the basic page-layout features in the third major release of the product) or to a decision not to waste resources on a premature implementation of incomplete functionality.

Why doesn't it do that? A first-generation handheld “digital diary” device provided calendar and date book functions equivalent to paper calendar books, but included no clock, no alarm, and no awareness of the current date, although such functions would have been minor additions to the hardware. In addition, there was no facility for scheduling repeating meetings, making such scheduling remarkably tedious. The only short cut was to use a rather clumsy copy–paste function, but it did not work for the meeting time field in the meeting information. A task analysis of typical user’s needs would have identified all of these as highly desirable functions. Including them would have made the first generation of these devices much more viable.

Progress is not necessarily monotonic. The second version of a personal digital assistant (PDA) also had a problem with recurring meetings. In the first version, a single interface dialog was used for specifying recurring meetings, and it was possible to select multiple days per week for the repeating meeting. Thus, the user could easily specify a weekly repeating meeting schedule of the sort common in academics, for example, scheduling a class that meets at the same time every Monday, Wednesday, and Friday for a semester. However, in the second version, which attempted many interface improvements, this facility moved down a couple of menu levels and became both invisible in the interface (unless a certain option were selected) and undocumented in the user manual. If any task analysis was done in connection with either the original or the second interface design, it did not take into account the type of repeating meeting patterns needed in academic settings — a major segment of the user population which includes many valuable early adopter customers.

46.2.1.1 The Role of Task Analysis in Development

Problems with misdefined functionality arise because first, there is a tendency to assume that the requirements specifications for a piece of software can and should contain all that is necessary to design and implement the software, and second, the common processes for preparing these specifications often fail to include a real task analysis. Usually, the requirements are simply a list of desirable features or functions, chosen haphazardly, and without critical examination of how they will fit together to support the user. Simply mentioning a user need in the requirements does not mean that the final system will include the right functions to make the system either useful or usable for meeting that need. The result is often a serious waste: pointless implementation effort and unused functionality. Thus, understanding the user’s task is the most important step in system and interface design. The results of task analyses can be used in several different phases in the development process:

Development of requirements. This stage of development is emphasized in this chapter. A task analysis should be conducted before developing the system requirements to guide the choice and design of the system functionality; the ultimate usability of the product is actually determined at this stage. The goal of task analysis at this point is to find out what the user needs to accomplish, so that the functionality of the system can be designed so that the user can accomplish the required tasks easily. Although some later

revision is likely to be required, these critical choices can be made before the system implementation or user interface is designed.

User interface design and evaluation. Task analysis results are needed during interface design to design and evaluate the user interface effectively. The usability process itself and user testing both require information about the user's tasks. Task analysis results can be used to choose benchmark tasks for user testing that will represent important uses of the system. Usage scenarios valuable during interface design can be chosen that are properly representative of user activities. A task analysis will help to identify the portions of the interface that are most important for the user's tasks. Once an interface is designed and is undergoing evaluation, the original task analysis can be supplemented with an additional analysis of how the task would be done with the proposed interface. This can suggest usability improvements either by modifying the interface or by improving the fit of the functionality to the more specific form of the user's task entailed by a proposed interface. In fact, some task analysis methods are very similar to user testing. The difference is that in user testing, one seeks to identify problems that the users have with an interface while performing selected tasks; in task analysis, one tries to understand how users will perform their tasks given a specific interface. Thus, a task analysis might identify usability problems, but task analysis does not necessarily require user testing.

Follow-up after installation. Task analysis can be conducted on fielded or in-place systems to compare systems or to identify potential problems or improvements. When a fully implemented system is in place, it is possible to conduct a fully detailed task analysis. The results could be used to compare the demands of different systems, identify problems that should be corrected in a new system, or determine properties of the task that should be preserved in a new system.

46.3 Research and Application Background

46.3.1 The Contribution of Human Factors to Task Analysis

Task analysis developed in the discipline of human factors, which has a long history of concern with the design process and how human-centered issues should be incorporated into system design. Much of human factors has been concerned with human participation in extremely large and complex systems, usually military systems. In fact, task analysis methods have been applied to a broad range of systems, ranging from handheld radios to radar consoles to whole aircraft, chemical process plant control rooms, and very complex multiperson systems such as a warship combat information center. The breadth of this experience is no accident. Historically, human factors is the only discipline with an extended record of involvement and concern with human-system design, long predating the newer field of HCI. These methods have been presented in comprehensive collections of task analysis techniques (e.g., Kirwan and Ainsworth [1992], Beevis et al. [1992], and Diaper and Stanton, [2004a]), and it remains a active area of research within human factors and allied fields [Annett and Stanton, 2000a; Schraagen et al., 2000]. One purpose of this chapter is to summarize some of these techniques and concepts. But there are some key differences between the interfaces of the traditional kinds of systems treated in the human factors experience and the interfaces to computer-based systems.

Task properties of both types of systems. At a general level, the task analysis of both traditional and computer-based interfaces involve collecting and representing the answers to the following primary overall questions:

1. What does the system do as a whole?
2. Where does the human operator fit into the system? What role will the operator play?
3. What specific tasks must the operator perform in order to play that role?

A large-scale general difference between the two kinds of systems shows up in response to these first three questions. Namely, the function or mission of the system as a whole often goes well beyond the immediate goals of the human operators, especially for high-complexity systems. For example, the mission of a system such as AEGIS is to defend a naval task force against all forms of airborne attack. While each human operator

of course has an interest in the success of this mission, the individual operator has a much more constrained set of goals, such as monitoring and identifying radar targets. HCI has tended to emphasize the design problem only at the single-operator level, as if only the third question were important. This myopic focus is another manifestation of the problem discussed previously, that the choice and the design of functionality are often not considered a part of the process of designing for usability.

Task properties of traditional systems. At the level of the detailed design of the interface, much of human factors expertise involves the detailed design of traditional interfaces constructed using conventional precomputer technology, often termed knobs-and-dials interfaces. A key design convention of traditional interfaces is that a single display device (e.g., a pressure gauge) displays a single system parameter or sensor value, and a single control device (e.g., a pump power switch) controls a single parameter or component of the system. Such interfaces require many individual physical devices and so tend to be distributed in space, resulting in control rooms in which every surface is covered with displays and controls. Thus, many of the interface design issues involve the visual and spatial properties of the devices and their layout. For example, some contributors to problems with nuclear power plant control rooms are gauges that cannot be seen by the operator, and misleadingly symmetrical switch layouts that have mirror-imaged on and off positions [Woods et al., 1987]. On the other hand, a useful design principle is to place related controls and displays together and organize them so that the spatial arrangement corresponds to the order in which they are used (e.g., left to right). The entire array of controls and displays should be always or readily visible and accessible simply by looking or moving, and thus constitute a large external memory for the operator. But the contents of this external memory are usually at the level of individual system parameters and components. This constraint is a product of the available interface and control technology used in traditional systems.

Thus, in addition to the first three task analysis questions, a task analysis of a traditional system seeks answers to the following fourth question:

4. What system parameters and components must be accessible to allow the operator to perform the tasks?

Once these four preliminary questions are answered, an interface can be designed or evaluated. If an interface design does not already exist, then human factors guidelines and principles can be used to guide the creation of a design. Once an interface design is available, a further, more detailed task analysis can then determine how the operator would access the controls and displays in order to carry out the tasks. Due to the spatiality of such interfaces, visual and spatial issues receive considerable emphasis. The sequential or temporal properties of the procedures followed by the operators are thus closely related to the spatial layout of the interface.

Task properties of computer-based systems. In contrast to the myriad controls and displays of traditional interfaces, computer-based systems often have few “in-place objects” [see Beevis et al., 1992], meaning that the interface for even an extremely complex system can consist of only a single screen, keyboard, and mouse. The operator must thus control the system by sequentially organized activities with this small number of mechanical or visual objects that tend to stay in the same place and compete for the limited keyboard and display space. Time has been traded for space; temporal layout of activity has been traded for spatial layout. The operator often must remember more, because the limited display space means that only a little information is visible at any one time, and complicated procedures are often needed to bring up other information. The user’s procedures have relatively little spatial content, and instead become relatively arbitrary sequences of actions on the small set of objects, such as typing different command strings on a keyboard. These procedures can become quite elaborate sequential, repeating, and hierarchical patterns.

On the other hand, the power of the computer behind the interface permits the displayed information to be potentially more useful and more relevant to the user’s task than the single-sensor/single-display traditional approach. For example, the software can combine several sensor readings and show a derived value that is what the user really wants to know. Likewise, the software can control several system components in response to a user command, radically simplifying the operator’s procedures. Thus, the available computer technology means that the interface displays and controls can be chosen much more flexibly

than the traditional knob-and-dial technology. In conjunction with the greater complexity of such systems, it is now both possible and critically important to choose the system display and control functionality on the basis of what will work well for the user, rather than simply sorting through the system components and parameters to determine the relevant ones.

Thus, a task analysis for a computer-based system must articulate what services or functions the computer should provide the operator with, rather than on what fixed components and parameters the operator must have access to. This leads to the following, additional question for computer-based systems:

5. What display and control functions should the computer provide to support the operator in performing the tasks?

In other words, the critical step in computer-based system design is the *choice of functionality*. Once the functions are chosen, the constraints of computer interfaces mean that the procedural requirements of the interface are especially prominent; if the functions are well chosen, the procedures that the operator must follow will be simple and consistent. Thus, the focus on spatial layout in traditional systems is replaced by a concern with the choice of functionality and interface procedures in computer-based systems. The importance of this combination of task analysis, choice of functionality, and the predominance of the procedural aspects of the interface is the basis for the recommendations in this chapter.

46.3.2 Contributions of Human-Computer Interaction to Task Analysis

The field of HCI is a relatively new and highly interdisciplinary field, which still lacks consensus on scientific, practical, and philosophical foundations. Consequently, a variety of ideas have been discussed concerning how developers should approach the problem of understanding what a new computer system must do for its users. While many original researchers and practitioners in HCI had their roots in human factors, several other disciplines have had a strong influence on HCI theory and practice.

These disciplines fall roughly into two groups. The first is **cognitive psychology**, a branch of scientific psychology concerned with human cognitive abilities such as comprehension, problem solving, and learning. The second is a mixture of ideas from the social sciences, such as social-organizational psychology, ethnography, and anthropology. While the contribution of these fields has been important in developing the scientific basis of HCI, they have either little experience with humans in a work context, as is the case with cognitive psychology, or no experience with practical system design problems, as with the social sciences. On the other hand, human factors is almost completely oriented toward solving practical design problems in an *ad hoc* manner and is almost completely atheoretic in content. Thus, the disciplines with a broad and theoretical science base lack experience in solving design problems, and the discipline with this practical knowledge lacks a comprehensive scientific foundation.

The current state of task analysis in HCI is thus rather confused [Diaper and Stanton, 2004b]; there has been an unfortunate tendency to reinvent task analysis under a variety of guises, as each theoretical approach presents its own insights about how to understand a work situation and design a system to support it. Moreover, many designers and developers have apparently simply started over with experience-based approaches. One example is contextual design [Holtzblatt, 2003], which is a collection of task-analytic techniques and activities that proponents claim will lead one through the stages of understanding what users do, what they need, and what system and interface will help them do it. Despite few explicit connections with previous work, many of the suggestions are familiar task-analytic techniques.

As each scientific community spawned its own ways of analyzing tasks, and as many development groups invented their own experienced-based approaches, the resulting hodgepodge of newly minted ideas has become bewildering enough to HCI specialists, but it is impenetrably obscure to the software developer who merely wants to develop a better system. For this reason, this chapter focuses on the tried-and-true pragmatic methodologies from human factors and a closely related methodology based on the most clearly articulated of the newer theoretical approaches: the GOMS model, defined later in this section.

New social-science approaches to task analysis. Since much computer usage takes place in organizations in which individual users must cooperate and interact as part of their work, viewing computer usage as a social activity can attempt to capture the larger context of a computer user's task. Some relevant social-science concepts can be summarized (see Baecker et al. [1995] for a sampling and overview). A general methodological approach is *ethnography*, which is the set of methods used by anthropologists to immerse oneself in a culture and document its structure (see Blomberg et al. [2003]). Another approach based on anthropology, called *situated cognition*, emphasizes understanding human activity in its larger social context (see Nardi [1995] for an overview). Another theoretical approach is *activity theory* [Nardi, 1995; Turner and McEwan, 2004] which originated in the former Soviet Union as a comprehensive psychological theory, with some interesting differences from conventional western or American psychology.

The proponents of all of these social-science approaches have had some successes, apparently due to their insistence on observing and documenting what people are actually doing in a specific situation and in their work context. In the context of common computer-industry practice in system design, this insistence might seem novel and noteworthy, but such attention to the user's context is characteristic of all competent task analyses. The contribution of these approaches is an emphasis on levels of the user's context that can be easily overlooked if one's focus is too narrowly on how the user interacts with the technological artifacts.

Contributions from cognitive psychology. The contribution of cognitive psychology to HCI is both more limited and more successful within that limited scope. Cognitive psychology treats an individual human as an information-processor who acquires information from the environment, transforms it, stores it, retrieves it, and acts on it. This *information-processing* approach, also called the *computer metaphor*, has an obvious application to how humans interact with computer systems. In a cognitive approach to HCI, the interaction between human and computer is viewed as two interacting information-processing systems with different capabilities, in which one, the human, has goals to accomplish, and the other, the computer, is an artificial system that should be designed to facilitate the human's efforts. The relevance of cognitive psychology research is that it directly addresses two important aspects of usability: how difficult it is for the human to learn how to interact successfully with the computer and how long it takes the human to conduct the interaction.

The underlying topics of human learning, problem solving, and skilled behavior have been intensively researched for decades in cognitive psychology.

The application of cognitive psychology research results to human-computer interaction was first systematically presented by Card et al. [1983] at two levels of analysis. The lower-level analysis is the Model Human Processor, a summary of about a century's worth of research on basic human perceptual, cognitive, and motor abilities in the form of an engineering model that could be applied to produce quantitative analysis and prediction of task execution times. The higher-level analysis was the **GOMS model**, a description of the procedural knowledge involved in doing a task. The acronym *GOMS* stands for the following. The user has **Goals** that can be accomplished with the system. **Operators** are the basic actions, such as keystrokes performed in the task. **Methods** are the procedures, consisting of sequences of operators, that will accomplish the goals. **Selection rules** determine which method is appropriate for accomplishing a goal in a specific situation.

In the Card et al. formulation, the new user of a computer system will use various problem-solving and learning strategies to figure out how to accomplish tasks using the computer system, and then, with additional practice, these results of problem solving will become procedures that the user can routinely invoke to accomplish tasks in a smooth, skilled manner. The properties of the procedures will thus govern both the ease of learning and ease of use of the computer system. In the research program stemming from the original proposal, approaches to representing GOMS models based on cognitive psychology theory have been developed and validated empirically, along with the corresponding techniques and computer-based tools for representing, analyzing, and predicting human performance in human-computer interaction situations (see John and Kieras [1996a, b] for reviews).

The significance of the GOMS model for task analysis is that it provides a method to describe the task procedures in a way that has a theoretically rigorous and empirically validated scientific relationship to human cognition and performance. Space limitations preclude any further presentation of how GOMS can be used to express and evaluate a detailed interface design (see John and Kieras, [1996a, b] and Kieras 1997 [2004]). In [Section 46.5](#), a technique based on GOMS will be used to couple task analysis with the design of functionality.

46.4 Best Practices: How to Do a Task Analysis

The basic idea of conducting a task analysis is to understand the user's activity in the context of the whole system, either an existing or a future system. Although understanding human activity is the subject of scientific study in psychology and the social sciences, the conditions under which systems must be designed usually preclude the kind of extended and intensive research necessary to document and account for human behavior in a scientific mode. Thus, a task analysis for system design must be rather more informal and primarily heuristic in flavor, compared to scientific research. The task analyst must do his or her best to understand the user's task situation well enough to influence the system design given the limited time and resources available. This does not mean that a task analysis is an easy job; large amounts of detailed information must be collected and interpreted, and experience in task analysis is valuable even in the most structured methodologies (e.g., see Annett [2004]).

The role of formalized methods for task analysis. Despite the fundamentally informal character of task analysis, many formal and quasi-formal systems for task analysis have been proposed and widely recommended. Several will be summarized. It is critical to understand that these systems do not in themselves analyze the task or produce an understanding of the task. Rather, they are ways to structure the task analysis process and notations for representing the results of task analysis. They have the important benefit of helping the analyst observe and think carefully about the user's actual task activity, specifying what kinds of task information are likely to be useful to analyze, and providing a heuristic test for whether the task has actually been understood. That is, a good test for understanding something is whether one can represent or document it. Constructing such a representation can be a good approach to trying to understand it. A formal representation of a task shows the results of the task analysis in a form that can help document the analysis, so that it can be inspected, criticized, and revised. Finally, some of the more formal representations can be used as the basis for computer simulations or mathematical analyses to obtain quantitative predictions of task performance, but such results are no more correct than the original, and informally obtained, task analysis underlying the representation.

An informal task analysis is better than none. Most of the task analysis methods to be surveyed require significant time and effort; spending these resources would usually be justified, given the near-certain failure of a system that fails to meet the actual needs of users. However, the current reality of software development is that developers often will not have adequate time and support to conduct a full-fledged task analysis. Under these conditions, what can be recommended? As pointed out in sources such as Gould [1988] and Grudin [1991], perhaps the most serious problem is that the developers often have no contact with actual users. Thus, if nothing more systematic is possible, the developers should spend some time in informal observation of real users actually doing real work. The developers should observe unobtrusively but ask for explanation or clarification as needed, perhaps trying to learn the job themselves. They should not, however, make any recommendations or discuss the system design. The goal of this activity is simply to try to gain some experience-based intuitions about the nature of the user's job, what real users do and why. See Gould [1988] for additional discussion. Such informal, intuition-building contact with users will provide tremendous benefits at relatively little cost. Approaches such as contextual design [Holtzblatt, 2003] and the more elaborate methods presented here provide more detail and more systematic documentation, and will permit more careful and exact design and evaluation than casual observation. Some informal observation of users, however, is infinitely better than no attempt at task analysis at all.

46.4.1 Collecting Task Data

Task analysis requires information about the user's situation and activities, but simply collecting data about the user's task is not necessarily a task analysis. In a task analysis, the goal is to understand the properties of the user's task that can be used to specify the design of a system; this requires synthesis and interpretation beyond the data. The data collection methods summarized here are those that have been found to produce useful information about tasks (see Kirwan and Ainsworth [1992] and Gould [1988]). The task-analytic methods summarized in [Section 46.4.2](#) are approaches that help analysts perform the synthesis and interpretation.

Observation of user behavior. In this fundamental family of methods, the analyst observes actual user behavior, usually with minimal intrusion or interference, and describes what has been observed in a thorough, systematic, and documented way. This type of task data collection is most similar to user testing, except that, as discussed previously, the goal of task analysis is to understand the user's task, not just to identify problems that the user might have with a specific system design.

The setting for the user's activity can be the actual situation (e.g., in the field) or a laboratory simulation of the actual situation. All of the user's behavior can be recorded, or it can be sampled periodically to cover more time while reducing the data collection effort. The user's activities can be categorized, counted, and analyzed in various ways. For example, the frequency of different activities could be tabulated, or the total time spent in different activities could be determined. Both such measures contribute valuable information about which task activities are most frequent or time-consuming, and thus are important to address in the system design. Finer-grain recording and analysis can provide information on the exact timing and sequence of task activities, which can be important in the detailed design of the interface. Videotaping users is a simple recording approach that supports both very general and very detailed analysis at low cost; consumer-grade equipment is often adequate.

A more intrusive method of observation is to have users *think aloud* about a task while performing it, or to have two users discuss and explain to each other how to do the task while performing it. The verbalization can disrupt normal task performance, but such *verbal protocols* are believed to be a rich source of information about the user's mental processes, such as inferences and decision making. The pitfall for the inexperienced is that the protocols can be extremely labor-intensive to analyze, especially if the goal is to reconstruct the user's cognitive processes. The most fruitful path is to transcribe the protocols, isolate segments of content, and attempt to classify them into an informative set of categories.

A final technique in this class is *walkthroughs* and *talkthroughs*, in which the users or designers carry out a task and describe it as they do so. The results are similar to a think-aloud protocol, but with more emphasis on the procedural steps involved. An important feature is that the interface or system need not exist; the users or designers can describe how the task would or should be carried out.

Critical incidents and major episodes. Instead of attempting to observe or understand the full variety of activity in the task, the analyst chooses incidents or episodes that are especially informative about the task and the system, and attempts to understand what happens in these. This is basically a case-study approach. Often the critical incidents are accidents, failures, or errors, and the analysis is based on retrospective reports from the people involved and any records produced during the incident. An important extension of this approach is the *critical decision method* [Wong, 2004], which focuses on understanding the knowledge involved in making expert-level decisions in difficult situations. However, the critical incident might be a major episode of otherwise routine activity that serves especially well to reveal the problems in a system. For example, observation of a highly skilled operator performing a very specialized task revealed that most of the time was spent doing ordinary file maintenance; understanding why led to major improvements in the system [Brooks, personal communication].

Questionnaires. Questionnaires are a fixed set of questions that can be used quite economically to collect some types of user and task information on a large scale. The main problem is that the accuracy of the data is unknown compared to observation, and can be susceptible to memory errors and social influences. Despite the apparent simplicity of a questionnaire, designing and implementing a successful one is not

easy, and can require an effort comparable to interviews or workplace observation. The newcomer should consult sources on questionnaire design before proceeding.

Structured interviews. Interviews involve talking to users or domain experts about the task. Typically, some unstructured interviews might be done first, in which the analyst simply seeks any and all kinds of comments about the task. Structured interviews can then be planned; a series of predetermined questions for the interview is prepared to ensure more systematic, complete, and consistent collection of information.

Interface surveys. An interface survey collects information about an existing, in-place, or designed interface. Several examples are: Control and Display surveys determine what system parameters are shown to the user and what components can be controlled. Labeling and Coding surveys can determine whether there are confusing labels or inconsistent color codes present in the interface. Operator Modifications surveys assess changes made to the interface by the users, such as added notes or markings, that can indicate problems in the interface. Finally, Sightline surveys determine what parts of the interface can be seen from the operator's position; such surveys have found critical problems in nuclear power plant control rooms. Sightlines would not seem important for computer interfaces, but a common interface design problem is that the information required during a task is not on the screen at the time it is required; an analog to a sightline survey would identify such problems.

46.4.2 Representing Systems and Tasks

Once the task data is collected, the problem for the analyst is to determine how to represent the task data, which requires decisions about what aspects of the task are important and how much detail to represent. The key function of a representation is to make the task structure visible or apparent in some way that supports the analyst's understanding of the task. By examining a task representation, an analyst hopes to identify problems in the task flow, such as critical bottlenecks, inconsistencies in procedures, excessive workloads, and activities that could be better supported by the system. Traditionally, a graphical representation, such as a flowchart or diagram, has been preferred, but as the complexity of the system and the operating procedures increases, diagrammatic representations lose their advantage.

Task decomposition. One general form of task analysis is often termed task decomposition. This is not a well defined method at all; it merely reflects a philosophy that tasks usually have a complex structure, and a major problem for the analyst will be to decompose the whole task situation into subparts for further analysis. Some of these subparts will be critical to the system design; others are possibly less important. For example, one powerful approach is to consider how a task might be decomposed into a hierarchy of subtasks and the procedures for executing them, leading to a popular form of analysis called (somewhat too broadly) *hierarchical task analysis* (HTA). Another approach would be to decompose the task situation into considerations of how the controls are labeled, how they are arranged, and how the displays are coded. This is also a task decomposition and might also have a hierarchical structure, but the emphasis is on describing aspects of the displays in the task situation. Obviously, depending on the specific system and its interface, some aspects of the user's task situation may be far more important to analyze than others. Developing an initial task decomposition can help to identify what is involved overall in the user's task, thus allowing the analyst to choose what aspects of the task merit intensive analysis.

Level of detail. The question of how much detail to represent in a task analysis is difficult to answer. At the level of whole tasks, Kirwan and Ainsworth [1992] suggest a probability \times cost rule: if the probability of inadequate performance multiplied by the cost of inadequate performance is low, then the task is probably not worthwhile to analyze. But even if a task has been chosen as important, the level of detail at which to describe the particular task still must be chosen. Some terminology must be clarified at this point: task decompositions can be viewed as a standard inverted tree structure, with a single item, the overall task, at the top, and the individual actions (such as keystrokes or manipulating valves) or interface objects (switches, gauges) at the bottom. A *high-level* analysis deals only with the low-detail top parts of the tree; a *low-level* analysis includes all of the tree from the top to the high-detail bottom.

The cost of task analysis rises quickly as more detail is represented and examined. On the other hand, many critical design issues appear only at a detailed level. For example, at a high enough level of abstraction, the Unix operating system interface is essentially just like the Macintosh operating system interface; both interfaces provide the functionality for invoking application programs and copying, moving, and deleting files and directories. The notorious usability problems of Unix relative to other systems only appear at a level of detail that the cryptic, inconsistent, and clumsy command structure and generally poor feedback come to the surface. The devil is in the details. Thus, a task analysis capable of identifying usability problems in an interface design typically involves working at a low, fully detailed level that involves individual commands and mouse selections. The opposite consideration holds true for the design of functionality, as will be discussed more below. When choosing functionality, ask how the user will carry out tasks using a set of system functions, and it is important to avoid being distracted by the details of the interface.

46.4.3 Task Analysis at the Whole-System Level

When large systems are being designed, an important component of task analysis is to consider how the system, consisting of all the machines and all the humans, is supposed to work as a whole in order to accomplish the overall system goal. This kind of very high-level analysis can be done even with very large systems, such as military systems involving multiple machines and humans. The purpose of the analysis is to determine what role in the whole system the individual human operators will play. Various methods for whole-system analysis have been used in routine use for some time. Briefly, these are as follows (see Beevis et al. [1992] and Kirwan and Ainsworth [1992]).

Mission and scenario analysis. Mission and scenario analysis is an approach to starting the system design from a description of what the system must do (the mission), especially using specific, concrete examples or scenarios. See Brooks (this volume) for a related discussion.

Function-flow diagrams. Function-flow diagrams are constructed to show the sequential or information-flow relationships of the functions performed in the system. Beevis et al. [1992] provide a set of large-scale examples, such as naval vessels.

Petri nets. Petri nets also represent the causal and sequential relationships between the functions performed in a system, but in a rigorous formalism. Various methodologies for modeling and simulating the system performance can also include timing information.

Function allocation. Function allocation is a set of fairly informal techniques for deciding which system functions should be performed by machines and which by people. Usually mentioned in this context is the *Fitts list*, which describes what kinds of activities can best be performed by humans vs. machines. However, according to surveys described in Beevis et al. [1992], this classic technique is rarely used in real design problems, because it is not specific enough to drive design decisions. Rather, functions are typically allocated in an *ad hoc* manner, often simply maintaining whatever allocation was used in the predecessor system or following the rule that whatever can be automated should be — even though it is known that automation often produces safety or vigilance problems for human operators.

In the military systems analyzed heavily in human factors, the overall system goal is normally rather larger in scale and well above the level of concerns of the human operators. For example, in designing a new naval fighter aircraft, the system goals might be stated in terms such as “enable air superiority in naval operations under any conditions of weather and all possible combat theaters through the year 2010.” At this level, the users of the system as a whole are military strategists and commanders, not the pilot, and the system as a whole will involve not just the pilot, but other people in the cockpit (such as a radar intercept operator) and maintenance and ground operations personnel. Thus, the humans involved in the system will have a variety of goals and tasks, depending on their role in the whole system.

At first glance, this level of analysis would appear to have little to do with computer systems. We often think of computer users as isolated individuals carrying out their tasks by interacting with their individual computers. However, when considering the needs of an organization, the mission level of analysis is clearly important; the system is supposed to accomplish something as a whole, and the individual humans all play

roles defined by their relationship with each other and with the machines in the system. HCI has begun to consider higher levels of analysis, as in the field of computer-supported collaborative work, but perhaps the main reason why the mission level of analysis is not common parlance in HCI is that HCI has a cultural bias that organizations revolve around the humans, with the computers playing only a supporting role. Such a bias would explain the movement mentioned earlier toward incorporating more social-science methodology into system design. In contrast, in military systems, the human operators are often viewed as parts in the overall system, whose ultimate user is the commanding officer, leading to a concern with how the humans and machines fit together.

Regardless of the perspective taken on the whole system, at some point in the analysis, the activities of the individual humans who actually interact directly with the equipment begin to appear. It is then both possible and essential to identify the goals that they, as individual operators, must accomplish. At this point, task analysis methodology begins to overlap with the concerns of computer user interface design.

46.4.4 Representing the User's Task

Once the whole system and the roles of the individual users and operators have been characterized, the main focus of task-analytic work is to identify more specific properties of the situation and activities of the human operator or user. These can be summarized as what the user must know, what the user must do, what the user sees and interacts with, and what the user might do wrong.

46.4.4.1 Representing What the User Must Know

The goal of this type of task analysis is to represent what knowledge the human must have in order to operate the system effectively. Clearly, the human must know how to operate the equipment; such procedural knowledge is treated under its own heading below. But the operator might need additional procedural knowledge that is not directly related to the equipment, as well as additional nonprocedural conceptual background knowledge. For example, a successful fighter aircraft pilot must know more than just the procedures for operating the aircraft and the on-board equipment; he or she must have additional procedural skills such as combat tactics, navigation, and communication protocols, and an understanding of the aircraft mechanisms and overall military situation is valuable in dealing with unanticipated and novel situations.

Information about what the user needs to know is clearly useful for specifying the content of operator training and operator qualifications. It can also be useful in choosing system functionality, in that large benefits can be obtained by implementing system functions that make it unnecessary for users to know concepts or skills that are difficult to learn. Such simplifications typically are accompanied by simplifications in operating procedures. Aircraft computer systems that automate navigation and fuel conservation tasks are an obvious example.

In some cases, where the user knowledge is mostly procedural in content, it can be represented in a straightforward way, such as decision–action tables that describe what interpretation should be made of a specific situation, as in an equipment trouble-shooting guide. However, the required knowledge can be extremely hard to identify if it does not have a direct and overt relationship to “what to do” operating procedures. An example is the petroleum geologist, who, after staring at a display of complex data for some time, comes up with a decision about where to drill, and who probably cannot provide a rigorous explanation for how the decision was made. Understanding how and why users make such decisions is difficult, because there is little or no observable behavior prior to producing the result; it is all in the head, a *purely cognitive task*.

Analyzing a purely cognitive task in complete detail is essentially a cognitive psychology research project, and so is not usually practical in a system design context. Furthermore, to the extent that a cognitive task can be completely characterized, it becomes a candidate for automation, making moot the design of the user interface. Expert systems technology, when successfully applied using knowledge acquisition methods (see Boose [1992]), is an example of task analyses carried out in enough detail that the need for a human performer of the task is eliminated.

Most cognitive tasks seem neither possible nor practical to analyze this thoroughly, but there is still a need to support the human performer with system functions and interfaces and with training programs and materials that improve performance in the task, even if that task is not completely understood. For example, Gott [1988] surveys cases in which an intensive effort to identify the knowledge required for tasks can produce large improvements in training programs for highly demanding cognitive tasks, such as electronics troubleshooting.

During the 1990s, there were many efforts to develop methods for **cognitive task analysis (CTA)**. CTA emphasizes describing the knowledge required for a task and how it is used in decision making, situation recognition, or problem-solving, rather than just the procedures involved. This is true even though most task analysis procedures developed prior to that time included cognitive activities, such as decision making and problem solving, and were often conducted in order to identify the required background knowledge for operator training. For example, Shepherd [2000] summarizes how the first systematic task analysis method, hierarchical task analysis (see [Section 46.4.4.2](#)) normally includes various cognitive information. Furthermore, as argued by Chipman et al. [2000], it makes little sense to attempt to divide cognitive processes such as decision making from the actions and procedures involved in actual task performance. There is currently a wide variety of CTA techniques proposed or under development; see Chipman et al. [2000] for an overview, and Dubois and Shalin [2000] and Seamster et al. [2000] for useful summaries of some important methods. Most current CTA methods involve some form of interview technique for eliciting a subset of the most critical knowledge involved in a task, often focusing on critical incidents (e.g., Militello and Hutton [2000] and Wong [2004]).

There are many cases in which CTA resulted in dramatically improved training materials and programs (e.g., O'Hare et al. [2000] and Schaafstal and Schraagen [2000]). However, an earlier review by Essens et al. [1994] reported that while cognitive task analysis techniques have demonstrated successes in developing training programs, there were few demonstrations of successful design of computer systems for decision aiding. Landauer [1995] notes that decision-support systems have yet to produce a convincing track record of improving human productivity; this result would be expected, given the general lack of task analysis in system design and the great difficulty of task analysis in the case of heavily cognitive tasks.

Given that support for cognitively demanding tasks is touted as one of the main contributions of computers, it is critical that more progress be made on how to conduct task analysis and system design for purely cognitive tasks.

46.4.4.2 Representing What the User Must Do

A major form of task analysis is describing the actions or activities carried out by the human operator while tasks are being executed. Such analyses have many uses. The description of how a task is currently conducted, or would be conducted with a proposed design, can be used for prescribing training, for assisting in the identification of design problems in the interface, or as a basis for quantitative or simulation modeling to obtain predictions of system performance. Depending on the level of detail chosen for the analysis, the description might be very high-level, or it might be fully detailed, describing the individual valve operations or keystrokes needed to carry out a task. The following paragraphs describe the major methods for representing procedures.

Operational sequence diagrams. Operational sequence diagrams and related techniques show the sequence of the operations (actions) carried out by the user (or the machine) to perform a task, represented graphically as a flowchart using standardized symbols for the types of operations. Such diagrams are often partitioned, showing the user's actions on one side and the machine's on the other, to illustrate the pattern of operation between the user and the machine.

Timeline analysis. Timeline analyses simply display activities, or some characteristic of them, as a function of time during task execution. For example, a workload profile for an airliner cockpit would show a large variety and intensity of activities during landing and takeoff, but not during cruising. After constructing a timeline display, the analyst looks for workload peaks, such as the operator's having to remember too many things, or conflicts, such as the operator's having to use two widely separated controls at the same time.

Hierarchical task analysis. HTA involves describing a task as a hierarchy of tasks and subtasks, emphasizing the procedures that operators will carry out, using several specific forms of description. The term *hierarchical* is somewhat misleading, because many forms of task analysis produce hierarchical descriptions; a better term might be *procedure hierarchy task analysis*. The results of an HTA are typically represented either graphically, as a sort of annotated tree diagram of the task structure similar to the conventional diagram of a function-call hierarchy in programming, or in a more compact tabular form. This is the original form of systematic task analysis [Annett et al., 1971] and still the single most heavily used form of task analysis. See Annett [2004] for additional background and a procedural guide.

HTA descriptions involve goals, tasks, operations, and plans. A *goal* is a desired state of affairs (e.g., a chemical process proceeding at a certain rate). A *task* is a combination of a goal and a context (e.g., get a chemical process going at a certain rate given the initial conditions in the reactor). *Operations* are activities for attaining a goal (e.g., procedures for introducing reagents into the reactor, increasing the temperature, and so forth). *Plans* specify which operations should be applied under what conditions (e.g., what procedure to follow if the reactor is already hot). Plans usually appear as annotations to the tree-structure diagram, explaining which portions of the tree will be executed under what conditions. Each operation in turn might be decomposed into subtasks, leading to a hierarchical structure. The analysis can be carried out to any desired level of detail, depending on the requirements of the analysis.

GOMS models. GOMS models, introduced in Section 46.3.2, are closely related to hierarchical task analysis. In fact, Kirwan and Ainsworth [1992] include GOMS as a form of HTA. GOMS models describe a task in terms of a hierarchy of goals and subgoals; methods, which are a sequence of operators (actions) that, when executed, will accomplish the goals; and selection rules that choose which method should be applied to accomplish a particular goal in a specific situation. However, both in theory and in practice, GOMS models are different from HTA. The concept of GOMS models grew out of research on human problem solving and cognitive skill, whereas HTA appears to have originated from the pragmatic, common-sense observation that tasks often involve subtasks, and eventually involve carrying out sequences of actions. Because of their more principled origins, GOMS models are more disciplined than HTA descriptions. The contrast is perhaps most clear in the difficulty HTA descriptions have in expressing the flow of control: the procedural structure of goals and subgoals must be deduced from the plans, which appear only as annotations to the sequence of operations. In contrast, GOMS models represent plans and operations in a uniform format, using only methods and selection rules. An HTA plan would be represented as simply a higher-order method that carries out lower-level methods or actions in the appropriate sequence, along with a selection rule for when the higher-order method should be applied.

46.4.4.3 Representing What the User Sees and Interacts With

The set of objects with which the user interacts during task execution is clearly closely related to the procedures that the user must follow, in that a full procedural description of the user's task will (or should) refer to all objects in the task situation that the user must observe or manipulate. However, it can be useful to attempt to identify and describe the relevant objects and events independently of the procedures in which they are used. Such a task analysis can identify some potential serious problems or design issues quite rapidly. For example, studies of nuclear power plant control rooms [Woods et al., 1987] found that important displays were located in positions where they could not be read by the operator. A task decomposition can be applied to break the overall task situation into smaller portions; the interface survey technique mentioned previously can then determine the various objects in the task situation. Collecting additional information (e.g., from interviews or walkthroughs) can lead to an assessment of whether and under what conditions the individual controls or displays are required for task execution. There are a variety of guidelines in human factors for determining whether the controls and displays are adequately accessible.

A related form of task analysis is concerned with the layout in space of the displays, controls, or other people with whom the operator must interact. *Link analysis* is a straightforward methodology for tabulating the pairwise accessibility relationships between people and objects in the task environment and

weighting them by the frequency and difficulty of access (e.g., greater distance). Alternative arrangements can easily be explored to minimize the difficulty of the most frequent access paths. For example, a link analysis revealed that a combat information center on a warship was laid out in such a way that the movement and communication patterns involved frequent crossing of paths, sightlines, and so forth. A simple rearrangement of workstation positions greatly reduced the amount of interference. An analog for computer interfaces would be analyzing the transitions between different portions of the interface, such as dialogs or screen objects. A design could be improved by making the most frequent transitions short and direct.

46.4.4.4 Representing What the User Might Do Wrong

Human factors practitioners and researchers have developed a variety of techniques for analyzing situations in which errors have happened or might happen. The goal is to determine whether human errors will have serious consequences, and to identify where these might occur and how likely they are to occur. The design of the system or the interface can then be modified to try to reduce the likelihood of human errors or mitigate their consequences. Some key techniques are summarized in the following paragraphs.

Event trees. In an event tree, the possible paths, or sequences of behaviors, through the task are shown as a tree diagram. Each behavior's outcome is represented either as success/failure or as a multiway branch (e.g., for the type of diagnosis made by an operation in response to a system alarm display). An event tree can be used to determine the consequences of human errors, such as misunderstanding an alarm. Each path can be given a predicted probability of occurrence based on estimates of the reliability of human operators at performing each step in the sequence. (These estimates are controversial; see Reason [1990] for a discussion.)

Failure modes and effects analysis. The analysis of human failure modes and their effects is modeled after a common hardware reliability assessment process. The analyst considers each step in a procedure and attempts to list all the possible failures an operator might commit, such as omitting the action or performing it too early, too late, too forcefully, and so forth. The consequences of each such failure mode can then be worked out, and again a probability of failure predicted.

Fault trees. In a fault-tree analysis, the analyst starts with a possible system failure and then documents the logical combination of human and machine failures that could lead to it. The probability of the fault occurring can then be estimated, and possible ways to reduce the probability can be determined.

Until recently, these techniques had not been applied in computer user interface design to any visible extent. At most, user interface design guides contained a few general suggestions for how interfaces could be designed to reduce the chance of human error. Recent work, such as Stanton [2003] and Wood [1999], shows promise in using task analysis as a basis for systematically examining how errors might be made and how they can be detected and recovered from. Future work along these lines will be an extraordinarily important contribution to system and interface design.

46.5 Using GOMS Task Analysis in Functionality and Interface Design

The task analysis techniques described previously work well enough to have been developed and applied in actual system design contexts. However, they have mainly developed in the analysis of traditional interface technologies rather than computer user interfaces. As discussed earlier, the general concepts of task analysis hold for computer interfaces, but there are some key differences and a clear need to address computer user interfaces more directly. In summary, the following problems exist with traditional analysis methods.

Representing a mass of procedural detail. Computer interface procedures tend to be complicated, repetitive, and hierarchical. The primarily graphical and tabular representations traditionally used for procedures become unwieldy when the amount of detail is large.

Representing procedures that differ in level of analysis and type. For example, in HTA, a plan is represented differently from a procedure, even though a plan is simply a kind of higher-order procedure.

Moving from a task analysis to a functional design to an interface design. To a great extent, human factors practice uses different representations for different stages of the design process (see Kirwan and Ainsworth [1992] and Beevis et al. [1992]). It would be desirable to have a single representation that spans these stages, even if it covers only part of the task analysis and design issues.

This section describes how GOMS models could be used to represent a high-level task analysis that can be used to help choose the desirable functionality for a system. Because GOMS models have a programming language-like form, they can represent large quantities of procedural detail in a uniform notation that works from a very high level down to the lowest level of the interface design.

46.5.1 High-Level GOMS Analysis

Using high-level GOMS models is an alternative to the conventional requirements of development and interface design process discussed in the introduction to this chapter. The approach is to drive the choice of functionality from the high-level procedures for doing the tasks, choosing functions that will produce simple procedures for the user. By considering the task at a high level, these decisions can be made independently of, and prior to, the interface design, thereby improving the chances that the chosen functionality will enable a highly useful and usable product after a good interface is developed. Key interface design decisions, such as whether a color display is needed, can be made explicit and given a well founded basis, such as how color coding could be used to make the task easier.

The methodology involves choosing the system functionality based on high-level GOMS analysis of how the task would be done using a proposed set of functions. The analyst can then begin to elaborate the design by making some interface design decisions and writing the corresponding lower-level methods. If the functionality design is sound, it should be possible to expand the high-level model into a more detailed GOMS model that also has simple and efficient methods. If desired, the GOMS model can be fully elaborated down to the keystroke level of detail, which can produce usability predictions (see Kieras [1997] and John and Kieras [1996a, b]).

GOMS models involve goals and operators at all levels of analysis, with the lowest level being the so-called *keystroke level*, of individual keystrokes or mouse movements. The lowest-level goals will have methods consisting of keystroke-level operators and might be basic procedures, such as moving an object on the screen or selecting a piece of text. However, in a high-level GOMS model, the goals may refer only to parts of the user's task that are independent of the specific interface, and they may not specify operations in the interface. For example, a possible high-level goal would be *Add a Footnote*, but not *Select INSERT FOOTNOTE from EDIT menu*. Likewise, the operators must be well above the keystroke level of detail, not specific interface actions. The lowest level of detail an operator may have is to invoke a system function or to perform a mental decision or action, such as choosing which files to delete or thinking of a file name. For example, an allowable operator would be *Invoke the database update function*, but not *Click on the UPDATE button*.

The methods in a high-level GOMS model describe the order in which mental actions or decisions, submethods, and invocations of system functions are executed. The methods should document what information the user must acquire in order to make any required decisions and to invoke the system functions. They also should represent where the user might detect errors and how these might be corrected with additional system functions. All too often, support for error detection and correction by the user either is missing or is a clumsy add-on to a system design. By including it in the high-level model for the task, the designer may be able to identify ways in which errors can be prevented, detected, and corrected, early and easily.

46.5.2 An Example of High-Level GOMS Analysis

The domain for this example is electronic circuit design and computer-aided design systems for electronic design (ECAD). A task analysis of this domain would reveal many very complex activities on the part of electronic circuit designers. Of special interest are several tasks for which computer support is feasible: after

a circuit is designed, its correct functioning must be verified, and then its manufacturing cost estimated, power and cooling requirements determined, the layout of the printed circuit boards designed, automated assembly operations specified, and so forth.

This example involves computer support for the task of verifying the circuit design by using computer simulation to replace the traditional slow and costly “breadboard” prototyping. For many years, computer-based tools for this process have been available and undergoing development, based on techniques for simulating the behavior of the circuit using an abstract mathematical representation of the circuit. For purposes of this example, attention will be limited to the somewhat simpler domain of digital circuit design. Here, the components are black-box modules (i.e., integrated circuits) with known behaviors, and the circuit consists simply of these components with their terminals interconnected by wires.

The high-level functionality design of such a system will be illustrated with an ideal task-driven design example, describing how such systems *should* have been designed. Then the design of a typical actual system will be presented in terms of the high-level analysis and compared to the task-driven design.

46.5.2.1 Task-Driven Design Example

Given the basic functionality concept of using a simulation of a circuit, the top-level method to accomplish this goal is the first method shown in Figure 46.1, which accomplishes the goal *Verify circuit with ECAD system*. This first method needs some explanation of the notation, which is the so-called natural GOMS language (NGOMSL) described in Kieras [1997] for representing GOMS models in a readable format.

The first line introduces a method for accomplishing the top-level user goal. It will be executed whenever the goal is asserted, and it terminates when the *return with goal accomplished* operator in Step 4 is executed. Step 1 represents the user’s black-box mental activity of thinking up the original idea for the circuit design. This *think-of* operator is just a place holder; no attempt is made to represent the extraordinarily complex cognitive processes involved. Step 2 asserts a subgoal to specify the circuit for the ECAD system; the method for this subgoal appears next in Figure 46.1. Step 3 of the top-level method is a high-level operator for invoking the functionality of the circuit simulator and getting the results; no commitment is made at this point as to how this will be done in the interface. Step 4 documents that, at this point, the user will decide whether the job is complete, based on the output of the simulator. Step 5 is another placeholder for a complex cognitive process of deciding what modification to make to the circuit. Step 6 invokes the functionality to modify the circuit, which would probably be much like that involved in Step 2, but which will not be further elaborated in this example. Finally, the loop in Step 7 shows that the top-level task is iterative.

The next step in the example is to consider the method for entering a circuit into the ECAD system. In this domain, schematic circuit drawings are the conventional representations for a circuit, so the basic functionality that must be provided is a tool for drawing circuit diagrams. This is reflected in the method for the goal *Enter circuit into ECAD system*.

This method starts with invoking the tool, and then has a simple iteration consisting of thinking of something to draw, accomplishing the goal of drawing it, and repeating until done. The method gets more interesting when the goal of drawing an object is considered, because in this domain there are some fundamentally different kinds of objects, and the information requirements for drawing them are different. Only two kinds of objects will be considered here.

A selection rule is needed in a GOMS model to choose what method to apply, depending on the kind of object, and then a separate method is needed for each kind of object. The selection rule set in Figure 46.1 thus accomplishes a general goal by asserting a more specific goal, which then triggers the corresponding method. The method for drawing a component requires a decision about the type of component (e.g., what specific multiplexer chip should be used) and where in the diagram the component should be placed to produce a visually clear diagram. Drawing a connecting wire requires deciding which two points in the circuit the wire should connect, and also how the wire should be routed to produce a clear appearance.

At this point, the analysis has documented some possibly difficult and time-consuming activities that the user must do. Candidates for additional system functions to simplify these activities could be considered.

```

Method for goal: Verify circuit with ECAD system
  Step 1. Think-of circuit idea.
  Step 2. Accomplish Goal: Enter circuit into ECAD system.
  Step 3. Run simulation of circuit with ECAD system.
  Step 4. Decide: If circuit performs correct function,
            then return with goal accomplished.
  Step 5. Think-of modification to circuit.
  Step 6. Make modification with ECAD system.
  Step 7. Go to 3.

Method for goal: Enter circuit into ECAD system
  Step 1. Invoke drawing tool.
  Step 2. Think-of object to draw next.
  Step 3. If no more objects, then Return with goal accomplished.
  Step 4. Accomplish Goal: draw the next object.
  Step 5. Go to 2.

Selection rule set for goal: Drawing an object
  If object is a component, then accomplish Goal: draw a component.
  If object is a wire, then accomplish Goal: draw a wire.
  ...
  Return with goal accomplished

Method for goal: Draw a component
  Step 1. Think-of component type.
  Step 2. Think-of component placement.
  Step 3. Invoke component-drawing function with type and placement.
  Step 4. Return with goal accomplished.

Method for goal: Draw a wire
  Step 1. Think-of starting and ending points for wire.
  Step 2. Think-of route for wire.
  Step 3. Invoke wire drawing function with starting point,
            ending point, and route.
  Step 4. Return with goal accomplished.

```

FIGURE 46.1 Preliminary high-level methods for an ECAD system.

For example, the step of thinking of an appropriate component might be quite difficult, due to the huge number of integrated circuits available. Likewise, thinking of the starting and ending points for the wire involves knowing which input or output function goes with each of the many pins on the chips. Some kind of on-line documentation or database to provide this information in a form that meshes well with the task might be valuable. Similarly, a welcome function might be some automation to choose a good routing for wires.

Although the analysis of the desirable functions has just begun, it is worthwhile to consider what errors the user might make and how the system functionality will support identifying and correcting them. In this domain, the errors the user might make can be divided into *semantic* errors, in which the specified circuit does not do what it is supposed to do, and *syntactic* errors, in which the specified circuit is invalid, regardless of the function. The semantic errors can only be detected by the user evaluating the behavior of the circuit and discovering that the idea for the circuit was incorrect or incorrectly specified. Notice that the iteration in the top-level method provides for detecting and correcting semantic errors. Syntactic errors arise in the digital circuit domain because there are certain connection patterns that are incorrect in terms of what is permissible and meaningful with digital logic circuits. Two common cases are disallowed

Method for goal: Enter circuit into ECAD system

- Step 1. Invoke drawing tool.
- Step 2. Think-of object to draw next.
- Step 3. Decide: If no more objects, then go to 6.
- Step 4. Accomplish Goal: draw the next object.
- Step 5. Go to 2.
- Step 6. Accomplish Goal: Proofread drawing.
- Step 7. Return with goal accomplished.

Method for goal: Proofread drawing

- Step 1. Find missing connection in drawing.
- Step 2. Decide: If no missing connection, return with goal accomplished.
- Step 3. Accomplish Goal: Draw wire for connection.
- Step 4. Go to 1.

Method for goal: Draw a wire

- Step 1. Think-of starting and ending points for wire.
- Step 2. Think-of route for wire.
- Step 3. Invoke wire drawing function with starting point,
ending point, and route.
- Step 4. Decide: If wire is not disallowed, return with goal accomplished.
- Step 5. Correct the wire.
- Step 6. Return with goal accomplished.

FIGURE 46.2 Revised methods incorporating error detection and correction steps.

connections (e.g., shorting an output terminal to ground) and missing connections (e.g., leaving an input terminal unconnected).

It is important to correct syntactic errors before running the simulator, because their presence will cause the simulator to fail or to produce invalid results. Functions to detect syntactic errors can be implemented fairly easily; the design question is exactly how this functionality should be defined so that it most helps the user. Note that disallowed connections appear at the level of individual wires, whereas missing connections only show up at the level of the entire drawing. Thus, the functions to assist in detecting and correcting disallowed connections should be operating while the user is drawing wires, and those for missing connections while the user is working on the whole drawing. Figure 46.2 shows the corresponding revisions and additions to some of the methods in [Figure 46.1](#).

The method for entering the circuit now incorporates a method invoked in Step 6 to proofread the drawing, which is done by finding the missing connections in the drawing and adding a wire for each one. The method for drawing a wire now has Step 4, which checks for the wire being disallowed immediately after it is drawn. If there is a problem, the wire will be corrected before proceeding.

At this point in the design of the functionality, the analysis has documented what information the user must get about syntactic errors in the circuit diagram, and where this information can be used to detect and correct the error immediately. Some thought can now be given to what functionality might be useful to support the user in finding syntactically missing and disallowed connections. One obvious candidate is the use of color coding. For example, perhaps unconnected input terminals could start out as red on the display, and then turn green when validly connected. Likewise, perhaps as soon as a wire is connected at both ends, it could turn red if it is a disallowed connection or green if it is legal. This use of color should work very well, because properly designed color coding is known to be an extremely effective way to aid visual search. In addition, the color coding calls the user's attention to the problems, but without forcibly interrupting the user. This design rationale for using color is an interesting contrast to actual ECAD displays, which generally make profligate use of color in ways that lack any obvious value in performing the task. [Figure 46.3](#) presents a revision of the methods to incorporate this preliminary interface design decision.

Method for goal: Proofread drawing

- Step 1. Find a red terminal in drawing.
- Step 2. Decide: If no red terminals, return with goal accomplished.
- Step 3. Accomplish Goal: Draw wire at red terminal.
- Step 4. Go to 1.

Method for goal: Draw a wire

- Step 1. Think-of starting and ending points for wire.
- Step 2. Think-of route for wire.
- Step 3. Invoke wire drawing function with starting point, ending point, and route.
- Step 4. Decide: If wire is now green, return with goal accomplished.
- Step 5. Decide: If wire is red, think-of problem with wire.
- Step 6. Go to 1.

FIGURE 46.3 Methods incorporating color codes for syntactic drawing errors.

At this point, the functionality design also has clear implications for how the system implementation must be designed, in that the system must be able to perform the required syntax-checking computations on the diagram quickly enough update the display while the drawing is in progress. Thus, performing the task analysis for the design of the functionality has not only helped guide the design to a fundamentally more usable approach, it also has produced some critical implementation specifications very early in the design.

46.5.2.2 An Actual Design Example

The preceding example of how the design of functionality can be aided by working out a high-level GOMS model of the task seems straightforward and unremarkable. A good design is usually intuitively “right,” and once presented, seems obvious. However, at least the first few generations of ECAD tools did not implement such an intuitively obvious design at all, probably because nothing was done that resembled the kind of task and functionality analysis just presented. Rather, a first version of the system was probably designed and implemented whose methods were the obvious ones shown in [Figure 46.1](#): the user will draw a schematic diagram in the obvious way and then run the simulator on it. However, once the system was in use, it became obvious that errors could be made in the schematic diagram that would cause the simulation to fail or to produce misleading results. The solution was simply to provide a set of functions to check the diagram for errors, but to do so in an opportunistic, *ad hoc* fashion, involving minimum implementation effort, which failed to take into account the impact on the user’s task. [Figure 46.4](#) shows the resulting method, which was actually implemented in some popular ECAD systems.

The top level is the same as in the previous example, except for Step 3, which checks and corrects the circuit after the entire drawing is completed. The method for checking and correcting the circuit first involves invoking a checking function, which was designed to produce a series of error messages that the user would process one at a time. For ease of implementation, the checking function does not work in terms of the drawing, but in terms of the abstract circuit representation, the *netlist*, and so reports the site of the syntactically illegal circuit feature in terms of the name of the node in the netlist. However, the only way the user can examine and modify the circuit is in terms of the schematic diagram. So the method for processing each error message first involves locating the corresponding point in the circuit diagram, and then making a modification to the diagram. To locate the site of the problem on the circuit diagram, the user invokes an identification function and provides the netlist node name; the function then highlights the corresponding part of the circuit diagram, which the user can locate on the screen. In other words, to check the diagram for errors, the user must wait until the entire diagram is completely drawn and then invoke a function whose output must be manually transferred into another function, which finally identifies the location of the error!

```

Method for goal: Verify circuit with ECAD system
  Step 1. Think-of circuit idea.
  Step 2. Accomplish Goal: Enter circuit into ECAD tool.
  Step 3. Accomplish Goal: Check and correct circuit.
  Step 4. Run simulation of circuit with ECAD tool.
  Step 5. Decide: If circuit performs correct function,
           then return with goal accomplished.
  Step 6. Think-of modification to circuit.
  Step 7. Make modification in ECAD tool.
  Step 8. Go to 3.

Method for goal: Check and correct circuit
  Step 1. Invoke checking function.
  Step 2. Look at next error message.
  Step 3. If no more error messages, Return with goal accomplished.
  Step 4. Accomplish Goal: Process error message.
  Step 5. Go to 2.

Method for goal: Process error message
  Step 1. Accomplish Goal: Locate erroneous point in circuit.
  Step 2. Think-of modification to erroneous point.
  Step 3. Make modification to circuit.
  Step 4. Return with goal accomplished.

Method for goal: Locate erroneous point in circuit
  Step 1. Read type of error, netlist node name from error message.
  Step 2. Invoke identification function.
  Step 3. Enter netlist node name into identification function.
  Step 4. Locate highlighted portion of circuit.
  Step 5. Return with goal accomplished.

```

FIGURE 46.4 Methods for an actual ECAD system.

Obviously, the functionality design in this version of the system will inevitably result in a far less usable system than the task-driven design. Instead of getting immediate feedback at the time and place of an error, the user must finish drawing the circuit and then engage in a convoluted procedure to identify the errors in the drawing. Although the interface has not yet been specified, the inferior usability of the actual design relative to the task-driven design is clearly indicated by the additional number of methods and method steps, and the time-consuming nature of many of the additional steps. In contrast to the task-driven design, this actual design seems preposterous and could be dismissed as a silly example — except for the fact that at least one major vendor of ECAD software used exactly this design.

In summary, the task-driven design was based on an analysis of how the user would do the task and what functionality would help the user do it easily. The result was that users could detect and correct errors in the diagram while drawing the diagram, and so they could always work directly with the natural display of the circuit structure. In addition, good use was made of color display capabilities, which often go to waste. The actual design probably arose because user errors were not considered until very late in the development process, and the response was minimal add-ons of functionality, leaving the initial functionality decisions intact. The high-level GOMS model clarifies the difference between the two designs by showing the overall structure of the interaction. Even at a very high level of abstraction, poor functionality design can result in task methods that are inefficient and clumsy. Thus, high-level GOMS models can capture critical insights from a task analysis to help guide the initial design of a system and its functionality.

46.6 Research Issues and Concluding Summary

The major research problem in task analysis is attempting to bring some coherence and theoretical structure to the field. Although psychology as a whole rather seriously lacks a single theoretical structure, the subfields most relevant to human–system interaction are potentially unified by work in cognitive psychology on cognitive architectures, which are computational modeling systems that attempt to provide a framework for explaining human cognition and performance (see Byrne [2003] for an overview). These architectures are directly useful in system design in two ways: First, because the architecture must be “programmed” to perform the task with task-specific knowledge, the resulting model contains the content of a full-fledged task analysis, both the procedural and cognitive components. Thus, constructing a cognitive-architectural model is a way to represent the results of a task analysis and verify its completeness and accuracy. Second, because the architecture represents the constants and constraints on human activity (such as the speed of mouse pointing movements and short-term memory capacity), the model for a task is able to predict performance on the task, and so can be used to evaluate a design very early in the development process (see Kieras [2003] for an overview).

The promise is that these comprehensive cognitive architectures will encourage the development of coherent theory in the science base for HCI, and also provide a high-fidelity way to represent how humans would perform a task. While some would consider such predictive models the ultimate form of task analysis [Annett and Stanton, 2000b], there is currently a gap between the level of detail required to construct such models and the information available from a task analysis, both in principle and in practice [Kieras and Meyer, 2000]. There is no clear pathway for moving from one of the well established task analysis methods to a fully detailed cognitive-architectural model. It should be possible to bridge this gap, because GOMS models, which can be viewed as a highly simplified form of cognitive architectural model [John and Kieras, 1996a, b], are similar enough to HTA that it is easy to move from this most popular task analysis to a GOMS model. Future work in this area should result in better methods for developing high-fidelity predictive models in the context of more sophisticated task analysis methods.

Another area of research concerns the analysis of team activities and team tasks. A serious failing of conventional psychology and the social sciences in general is a gap between the theory of humans as individual intellects and actors and the theory of humans as members of a social group or organization. This leaves HCI as an applied science without an articulated scientific basis for moving between designing a system that works well for an individual user and designing a system that meets the needs of a group. Despite this theoretical weakness, task analysis can be done for whole teams with some success, as shown by Zachary, et al. [2000], Essens et al. [2000], and Klein, [2000]. What is less convincing at this point is how such analyses can be used to identify an optimal team structure or interfaces to support team performance optimally. One approach will be to use computational modeling approaches that take individual human cognition and performance into account as the fundamental determiner of the performance of a team, as in preliminary work by Santoro and Kieras [2001].

The claim that a task analysis is a critical step in system design is well illustrated by the introductory examples, in which entire systems were seriously weakened by failure to consider what users actually need to do and what functionality is needed to support them. This claim is also supported by the final example, which shows how, as opposed to the usual *ad hoc* design of functionality, a task analysis can directly support a choice of functions, resulting in a useful and usable system. While there are serious practical problems in performing task analysis, the experience of human factors shows that these problems can be overcome, even for large and complex systems. The numerous methods developed by human factors for collecting and representing task data are ready to be adapted to the problems of computer interface design. The additional contributions of cognitive psychology have resulted in procedural task analyses that can help evaluate designs rapidly and efficiently. System developers thus have a powerful set of concepts and tools already available, and they can anticipate even more comprehensive task analysis methods in the future.

Acknowledgment

The concept of high-level GOMS analysis was developed in conjunction with Ruven Brooks, of Rockwell Automation, who also provided helpful comments on the first version of this chapter.

Defining Terms

Cognitive psychology: A branch of psychology concerned with rigorous empirical and theoretical study of human cognition, the intellectual processes having to do with knowledge acquisition, representation, and application.

Cognitive task analysis: A task analysis that emphasizes the knowledge required for a task and its application, such as decision making, and its background knowledge.

Functionality: The set of user-accessible functions performed by a computer system; the kinds of services or computations performed that the user can invoke, control, or observe the results of.

GOMS model: A theoretical description of human procedural knowledge in terms of a set of **Goals**, **Operators** (basic actions), **Methods** (sequences of operators that accomplish goals), and **Selection rules**, which select methods appropriate for goals. The goals and methods typically have a hierarchical structure. GOMS models can be thought of as programs that the user learns and then executes in the course of accomplishing task goals.

Human factors: Originating when psychologists were asked to tackle serious equipment design problems during World War II, this discipline is concerned with designing systems and devices so that they can be used effectively by humans. Much of human factors is concerned with psychological factors, but important other areas are biomechanics, anthropometrics, work physiology, and safety.

Task: This term is not very well defined and is used differently in different contexts, even within human factors and HCI. Here, it refers to purposeful activities performed by users, either a general class of activities or a specific case or type of activity.

Task domain: The set of knowledge, skills, and goals possessed by users that is specific to a kind of job or task.

Usability: The extent to which a system can be used effectively to accomplish tasks. A multidimensional attribute of a system, covering ease of learning, speed of use, resistance to user errors, intelligibility of displays, and so forth.

User interface: The portion of a computer system with which the user interacts directly, consisting not just of physical input and output devices, but also the contents of the displays, the observable behavior of the system, and the rules and procedures for controlling the system.

For Further Information

The reference list contains useful sources for following up this chapter. Landauer's book provides excellent economic arguments on how many systems fail to be useful and usable. The most useful sources on task analysis are the books by Kirwan and Ainsworth and by Diaper and Stanton, and the report by Beevis et al. A readable introduction to GOMS modeling is B. John's article, "Why GOMS?" in *Interactions* magazine, 1995, 2(4). The references by John and Kieras and by Kieras provide detailed overviews and methods.

47.1 Introduction

The last decade has seen a significant change in the information technology (IT) landscape, resulting in a fundamental shift in the activities and skills required of IT professionals and teams. The mystical stories of isolated technical programmers huddled in the basement generating code are not the driving reality. Instead, while still demanding deep technical expertise, the work of IT individuals and teams is also becoming more interdisciplinary and interpersonal in nature, requiring a broader range of skills to meet end user needs.

Today's IT professionals are no longer solely technical specialists; they are also educators, facilitators, and consultants, working as teams in conjunction with end users to solve business needs. Amidst these new demands and roles, IT teams are under increasing pressure to create and deliver products and services that are on time, within budget, and of high quality.

These realities force a reexamination of the factors influencing the work of IT teams from a human dynamics perspective. Today's setting requires IT professionals and teams to possess a wide range of communication and interpersonal skills, skills that have not always been taught and supported in the technically focused environment of IT. This chapter considers these issues of human dynamics in system development, describes the changing role of the IT professional and team as technology has evolved, explores the skills required in today's setting, and proposes best practices for managing the "human side" of IT.

47.1.1 The Changing IT Landscape

The advent of ubiquitous computing and the birth of e-terms (e.g., e-mail, e-business) are small indicators of the degree of change that an information-hungry culture has experienced over the past 10 to 15 years. For many end users, IT is now an enabler, rather than an enigma — and has become the province of a broad user base, rather than a select group of technical gurus.

This rate of technological advance reflects the extensive study and development of both technical and process dynamics and principles. Despite this progress, system development efforts still continue to face failure at a high rate. The CHAOS 2000 Report [Standish Group, 2001] estimated that 23% of application development efforts failed between 1994 and 2000; an additional 49% were “challenged” (i.e., completed over budget, past deadline, and with fewer features).

What factors contribute to this situation? Even with our best development methodologies and technological sophistication, the human dimension of systems and software development remains the key element to success. For example, the CHAOS 2000 Report concludes that “user involvement” is the second most important criterion for project success, falling only behind “executive support” [Standish Group, 2001]. At the most basic level, the output from any development project emerges from the conversations and collaboration among many individuals working together over time. As such, success may ultimately be influenced by the development team’s ability to manage the following types of human dynamics:
