Team technical diversity — The range of talents required of an IT development team today is both broad and deep. Ten or fifteen years ago, a development team might have consisted primarily of programmers; today, the team is also likely to include functional experts, analysts, architects, writers, network and systems administrators, and perhaps even a facilitator. In fact, in a recent study across 36 IT-focused organizations, only 12% of IT professionals surveyed reported their role as being programmer or developer [DAU, 2003]. The result of this trend is that IT teams, which once shared at least a common technical base for building relationships, are now coming together from separate specialties and backgrounds within their own fields. This diversity creates profound opportunities for collaboration, but it can also lead to miscommunication and “stove-piped” efforts if not managed effectively.

Team collaboration — With decreased development times and increased focus on product integration over development, information technology activities demand that IT team members are able to transfer knowledge internally and communicate effectively. Gartner [2002] notes, “teamwork is key to software life cycle planning,” and recommends that managers “establish cross-functional teams to enable consistent and constant communication across multiple groups.” A study of the Microsoft NT operating system development effort concluded that the *team* was the most vital operating level of that organization. “So rapid are technological developments that the core of the corporation is now the team, the only unit small enough to maintain its intellectual edge” [Zachary, 1998].

Interaction with user — The emergence of the Internet and ubiquitous computing has resulted in a new type of end user — one who is more IT savvy than in the past and who faces uncertain and highly volatile requirements as business needs shift and demands grow. This has led to development efforts that are more connected to the user, and more dependent on social and technical interactions as systems are iterated through collaborative development efforts.

47.1.2 Human Dynamics Research

Research in human factors and human–computer interaction has predominantly focused on interface design, object-oriented techniques, and other issues related to a person’s interaction with a computer or system. In the world of computer science and engineering, human factors often avoid the personal — and profoundly messy — areas of human-to-human interaction inherent in the system development process. This work has been primarily the realm of industrial psychology and organizational development, often difficult to translate to the unique setting of the system development experience. One of the books first connecting the fields of psychology and computer science even acknowledged that “the idea of the programmer as a human being is not going to appeal to some people” [Weinberg, 1971].

During that period, the field of software psychology brought new focus to the programmer’s interaction with computing problems and solutions. Still, with some exceptions, early research in this area primarily involved the programmer’s interaction with the computing environment — focusing on cognitive problem-solving skills, rather than the ability to work within a team or with others.

Recent research suggests that the focus has shifted to IT management and process, viewing the problems of system development from a project or management science perspective, rather than a personal one. When IT professionalism is discussed, it usually includes the context of technical or human resource-related issues, such as skills development, recruiting, and retention incentives. Still, while some of these works note the need for effective teamwork and communication among IT workers and users, they rarely describe how these dynamics can be assessed, taught, or developed [Curtis et al., 1988].

Recent notable works that describe the human dimension of the IT development experience include *Death March* [Yourdon, 1999], *Peopeware* [DeMarco and Lister, 1999], *Managing Technical People* [Humphrey, 1997], and *Adaptive Software Development* [Highsmith, 2000]. These works are insightful and useful; however, more often than not, the messages are not based on empirical evidence related to IT dynamics, as they rely heavily on case studies or anecdotal evidence. One notable exception to this is work by DeMarco and Lister [1999], which describes team productivity as it relates to several work environment characteristics, such as floor space allocation, noise levels, and degree of interruption.

In the first edition of this Handbook, Rosson [1995] notes the need for more empirical studies of computer professionals working in the field. This type of research poses unique challenges, because the range of variables and potential interactions impacting the human process carries a complexity that is difficult to manage. As a result, such studies are best approached from an epidemiological viewpoint, rather than as an experimental study based on controllable variables. Later in this chapter, we report the results of such a study, conducted with 632 IT professionals working in 77 different teams across the IT profession. This study is unique because it contains data for more than 80 variables, generated through both self-report and observational methods, collected from IT professionals [DAU, 2003]. This research can be used as a basis for developing new, human-focused training standards for IT managers, teams, and educators to assist them in responding to the changing demands of the IT landscape. First, however, we describe this changing landscape.

47.2 Underlying Principles

47.2.1 IT System Development Trends: History and Impact

New technology innovations over the past 10 to 15 years have profoundly impacted both the community of IT developers and the community of IT users. In this section, we review four key areas that have influenced the human dynamics of system development: distributed systems, ubiquitous computing, the growth of off-the-shelf software, and the Internet revolution. For each area, we describe its recent history and its impact on the human dynamics of system development.

47.2.1.1 Distributed Systems

In its simplest form, a *distributed system* is a collection of autonomous computers interconnected by a network. The emergence of distributed systems occurred in the early 1990s, in response to many of the problems associated with mainframe or mini-computing environments prevalent in the 1980s.

Distributed systems rely on software to produce a virtual integrated computing capability. These systems share several key characteristics: resource sharing, greater fault tolerance, transparency, scalability, concurrency, and openness. Resource sharing helps to reduce the overall costs of running concurrent systems, by allowing key resources such as hardware, software, and data to be shared across the system. Fault tolerance on distributed systems dampens the impact of hardware, software, or communications failures. Distributed systems allow for hardware redundancy, and they introduced the idea of recovery plans for system software failures. The openness of a distributed system governs its extensibility and the degree to which it adheres to industry standards for hardware, software, and communications protocols. *Concurrency* is the ability of the system to handle many different users accessing the same hardware and software resources. It is also concerned with the coordination of multiple responses to client requests in a coherent manner. *Scalability* relates to a system's ability to grow. Growth in a distributed environment

usually involves an increased number of users, platforms, or additional software applications. In order for a distributed system to be robust, it must be scalable.

The emergence of distributed systems fundamentally impacted the human dynamics of system development. In this landscape, system users should not have to know (or care) where their hardware or software is physically located. The beauty of distributed system architecture is that it allows the administration and upkeep of the system to be located virtually anywhere without impacting the user. While this flexibility is beneficial, it can also affect the relationship between user and IT professional — with distributed systems, the easier face-to-face interactions encouraged by a centralized environment may take a back seat to the convenience and potential physical remoteness of a more virtual reality, where interaction with the end user may occur more through phone and e-mail.

The move to distributed systems has also had a major impact on the variety of IT positions in the workforce, as well as the IT professional pecking order. Distributed processing suddenly placed more emphasis on network and the system administration skills needed to keep the large, distributed infrastructures running. Additionally, new IT specialties, such as open system architecture and system security, have emerged. With the addition of these new specialties and the IT roles that accompany them, the traditional programmers and database experts of the prior decade have been relegated to secondary roles. System development is no longer focused solely on programming, but has broadened to include a new set of skills — and the diversity and complexity of the IT system development team has grown in response.

47.2.1.2 Ubiquitous Computing

The history and evolution of the personal computer (PC) is steeped in both folklore and competition. Many trace the origins of today's PCs to the Xerox Alto, but not all agree. For example, the history of IBM's PC, especially the XT and its spinoffs, have little or nothing to do with research done by Xerox on the Alto. Many believe that the first true personal computer was the Altair, introduced in 1975 [Pres, 1993]. The story of the Altair coincides with the emergence of two key people in system development: Bill Gates and Paul Allen, who started Micro-soft (*sic*) Corporation and developed programs for the Altair.

In 1977, Steven Jobs and Stephen Wozniak introduced the Apple II personal computer, the flagship for the newly introduced Apple Computer, Inc. For the first time, personal computers became affordable and accessible to the general population. Apple also introduced the intuitive graphical interface, opening the world of computing to millions.

Before the early 1980s, Digital Research, the developers of the CP/M operating system, had yet to build a CP/M version that would work with Intel's 16-bit central processing units. A small hardware vendor named Seattle Computer, with programmer Tim Paterson, offered an operating system much like CP/M, but which used Intel's 8086 processor. Under tremendous time pressure to get it to market, Paterson wrote the code hastily. Subsequently, the 8086-DOS operating system was dubbed QDOS, for *quick and dirty operating system*. Bill Gates, aware of IBM's problems obtaining an Intel-compatible operating system, acquired a license for and later bought QDOS. He then licensed it to IBM, where it became known as PC-DOS. The PC was a market success, and third-party applications developers began developing a wealth of products that would run on this platform [Pres, 1993].

Despite the rich, colorful, and very human history of the PC, most computing historians agree that current desktop configurations stabilized around 1990 [Pres, 1993]. During this time, the workstation became part of most professional business environments and appeared in many homes. Between 1993 and 1998, the percentage of U.S. households with a computer jumped from 23% to 42%; by 2000, the percentage had reached 51% [U.S. Census Bureau, 2000].

The 1990s' explosion of PC usage would forever change the human dynamics of computing, as IT professionals faced a redefinition of the term *user*. The number and variety of users in the PC world had become far greater than those of the earlier mainframe or mini-computer world. Users became much more sophisticated in the ways of computing, as they started thinking of computers more as interactive tools to meet business needs and less as sophisticated filing cabinets. This led to an increase in user demands from their systems and to heightened expectations of the programmers designing their applications. The ability to code was no longer the sole priority for an IT professional. Other key talents were now required: the

ability to design effective user interfaces, an understanding of the client's business setting and requirements, and the ability to communicate effectively with IT-savvy clients.

47.2.1.3 The Emergence of Commercial Off-the-Shelf Applications

Spreadsheets, which originated in the 1970s with the package VisiCalc, led the proliferation of software applications in the 1980s in the growing PC market. Today, the market is inundated with commercially available software products or *commercial off-the-shelf* (COTS) packages. Sales of the top 500 software vendors were estimated at \$72 billion in 1996, and the packaged software market grew by an estimated 269% between 1984 and 1994 [Carmel and Sawyer, 1998].

COTS components, in general, have the following characteristics [Vigder et al., 1996]:

Products are designed to sell multiple copies to multiple customers with no customization.

Design improvements and enhancements come from success, failure, and complaints in the marketplace.

The software vendor is responsible for ongoing customer support.

No single user, or group of users, has control over evolution of the product.

There is usually no access to source code except through applications programming interfaces (APIs).

System documentation may not be accessible by the user community, but user-oriented documentation and training is usually well developed.

COTS are typically designed to meet specific, widespread needs. Today, it is common to see *COTS integration* projects, in which different COTS packages are fused together by custom-developed “glue code.” Why is COTS integration so popular? Many, including the federal government, believe that COTS integration helps to reduce risk and cost in the long term. Successful examples of COTS integration have included graphical information systems, primarily because the components are usually bundled as a procedural library, various tools such as graphical user interface (GUI) constructors, office automation software, e-mail and messaging systems, Web browsers, database management systems, and system software components such as operating systems, windowing systems, and device drivers [Vigder et al., 1996].

Despite this trend, the success of COTS integration has been mixed [Sledge and Carney, 1998]. Pitfalls and limitations have included attempts to integrate components not designed for interworking, unstable or unsupported APIs, unanticipated labor required to wrap COTS in custom code to achieve required functionality, and inadequate stability and support from the COTS vendor. Furthermore, maintenance and upgrade of an integrated COTS-based system are tricky at best. COTS vendors have different release schedules, which must be coordinated into the integrated system's upgrade schedule. Every time upgrades of the various components are made, the system requires regression testing and often must be recalibrated, with changes to the custom glue code. COTS products also require custom code service providers to invest significant resources to stay current with existing and emerging products and tools in the marketplace.

Building an integrated COTS system is like building a house from a prefab kit for which the components come from different companies. Some are easier to fit together than others. Such an endeavor requires an extraordinary system architect and an integration team well versed in the integrated products. Even with such an extraordinary team, integrated systems remain at the mercy of changes made to future versions of individual components — changes that usually influence the functionality of the integrated system.

As with the skills shift accompanying distributed systems, the desirable IT skills associated with COTS integration have moved the emphasis away from programming. In the world of COTS integration, IT management and business requirements analysis skills become key, as IT professionals help users articulate their requirements and preferences in ways not thought of before. IT professionals must also remain current with the COTS products available on the market, from both a functional and a technical perspective.

Requirements and product research skills are not the only challenge; developers must also understand the intangible human dynamics at work in the COTS integration process. For example, a requirement will often start with the user preferring an existing software package or familiar GUI. If research suggests that better alternatives exist, then the IT professional must communicate with and educate the end users about these options. Often, users will reject a new package — even after training — because it pushes them beyond their comfort level. IT professionals often ignore this dynamic, perhaps because they cannot

understand why end users would not jump at any chance to increase their functionality. The choice of software is often an emotional issue for users, and ignoring this reality can create gaps in the developer–user relationship, ultimately impacting the final product.

IT engineering courses often fail to teach the interpersonal communication and change management skills vital to these efforts. Failures in COTS integration efforts are often caused not by technical or feature failures (although this is sometimes the case in poorly integrated systems), but because the system has not been properly socialized with the end users. This understanding on the part of IT professionals will go a long way toward increasing customer satisfaction with the systems developed from COTS.

47.2.1.4 The Internet Revolution

In August 1962, J.C.R. Licklider described his “galactic network” concept in a series of memos, focusing on the major premise that social interaction could be enabled through widespread networking. He envisioned global, interconnected computers that would facilitate access to data and programs from anywhere in the world. Licklider went on to become the first head of the computer research program at the Advanced Research Projects Agency (ARPA), now the Defense Advanced Research Projects Agency (DARPA). While there, he refined the theory of the galactic network concept with Ivan Sutherland, Bob Taylor, and Lawrence Roberts [Leiner et al., 2002].

In 1961, Leonard Kleinrock published a paper on packet switching theory, following it with a book in 1964. Working with Lawrence Roberts, Kleinrock explored the feasibility of communications using packets rather than circuits. This theoretical milestone would prove crucial to the future of computer networking. In 1965, Roberts worked with Thomas Merrill to connect the TX-2 computer in Massachusetts with the Q-32 computer in California by way of a low-speed, dial-up telephone line. This experiment created the first wide-area computer network. The success of the experiment came with the realization that circuit-switched telephone systems would be insufficient for this massive level of communications. This realization helped to confirm Kleinrock’s belief in packet switching as the critical component for the future Internet.

Working at ARPA in 1966, Roberts conceived a plan for the ARPANET and presented it at a conference attended by other researchers examining the same issues. Collaborative discussions among these researchers yielded a common understanding of the word *packet* and a projection for the proposed ARPANET of a speed of 50 kbps. By August 1968, the structure and specifications for the ARPANET were solidified, and in 1969, four host computers were networked together to form the initial ARPANET (Stanford University, University of California at Los Angeles, University of California at Santa Barbara, and University of Utah). Over time, more computers were added to the ARPANET, and in 1970, the host-to-host protocol called the *network control protocol* was completed and implemented. With the protocol in place, users began to develop applications to run on the network.

In 1972, ARPANET was publicly demonstrated at the International Computer Communications Conference (ICCC). It was also the year that the first e-mail application was written, primarily to facilitate discussion among ARPANET members. ARPANET would grow into the Internet we enjoy today. A key step in this evolution was the development of open architecture networking, formulated by R.E. Kahn, working at DARPA in the early 1970s. By 1985, the Internet was supporting a large number of system developers and researchers and was starting to branch out to include other communities, as well.

By the mid-1970s, other networks started springing up, primarily in the federal government. In addition to developing and introducing new thinking and technologies, the expanding federal government networking population made fundamental policy decisions that enabled the growth of the true World Wide Web. These policy decisions included the following [Leiner et al., 2002]:

- Shared development costs and coordinated network access points were established for common infrastructure among federal agencies.

- The Federal Networking Council in the U.S. and RARE in Europe were established. These organizations, along with others, developed the Coordinating Committee on Intercontinental Research Networking, to coordinate Internet research worldwide.

- A culture developed that fostered sharing and cooperation between agencies. For example, DARPA allowed CSNET and the National Science Foundation (NSF) to share ARPANET’s infrastructure.

In addition, the NSF encouraged its regional NSFNET networks to develop commercial customers, expanding their services and facilities to accommodate them.

The NSF instituted an acceptable use policy, which limited use of the NSFNET backbone to research and educational use. Consequently, a market in providing private, competitive, long-haul networks, such as PSI and UUNET, was born.

In 1988, an NSF-commissioned report, *Toward a National Research Network* proved to be very influential, particularly for then-Senator Al Gore. This report, and the subsequent political attention it prompted, established the high-speed networks that would become the foundation of the future information superhighway.

In 1994, a National Research Council report, *Realizing the Information Future: The Internet and Beyond* was released to the public. This document became the blueprint for the information superhighway. This report anticipated and discussed several key issues for Internet governance, including intellectual property rights, ethics, and the regulation of the Internet.

From a human dynamics perspective, the Internet has far exceeded even Licklider's vision of a "galactic network" to facilitate social interaction. Between 1997 and 2000, the percentage of U.S. households with Internet access jumped from 18% to 42% [U.S. Census Bureau, 2000]. Today, the Internet can facilitate almost every aspect of human interaction, including voice, video, and text-based communication.

The Internet fundamentally changed the way IT professionals do business. Even systems designed to meet individual group needs must now be considered in a broader context. Information contained in a stand-alone system often must be shared or even sold over the Internet. Consequently, many new stand-alone systems are designed to allow Web-enabling in the future. As a result, IT professionals are often asked to predict the requirements for a user population far beyond the local institution.

The Internet also helped to create a far more computer savvy user population, with high expectations for both attractive user interfaces and effective functionality. The length of development life cycles also continued to shorten. Because users can create their own Web pages and make these instantly available on the Web, expectations from IT developers for the same type of rapid development increased. System owners and business experts now see how the Internet and associated technology enable them to reach out to their customers and stakeholders in a way never before possible.

All these developments suggest that the IT professional must tap into this IT-savvy population and harness the power of the human factor to help build better systems for new and emerging applications. In addition, the IT profession needs to understand better its own biases, blind spots, and strengths, and learn how to use this knowledge to benefit future developments.

47.2.2 IT Management – Process Challenges

As users became more sophisticated and development times decreased, new engineering life cycles emerged to help guide development in this new and dynamic environment, with its ever evolving requirements. This section describes the changing face of the process side of IT and will focus on two themes. First, as engineers, IT professionals have attacked the dynamic problems of system development with process and procedure, creating a plethora of standards, protocols, and maturity models. Second, the IT profession has failed to address adequately — except through problem-focused exercises such as usability engineering (see [Chapter 45](#) of this Handbook) — the human dynamics of our users' perspectives. Classical engineering training does not equip IT professionals to think in these terms, preferring the comfortable realm of the "problem first, people second" approach.

47.2.2.1 System Development Methodologies

Every complex endeavor needs an organized plan to keep it on track. Software engineering is no exception. In the world of software applications development, user requirements are usually not well defined, yet most users want their applications done quickly. Consequently, a number of software engineering life cycle

models have evolved, describing the activities that must occur. Here, we summarize the most commonly used models, focusing in each case on the human dynamics for both for the development team and the user. (See also [Chapter 110](#) in this Handbook.)

Pure waterfall. The waterfall life cycle model, first developed in the 1970s using traditional engineering processes and discipline, forms the basis for almost every other software development model. In the waterfall model, development occurs through a series of sequential phases, with a major milestone review or audit marking the end of each phase. The waterfall life cycle progresses through seven basic steps: software concept phase, requirements analysis, high-level or general design, detailed design, coding/unit test/debug phase, system testing, and implementation.

The waterfall life cycle works well for low-speed, low-change projects, in which there is a very clear and stable definition of the requirements, the product, and the supporting technology. It is also widely used in large projects where outputs are combined with other engineered systems. A project that would fit this approach is porting an existing application to a new platform.

The waterfall model is likely to appeal to developers and users who have lower tolerance for ambiguity, enjoy the stability of long-term projects, and prefer concrete milestones and metrics measuring completion. Such a process can be frustrating for users and developers, however, since the product often is not seen until late in its development cycle.

Code and fix. Probably the least disciplined, but still widely used, software engineering methodology is the *code-and-fix* approach. Although most software engineers would argue that code and fix is not really a life cycle at all, its frequency of use cannot be ignored. Code and fix is, of course, an *ad hoc* methodology. A development team will typically start with a general understanding of what they want to build, and then will proceed through steps that combine informal design, coding, and debugging (and maybe, but rarely, some documentation). The end result is rarely robust, but code and fix is attractive because it shows users results very quickly.

Should code and fix be avoided at all costs? Not necessarily. Code and fix is a useful methodology in a few distinct cases. For example, code and fix can be effective for very limited proof-of-concept demonstrations or throwaway prototypes to help evolve requirements. It can also be useful in testing the feasibility of a certain approach before more serious development is pursued.

Code and fix is often appealing to programmers because development moves directly to coding, away from the more abstract tasks of design and integration. It also appeals to ego, in the sense that a few very good hackers can actually build a fairly good system without the overhead associated with more complex methods. However, there is a danger in this approach: developers less schooled in formal methods often mistake code and fix for more disciplined approaches, such as those that follow.

Spiral model. Almost every software engineering project carries risk of failure. Risks can result from poorly understood requirements, for example, or from problems with the underlying technology. The *spiral model* (see [Chapter 110](#)) is designed to minimize risk [Boehm, 1998]. While successive rings of the spiral include the waterfall phases, the iterative steps inside each spiral enable designers to identify and address risks while it is still reasonably inexpensive to do so. Each iteration involves six basic steps [McConnell, 1996]: determine objectives, alternatives, and constraints; identify and resolve known risks; examine alternatives; produce and verify iteration deliverables; plan for the next iteration; and agree to the approach for the next iteration.

The spiral model is attractive because it allows developers to tailor the model continually to meet project objectives. For example, developers can use the model to identify and clarify risk at the beginning of the project. Once all major risks are identified and addressed, they may move into a more waterfall-oriented development process. Of course, like any of the development methodologies, the spiral model has its limitations. It is complex and requires diligent management, including the ability to establish verifiable milestones and validate them before proceeding.

Evolutionary prototyping. Often, users can articulate general needs for a system, but they are unable to express these needs in the form of specific requirements. Such systems can be designed with *evolutionary prototyping*, which focuses on the most visible parts of the system, usually the GUI and the reporting module. Through successive sessions with the end users, the prototype is modified and enhanced until it

achieves the end users' desired result. At that point, the prototype becomes a *de facto* as-built specification and is solidified by the development team. The back-end development team then designs a more robust foundation that incorporates the agreed-upon user interface.

Techniques such as rapid application development (RAD) and joint application development (JAD) are often used to facilitate these evolutions. RAD refers to a process that delivers functionality to users quickly by dividing system functionality into logical segments for rapid development, often with some combination of prototyping, JAD sessions, SWAT teams, CASE tools, and time-boxed deliverables. JAD sessions bring users together with the development team to elicit consensus-based user requirements. Roles required for the development team include the JAD facilitator, who asks a series of prepared questions to elicit decisions from the users; observers, who listen to the interactions; and documenters, who capture the session discussions and decisions.

Many of the iterative development life cycles used today are criticized because of the amount of overhead and time required to implement them. Consequently, newer, "lightweight" software methodologies have begun to attract some attention. One of these is *extreme programming* (XP). XP came on the scene in about 1997 to force a reexamination of standard software development practices and to provide an alternative that would reduce cost. The rules and practices around XP can be grouped into four categories: planning, designing, coding, and testing. Designed for use by IT teams of up to 10 people, XP emphasizes iterative development centered on "user stories" to elicit requirements and drive design. It also encourages rapid iterations, developer-created schedule estimates, programming in pairs, continuous testing, and active user involvement [Beck, 1999].

The greatest strength of evolutionary prototyping is its ability to facilitate the discovery of requirements. There are also secondary benefits. Intimate end user participation in the system's evolution supports user buy-in at the end of the project. In addition, a representative user group participating in this way trains itself, subsequently yielding in-house personnel familiar with how the system works. The greatest weakness of evolutionary prototyping is defining when the project is complete. This becomes a subjective judgment, unless ground rules are well established in advance (e.g., number of iterations before requirements are locked, budget or schedule constraints, etc.). In addition, as with all life cycles, the development team must be constantly vigilant about requirements creep, managing this in a way that neither offends the client nor compromises the development schedule.

Evolutionary prototyping requires a diverse programming team and a broad set of communication and technical skills. This method introduces the role of facilitator to the IT team for JAD sessions and requires the GUI developer to spend extensive time working directly with the user. One of the developer's key roles is expectation management — for example, explaining to users the time required for robust back-end development once the GUI requirements are complete and locked.

Staged delivery. In staged delivery, the user receives incremental or *staged* deliveries of the system. The biggest difference between the staged model and other evolutionary models is that a complete set of requirements is well documented and understood before the first release. Once the detailed design is complete, a schedule of delivered functionality is agreed upon.

Staged delivery begins much like a pure waterfall process, but by iterating the activities of detailed design, coding, debugging, testing, and implementation, the user receives functionality much earlier in the life cycle. One of the major constraints of staged delivery is that it requires careful planning from both management and technical viewpoints. Deliveries must yield products that are both tangible and useful to clients. At the same time, functionality must be grouped in such a way that a feature slated for early release is not dependent on a feature slated for later development. Although this sounds like common sense, it can become very complicated on large-scale projects. This requires that the development team has clear communication processes and coordination skills; it also requires careful documentation to support future stages of the development process.

Design to schedule or cost. Closely associated with a staged release life cycle, this method is used when users do not have a firm understanding of requirements but are constrained by either a firm deadline or cost limits. In this life cycle, there is constant rescoping of requirements to ensure that the system can be delivered on time and below a ceiling cost.

This approach is often used by developers needing to demonstrate functioning software for a particular event, like a trade show or year-end. This approach often works for auxiliary products that are not on the critical path. For example, Microsoft Windows includes applets like WordPad, Paint, etc. Microsoft might use a design to schedule methodology for releasing new applets, to ensure that the released version does not delay or interfere with the primary product.

Design to schedule or cost requires the development team to predict accurately the time it will take to complete a specific task and to understand the essentials of project management, so that the most effective trade-offs can be made. This method can be frustrating for developers, who may feel held back by the user's limitations and who are not always aware of the management constraints at work.

47.2.2.2 Process Improvement Initiatives

The emphasis on system development models has been accompanied by a number of process improvement models. These process initiatives, primarily based on the principles of Deming and Crosby [Ahern et al., 2001], stress the concepts of critical thinking, root cause analysis, repeatable process, and assessment metrics. The “theory in use” manifestation of these initiatives has taken several forms, ranging from the level of organizational culture to the level of individual programmer processes (see also several chapters in [Section XI](#), Software Engineering). This section provides examples and considers the potential impacts on the human dynamics of the development team.

ISO 9000 standards. At the organizational level, the ISO 9000 family of standards is a basis for documenting an organization's management system (what it does to manage its processes) and its approach to quality. Key areas of ISO include customer focus, leadership, involvement of people, process approach, system approach to management, continual improvement, factual approach to decision making, and mutually beneficial supplier relationships (ISO 2002).

From a human dynamics perspective, the strength and the weakness of the ISO system lie in its generic nature. ISO standards delineate specific areas of consideration for an organization (the *what*), but purposefully avoid implementation guidance (the *how*). For example, the leadership principle is encouraged to achieve results such as “establishing trust and eliminating fear.” This is a noble goal, but how can a system development manager proceed to achieve it, amidst looming deadlines and irate clients? Unless significant organizational investment is made to articulate and introduce ISO within an organization, its principles are not likely to be embraced formally as a systemic and guiding set of values. Furthermore, ISO standards are grounded in the concepts of standardization and repeatable process — ideal for stable systems engineering processes, but less immediately attainable for the dynamic world of iterative design. On the other hand, for organizations with the investment resources and time, determining how to apply ISO standards can yield meaningful dialogue, resulting in fundamental cultural change if managed effectively.

The ISO publication related to human-centered design (ISO 13407) specifically outlines methods for considering usability in the system development process. Key activities include planning the design process, understanding context of use, specifying user requirements, producing designs and prototypes, and completing user-based assessments [Maguire, 2001].

Personal and team process metrics. Some software process improvement efforts, such as the *personal software process* and the *team software process*, focus on the documentation of time spent on specific activities performed by system engineers during the planning, development, and testing phases of the system development process. The underlying premise of these efforts is that quantifying the daily human activities of system development allows the developer or team to predict more accurately timelines associated with design projects, leading to more effective management of individual and team time [Humphrey, 1997].

From a human dynamics perspective, there are both benefits and risks to this approach. For developers who prefer the structure and predictability of time management techniques, these methods provide a useful tool for organizing and structuring the design continuum. On the other hand, for developers preferring a more flexible and adaptable approach to accomplishing work (and who may actually be most efficient

when allowed to move between activity bursts and lulls), forced documentation may discourage the natural flow of their efforts.

Another possible risk of introducing team metrics relates to the strict documentation of specific activities and associated timelines. Such tasks represent a strong emphasis on goal orientation and product achievement — achieving the end by measuring the means. While understanding one's own process in pursuing a goal is an important aspect of self-management, such a strict emphasis on goal-focused time management and personal efficiency may decrease the spontaneous and creative outcomes that may emerge if the developer simply experiments with new ideas, with no particular goal in mind. (See Apter [2001] for an overview of telic and paratelic motivational states.)

It is interesting to note the general absence of human interaction time built into the standard worksheets associated with these process tools. The interaction time that supports the development of a relationship between IT professional and user is not recognized as a formal activity in these methods, yet this relationship can fundamentally impact project success. Customer management often includes the social aspects of IT development. Not all contributors to quality can be measured — the personal connection made during the basic activities of human interaction is one such intangible contributor.

Process tools. In the problem-focused world of information technology, software process improvement initiatives have been accompanied by a full suite of software packages, tools, and methodologies. From requirements management techniques and databases to object-oriented design techniques, CASE tools, and debugging tools, the emergence of tools to assist in the system development process are far reaching and have streamlined many traditionally chaotic development processes and management efforts (see also Chapter 116).

Fancy tools can be seductive, and development teams can easily fall into a trap of “form over function” when using them. As Yourdon notes in *Death March*, “What the users understand is their own native language . . . and what most users are willing to read is a short document that summarizes the requirements for the system. The key point is that it's English, it's terse, and it's to the point. . . . We already have a tool for creating such requirements documents; it's called a word processor” [Yourdon, 1997]. The use of structured tools does not eliminate ambiguous requirements, nor does it replace the independent critical thinking that is required for good problem solving. When the final system is complete and delivered, little attention will be paid to the tools used to construct it.

Capability maturity model (CMM). Developed by the Software Engineering Institute (SEI) at Carnegie Mellon University, the CMM process improvement model outlines five levels of process maturity, ranging from a state of no control or documentation (level 1) to a state of continuous improvement at the organizational level (level 5). Each of the five levels is associated with key process areas, focusing on the following concepts [Curtis, 2002]:

Stability as a path to improvement — “A fundamental premise of the process maturity framework is that a practice cannot be improved if it cannot be repeated.”

A foundation for common practice — “Until basic management control of daily work is established, no organization-wide practices have a chance of being deployed successfully, because no one has the time to master them.”

Quantitative management — “The premise underlying quantitative management is that if a well-understood process is repeated, you should get essentially the same result.”

The staged progression of the CMM program is a key advantage, for it allows organizations to target the level most appropriate to their needs and most attainable with their resources. Not every software development organization needs to operate at level 5. Bringing an organization even to CMM level 2 or 3 requires commitment throughout the organization — from top management to the junior programmer. Like the personal and team process metrics described previously, CMM comes with a clear requirement for effective planning and documentation, which may not appeal to the brilliant hacker still in code-and-fix mode.

Adopting process improvement initiatives. Research has shown that adopting new IT process models and tools can be a difficult process, highly dependent on developer acceptance. For example, a 1999 SEI

research study found that IT process tool adoption can be linked to three key factors: the developer's perceived control over the work, the developer's perception of the new tool, and the developer's perception of the impacts of using the new tool or process [Green and Hevner, 1999]. Understanding the personality of the IT professional may yield valuable insights into process improvement efforts and their potential impacts on different systems and individuals. These human dynamics are addressed in the following section.

47.2.3 IT Personality

Recent changes in the IT landscape, and the resulting change in the developer–team–user relationships, force a fresh look at the IT personality and the psychology of computer programming. In the past, much of the literature on software psychology used cognitive and skills-based assessments, focusing on the IT individual's abilities and orientation with respect to problem solving and the task at hand. Equally vital in today's setting are tools that help IT professionals understand their relationships with other people. Today's development environment requires tools that enable individuals and teams to identify their personal preferences and styles and to manage better themselves, their interactions with team members, and their interactions with users. This section describes two tools that are often useful when working with IT teams.

Personality type: background and theory. Several writers in the IT field (e.g., Weinberg [1998], DeMarco and Lister [1999], Humphrey [1997], and Yourdon [1997]) have recognized the importance of personality or psychological characteristics on team performance and success. One of the most popular and useful tools in assessing these characteristics is the Myers–Briggs type indicator (MBTI), an assessment tool grounded in the theory of personality types proposed by Carl Jung [Myers et al., 1998]. The MBTI measures an individual's personality preferences on four distinct scales, each with two opposite sides:

Energy scale: Extraversion–Introversion (E/I) — How people prefer to gather energy

Perceiving scale: Sensing–Intuitive (S/N) — How people prefer to gather new information or data (perceptions)

Judging scale: Thinking–Feeling (T/F) — How people prefer to make decisions (judgments)

Orientation scale: Judging–Perceiving (J/P) — How people express their perceptions or judgments

The theory of personality type proposes that each individual has a preference for one side of each of these dichotomous scales. For example, people energized by the outer world of people, action, and things, who prefer to process new ideas with others, have a preference for Extraversion. Conversely, people energized more by their inner world of concepts and ideas, who prefer to process new ideas alone before sharing them with others, may have a preference for Introversion. Table 47.1 lists each of the MBTI scales and the two preferences associated with each [OKA, 2000].

One key point is worth emphasizing: personality type is about preferences, not absolutes. Although someone might prefer subjective decision making based on what is best for the people involved (Feeling judgments), this does not prevent that person from making objective decisions based on analysis of cause and effect. It simply means that this person accesses the subjective decision making process first and with more ease, whereas it might take more effort and feel less comfortable to make the impersonal judgments that some decisions require. As a result, this person might self-select into activities that allow use of the preferred styles — in this case, working with people directly, rather than with impersonal problems.

Once an individual's letter preference on each scale is selected, a personality type is determined. This *MBTI type* is the four-letter grouping of preferences along the scales. For example, someone with the type ISTJ has preferences for Introversion, Sensing, Thinking, and Judging. With four scales and two possible preferences along each scale, there are 16 possible personality types, each reflecting a unique combination of personality preferences.

TABLE 47.1 Myers-Briggs Type Indicator (MBTI) Personality Scale Descriptions

Scale	Scale Descriptions	
E/I — Energy sources: introversion/extraversion	Extravert (E) — Gains energy from interacting with outer world of people, action, and things. Quiet time can be draining. Applicable words: interactive, expressive, disclosing, “speak to think.”	Introvert (I) — Gains energy from inner world of concepts and ideas. Extensive interaction can be draining. Applicable words: concentrating, internal, contained, reflective, “think to speak.”
S/N — Perceiving mental function: data gathering (What do you first notice?)	Sensor (S) — Prefers to perceive the immediate, practical, real facts of experience and life, collecting information through use of the five senses.	Intuitive (N) — Prefers to perceive possibilities, patterns, and meanings of experience, relying on a sixth sense of hunches to gather information.
T/F — Judging mental function: decision making (How do you prefer to make decisions?)	Thinker (T) — Makes decisions objectively and impersonally, seeking clarity by detaching from the problem. Cause–effect oriented.	Feeler (F) — Makes decisions subjectively and personally, seeking harmony with inner values by placing him- or herself within the problem. Relationship oriented.
J/P — Orientation attitude: (What is the world most likely to see from you: data or decisions?)	Judge (J) — More likely to show the external world his or her decision-making (judgments). Behaviorally, prefers to live in a decisive, planned, orderly way, aiming to regulate and control events. Often appears closure-oriented, with a focus on the goal to be reached.	Perceiver (P) — More likely to show the external world his or her perceiving mental function, sharing data and perceptions rather than decisions. Behaviorally, prefers to live in a spontaneous, flexible way, aiming to understand life and adapt to it.

Four specific pairings of MBTI letter preferences also result in four unique *temperaments*, which map well to specific behavioral, learning, and leadership styles. These four temperament groups follow [OKA, 2000]:

Sensing Judges (SJ) — Stabilizers who prefer structure, order, accountability, reliance on existing systems that work, policies and procedures, and the proven way of doing things

Intuitive Thinkers (NT) — Visionaries who prefer nonconformity, systems theory, conceptualization, independence, objective complexity, and change for the sake of change (if it produces learning)

Intuitive Feelers (NF) — Catalysts who prefer interpersonal support, relationships, possibilities for people, interaction, cooperation, imagination, and supportiveness

Sensing Perceivers (SP) — Troubleshooters who prefer hands-on action and experimentation, practical solutions, variety and change, immediacy, flexibility, and adaptation

Personality type: applications. One of the key benefits to using the MBTI is that an individual or team can complete the assessment and learn about the results and applications in approximately four hours. Understanding personality type reveals important human dynamics in the development team or process. For example, consider requirements gathering in light of the Intuition–Sensing scale described previously. End users and developers who prefer gathering information through Sensing (called *Sensors*) may communicate detailed specifications and develop requirements by addressing specific technical needs. Sensors often describe systems from the ground up. End users and developers who prefer gathering information by Intuition (called *Intuitives*) may start by painting a broad picture of a future system, focusing on the possibilities that could be achieved — requirements that begin with the big picture, with specifics added later.

Communication difficulties often can be traced directly to the preferences associated with personality type. As an example, the authors once conducted requirements interviews with two different users

describing the same need: a document management system allowing the user to search on key words or phrases within the stored documents. One user started the interview with, “I need golden words; help me find the golden words!” This user was likely an Intuitive, starting by painting a figurative picture of the need. The other user started the interview by presenting several sample screen shots from other similar systems, displaying the documents requiring storage. This user was likely a Sensor, communicating requirements by presenting existing, tangible samples of specific needs. Which response is better? The answer may depend on the interviewer’s own preference for Sensing or Intuition. In fact, each response brings a unique and valuable perspective.

Helping IT professionals to identify their personality preferences enables them to manage better themselves and their interactions with team members and users. Consider the advantage to the requirements analyst armed with an understanding of personality type before entering the interviews just described. The educated analyst will begin where the user begins, and then migrate to the other preference to obtain a more complete picture. This often means starting with the big picture and drilling down with Intuitives, or starting with the details and broadening up with Sensors. Analysts unaware of this technique may force the client to begin where the analyst does (the client’s nonpreference if they are opposites) or may never reach the other level of information (if client and analyst share the same preference).

Interpersonal needs: background and theory. The MBTI helps individuals understand their own personality preferences and apply that knowledge for self-management. A second tool, the fundamental interpersonal relations orientation–behavior (FIRO-B) survey, is a personality instrument that measures how one typically behaves toward a team or a group of people and what behaviors are expected in return [Waterman and Rogers, 1996]. This tool assesses three different scales:

Inclusion — Needs related to community, belonging, involvement, participation, recognition, and distinction. Inclusion assesses the extent of contact and prominence that a person needs.

Control — Needs related to power, authority, influence, responsibility, and consistency. Control relates to decision making, influence, and persuasion between people.

Affection — Needs related to acceptance, feedback, personal ties, consensus, sensitivity, support, and openness. Affection relates to emotional connections between people and determines the extent of closeness that a person seeks.

Each of these three scales has two dimensions: expressed (how much a person needs to extend this to others) and wanted (how much a person needs others to extend this back). Table 47.2 describes the six components of a FIRO-B assessment [Waterman and Rogers, 1996].

The FIRO-B assessment provides feedback on each of these six components, with scores ranging from low (limited or highly selective need) to high (strong preference or need for the behavior). For example, a person with low expressed control needs and high wanted control needs probably feels a limited need to exert individual power or influence in many situations, preferring someone else to provide the structure and direction. A person with high expressed control and low wanted control scores may prefer to exercise the control and direct a situation but not wish others to exert that same control in return.

TABLE 47.2 FIRO-B Interpersonal Needs Scale Descriptions

	Inclusion	Control	Affection
Expressed	How much do you try to include others in activities? How hard do you try to belong to groups and be with others?	How much do you try to exert control and influence, and to direct others?	How much do you try to be close to people? What is your level of comfort in expressing personal feelings and supportiveness?
Wanted	How much do you want others to include you in activities? How much do you want others to invite you to belong?	How strong is your need to be in well defined situations? To what degree do you want others to take control?	How much warmth do you want from others? What is your level of enjoyment when people share feelings, and when they encourage efforts?

Interpersonal needs: applications. The FIRO-B is useful in learning about team dynamics and the range of possible needs within a group. For example, it has been proposed that IT managers should hold weekly team sessions outside the work environment to encourage communication among members [Yourdon, 1997]. Some managers may wish to temper this recommendation, based on a consideration of the FIRO-B. If most team members have a very selective need for both expressed and wanted inclusion, the attractiveness of such social gatherings becomes less marked — most team members may not consider that type of interaction a prerequisite for effectiveness.

The challenge for many teams comes when there is incompatibility between the expressed needs and the wanted needs on a specific scale. If a manager with high expressed control needs (prefers to provide structure and direction and to be in a position of power) manages an IT team with low wanted control needs (generally do not want others to exert power or control over them), then the potential exists for conflict within that group over these issues. Understanding FIRO-B helps teams to discuss sensitive issues such as power and feedback, which may help articulate roles, process, and structure in the IT development process.

47.2.3.1 Psychology of the IT Professional

With this background, it is useful to look at the personality preferences and interpersonal needs of IT professionals and to consider the potential impact of these characteristics in the team environment and with the user. Recent research led by the authors with a representative sample of more than 600 IT professionals in 77 different IT teams revealed interesting insights into the psychology of the IT professional [DAU, 2003]:

Three quarters (77%) of the IT professionals surveyed reported an MBTI preference for Thinking decision making, with only 23% preferring Feeling decision making. Given that the split in the general population is generally even between these preferences, this represents a significant overrepresentation of IT individuals with the Thinking preference. Thinkers, as they are termed, generally prefer logical, objective, impersonal decision making, focused on cause-effect relationships and the clarity that comes from objectivity (problem first, people second). The underrepresented Feelers, conversely, prefer to make decisions by placing themselves within a problem, using empathy to connect with the individuals involved (people first, problem second).

Almost half of the IT professionals surveyed (41%) reported as Introverted Thinkers (a combination of the introversion and thinking preferences). This is nearly twice the percentage seen among the general population. Introverted Thinkers often prefer a “lone gun” approach to much of their work, avoiding teams, collaborative efforts, and the training that support such structures. This group is least likely to engage and connect interpersonally with others, and may be reluctant to create personal bridges of trust and openness with colleagues. This finding was supported with FIRO-B results, which revealed that 55% of IT professionals have very low wanted inclusion scores (i.e., a low or highly selective need to be included in the activities of others).

The two most prevalent temperaments among IT professionals are the Intuitive Thinking (NT) and the Sensing Judging (SJ) temperaments. These are represented at 27% and 48%, respectively, in IT teams, compared to 13% and 39% in the general population. Interestingly, these are also the most dynamically opposed temperaments, with SJs typically finding fulfillment in belonging to meaningful institutions and proven systems, and with NTs typically preferring to reinvent systems to experiment with new way of doing things.

Despite the trends toward individualism and autonomy noted previously, IT professionals do have trends toward moderate needs for affection and expressed inclusion (FIRO-B), meaning that they are willing to involve others and to provide a sense of connection with others at a moderate rate.

These findings are generally consistent with earlier studies investigating MBTI types among computer professionals [Hildebrand, 1995; Westbrook, 1988; Lyons 1985], although we found a slightly higher representation of the ESTJ whole type than those studies, which showed a higher percentage of INTJs.

The preferences associated with some of these findings echo the legendary portrait of the secluded IT programmer, content to spend hours at the keyboard as long as the work is challenging and someone occasionally shoves pizza under the door. Likewise, the personality preference characteristics described previously appear less consistent with the new vision of the IT professional as facilitative consultant, working side by side with end users to articulate requirements and build systems. The learning point, however, revolves around the concept that if IT professionals understand their basic preferences, they can use this information to identify individual preferences on a team, potential blind spots (often associated with a nonpreference), and potential interaction dynamics with other team members and clients.

For example, the ISTJ programmer's personality type suggests preferences for organization, privacy, practicality, responsibility, objectivity, and individual attention to detail. Under no circumstances do these preferences preclude an ISTJ from effectively facilitating a JAD session or from working collaboratively with users during an evolutionary prototyping effort, even though these activities are more obviously associated with Extraversion or Feeling personality preferences. It does mean that an ISTJ programmer introduced to these roles for the first time may not prefer to engage in these activities and may have more difficulty in accessing the personality characteristics that best support such work. Well structured training can help bridge these gaps, to help IT professionals develop the interpersonal skills required to meet today's IT needs.

47.2.3.2 IT Team Dynamics

System development is becoming more and more a team sport. This requires that team members have not only a fundamental grasp of their own personality preferences, but also of the needs and preferences of other team members, managers, and end users. The same research that identified personality preferences among IT individuals [DAU, 2003] also reveals interesting human dynamics at the team level.

Team dynamics. As noted previously, a recent study revealed that almost half of IT team members can be characterized as "lone gun" professionals, preferring to contribute through individual efforts with a strong focus on independence and self-sufficiency. For the study, these preferences were also assessed at the team level using a social climate instrument called the *work environment scales* (WES) [Moos, 1994]. The WES measures group-level dynamics across 10 scales and gathers data related to what team members believe the work place is like vs. their perception of the ideal work place. The preferences toward individuality were (not surprisingly) echoed in this team-level assessment, with teams reporting higher desired levels of autonomy, self-sufficiency, and task focus than currently experienced.

Despite this desire, however, these teams also reported desiring a significantly higher level of peer cohesion than currently experienced. Results also revealed that although team members generally desire little control exerted from management (consistent with the FIRO-B low wanted control scores), they desire a high level of supervisor support and want to know what is expected in their work.

Factors influencing IT success. Many studies have assessed the factors contributing to the success of IT projects [Standish Group, 2001]. Recent research [DAU, 2003] also assessed this factor, focusing on the level of the team (rather than the specific project). In this case, IT managers and team members were asked to describe the factors contributing to their success or their turmoil, depending on how they classified their teams. Managers and teams generally agreed on the three most important factors, regardless of whether the team was successful or in turmoil. These included delivers (or does not deliver) products on time, delivers (or does not deliver) high-quality products, and works together effectively (or does not). Although each team may have a different perception of what working together effectively requires, the finding echoes the theme that collaboration at the team level is a valued contributor to success.

Team dynamics: applications. Here is an example of how personality indicators such as the MBTI and FIRO-B can be used with a development team. The authors recently worked with a development team led by an ESTJ manager with high inclusion and affection needs on the FIRO-B. These results were consistent with her frank, direct, outgoing nature; evidence of frequent interaction with both the client and the team; and frequent feedback sessions about project status and metrics. The manager was frustrated because she sensed resistance to her requests for feedback from team members, and the team expressed little interest in engaging socially with her or with each other. The technical work generated by the team was excellent, but there appeared to be little interest in whether it met the client's aesthetic preferences.

Completing the MBTI and FIRO-B in a half-day workshop revealed that 80% of the manager's team were Introverted Thinkers with collectively low FIRO-B scores. They, too, were frustrated, because there were too many meetings, the client continually changed his mind about screen layout and colors, and the manager seemed too focused on group sharing.

Sharing and discussing MBTI and FIRO-B scores gave this manager and team a neutral vocabulary for discussing frustrations. Seeing the differences between the manager and the team helped the group to identify specific sources of conflict and to discuss them in a nonconfrontational way. Ultimately, the team established new ground rules related to communication pathways and frequency, designed to meet both managerial and team needs.

Once the team had moved past these basic communication issues, they were also better able to predict the personality preferences of the client. This led to clearer ground rules related to requirements management and review procedures. Although one four-hour workshop cannot heal the wounds of an IT team in turmoil, it is a useful starting point for more effective self-management, and it can open the door for more constructive discussion about the people issues that the IT personality tends to avoid.

47.2.3.3 IT Meets the User

No developer sets out to design or develop a substandard system that will not meet his or her users' needs. Moreover, no user purposefully sets out to confuse or muddy the requirements that he or she is trying to articulate. Effective communication and a positive, trusting working environment between IT professionals and their end users is vital to ensure a successful outcome, but both sides are often ill equipped to create such an environment. The creation of this environment is becoming increasingly important as the evolution of COTS integration and the sophistication of end users continue to develop.

The results of our IT study [DAU, 2003] demonstrate that there are significant differences between IT professionals and the general population. By understanding these differences and by formulating strategies that can help turn these differences into strengths, we can help to establish best practices to ensure team success and better systems. Here is an overview of some key human dynamics facing the development team when working with an end user:

User requirements — One of the key challenges in today's development environment is balancing the elicitation of often uncertain and changing user requirements against the minimization of development risk to result in a final product. Although many tools are available to assist IT developers with the documentation and management of requirements, little focus has been spent on the specific conversations and communication tools and approaches developers can take during interviews and sessions with the end users.

User as contributor — A second challenge in working with users is understanding their current perceptions with respect to information technology, and any assumptions they have about the development process. If the user has preferences for specific COTS products or unspoken concerns about specific possible outcomes, the developer must understand these at the outset. For example, sophisticated users may understand the need for a large-scale relational database with a COTS reporting module to fulfill requirements, but they may fear the loss of personal power that the hands-on control over the resident data currently provides. Understanding the personal history that a user brings to the process may sound trivial; however, given the significant impacts that these issues may have as work proceeds, it is important that the developer be sensitive toward them. Training in effective communication skills and coaching techniques is a first step toward developing this awareness among technical professionals.

Process problems vs. system needs — An IT development project is usually initiated to help resolve a business problem or to improve or streamline an existing business process. Even with the sophistication of today's technology, IT is not a panacea for business process woes or organizational turf battles. IT developers in today's business environment need the capability to recognize the difference between process, organizational, and technical problems, so that process mapping and reengineering efforts can be introduced if necessary. Some organizations address process issues by introducing a new system to manage roles and responsibilities, process, and interactions

between players. Recognizing the connection between existing or desired business processes and the articulated requirements requires personal insight on the part of the IT analyst and should be included in the analyst's training and development as a professional.

Service focus — Today's relationship between end user and IT team is often long term and consultative in nature. Databases require long-term administrative support; Web sites require maintenance; technology changes lead to application upgrades; and changing business needs require future iterative development. This reality means that IT professionals must be able to build lasting relationships with their clients — clients who are more likely to desire and need that interpersonal connection than the typical IT professional.

47.3 Best Practices

Myriad best practices are available to the IT professional and manager. Most of these practices are either technical or process in nature, focusing on the technical and/or management skills and tasks required to successfully navigate through a system development effort. This section presents a new perspective on the area of best practices, focusing purely on the human level of the IT individual and team. These best practices are personal in nature and result from our experience and belief that the success of an IT development effort depends heavily on the daily conversations between people — from the day the project need is identified to the day the first user accesses the completed system.

47.3.1 IT Developers

Self-understanding and management benefits technical work. Many IT professionals tend to avoid training that focuses on the development of interpersonal and communication skills, believing that such investment of time and resources is not as beneficial as learning a new technical skill. At the same time, it is hard to find a technical specialist who has not experienced conflict with team members, misunderstandings with the boss, or confusion with end users or clients. Many of these interpersonal issues can be traced to a fundamental style or communication mismatch, rather than a technical deficiency. IT professionals who recognize these root causes are better prepared to manage problems effectively, leading to better technical work. Understanding what one brings to the team from a human dynamics standpoint, and how that might mesh or clash with coworkers, is a key starting point.

Imagine the following scenario, using the MBTI principles described in [Section 47.2.3](#). You are an Introverted Judging developer in a prototype review session with an Extraverted Perceiving client. Recall, this means that you prefer introversion and judging, and you may generally prefer to spend your time in your inner world of ideas and concepts. When you do engage with the outer world, you prefer it to be in a structured way, aiming for brevity, closure, and the regulation of events. Because you prefer to communicate final thoughts in a decision-based format, you expect that others generally operate this way, as well. Conversely, your Extraverted Perceiving client may view such interaction periods as open brainstorming sessions, designed to explore new ideas, cover the possibilities, and think out loud. Comments from this client may be alternatives for consideration or triggers for more thought (at least in the client's eyes), although you generally hear them as decisions. The result is that you leave with a long list of new requirements, and the client leaves thinking that some interesting new possibilities have been discussed, no strings attached.

This scenario, which is neither exaggerated nor uncommon, brings a fresh perspective to the enduring problem of requirements creep, noted as a key issue facing the IT community. Requirements creep is usually described as a problem at the system or project level; however, every need ever articulated for a system came from a human user expressing an individual thought. How that thought is heard and managed is ultimately what leads to the project-level problem of requirements creep. This is only one example: consider the other personality preferences and interpersonal needs, and the complexity and potential impact of human dynamics in the development process becomes even more dramatic.

What is the best practice for developers? Invest the time and effort to learn about your own personality preferences, and learn how to recognize them in others. In our experience, IT professionals with this knowledge reported better client management skills and less frustration, because having a language with which to talk about differences makes them easier to resolve. This conclusion is also supported by evidence from a study of 40 software development teams, which concluded “how people work together is a stronger predictor of performance than the individual skills and abilities of team members” [Sawyer, 2001].

Take accountability for requirements elicitation. A common complaint in failing IT development efforts takes the form of the developer’s lament: “Customers just do not know what they want.” This comment, made acceptable in IT literature, is fundamentally unhelpful, because it assigns blame to the customer, fails to capture the real problem, and broadens the divide between the end user and the developer.

Usually, in fact, customers do know what they want, or they would not have called the IT developers in the first place. Each customer has a problem, and what is needed is a solution to that problem. The burden is on the developer to help the user express that problem in the form of a functional requirement or specification. This fundamental shift in accountability is both frightening and empowering: frightening because it forces IT professionals to come down from a high perch and interact with clients in their functional domain, and empowering because the potential for success is greatly enhanced.

Shifting the problem from a lack of user knowledge to a lack of developer understanding or communication makes that problem more manageable and solvable. The result is more effective dialogue between developer and customer. Deming said it best: “If you do not know how to ask the right question, you discover nothing.” The end user’s ability to articulate what is wanted depends heavily on the developer’s ability to elicit useful and meaningful information. If this is done properly, requirements that are more closely linked to the problem will result.

Two best practices evolve from this observation. First, developers should not let requirements management overtake requirements elicitation. They should learn the arts of active listening, reflective dialogue, and coaching, and use these when working with end users. Second, when a project is in turmoil, developers should go back to the beginning and talk openly with clients about the core need or root cause of the problem. They should ask probing questions that get at the *why* driving the effort, or they should have the client complete a structured visioning exercise describing what success looks like. Done well, this raises the level of dialogue, moving back from the technical negotiations to the overarching mission, until common ground and understanding are once again established.

Consider personality preferences in interface design. Just as personality preferences influence discussions between IT developer and users, they also influence the end user’s experience with the final product. Consider the *Contact Us* page from the Web site of the Internal Revenue Service (IRS) in light of the personality preferences for data gathering and decision making described previously (see Figure 47.1). This page and its contents are designed to appeal to a variety of user preferences and styles. Here are some examples:

The site allows users to search for information in three different ways: by drilling down through subject menus, by selecting target audience category, or by searching on specific key words. This approach covers a variety of user and information-gathering preferences.

The language of the site includes objective information (a detailed sequential publication outlining methods for tracking one’s return) delivered with a personal touch. For example, one IRS menu item describes a connecting link with: “Get the lowdown on your refund now. Secure access anytime from anywhere. What a deal!” (www.irs.gov, 2003). For those struggling with taxes, this balanced presentation builds a connection with a variety of users, from the no-nonsense filer locating a document to the more subjective user appreciating the humor of the moment.

The specific page in Figure 47.1 offers users two options for interaction: on-line resources for those who prefer to receive help without human intervention, and Customer Assistance Centers for those who prefer the face-to-face approach. While this relates more to business process than design, it reflects the IRS’s accessibility through multiple channels.

FIGURE 47.1 Example of effective user interface design.

This example suggests that developers test products with a variety of users early in the development process and consider different preferences when designing the product. Usability means different things to different people — a broad perspective with respect to user perceptions will add to the perceived value of the end product. (For other topics related to user interface design, see [Chapter 45](#) and [Chapter 48](#).)

Consider implementation issues early. In the heat of requirements, design, programming, and testing, it is easy to underestimate the logistics and politics of implementation once the system has been tested and accepted by the user. What business process will the system replace? Will roles and responsibilities within the sponsoring organization shift as a result? How will this be managed? What training will be required? What unforeseen changes may result from system introduction? Are any stakeholder groups likely to resist system use or introduction?

IT professionals should look ahead to the end game while still within the development process, so that potential production risks can be identified and mitigated early. Resulting activities may include business process reengineering, training, and an increased emphasis on socializing the ultimate product and its goals within affected stakeholder groups, particularly if these have not been included in the requirements process. (For other topics related to organizational contexts of development and use, see [Chapter 45](#).)

Consider personal preferences when entering a project or role. Recognizing personality preferences and behavioral styles may help IT professionals select projects or roles that support personal values and areas of personal strength. Some people simply would rather work alone to generate a product that later can be joined with the efforts of others. Other people enjoy the shared nature of actively collaborative efforts. Some developers enjoy the iterative nature of evolutionary prototyping; others find the constant change and uncertainty more frustrating than freeing.

Developers should take the time to recognize their strengths, preferences, and potential blind spots when selecting jobs or projects. If a developer, for example, chafes against the requirements for structure and documentation that come with working on a CMM level 3 project, it is better to know this in advance. Self-knowledge is the key to making more effective decisions: decisions that will impact the individual, the development team, and ultimately the end user.

47.3.2 IT Managers

Early in this chapter, we highlighted an apparent conflict within IT teams: individual preferences for autonomy, coupled with the desire for improved effectiveness and cohesion at the team level. This leads to the key question: how can managers best support IT teams that clearly value effective team relationships, while also fulfilling strong needs related to objectivity, individual contribution, and independence?

Develop understanding of human dynamics within the team. Understanding the dynamics within the IT team and with the user empowers managerial leveraging of existing strengths and diversity, and the mitigation of weaknesses and blind spots. Whenever possible, analyze the client's dynamics and pinpoint risk or possible conflict areas early in the development life cycle. Insist on spending time on team dynamics as a necessary part of any development project. This includes training in people skills, such as communication and active listening, facilitation, coaching, and conflict management. This training allows IT professionals to develop their typically underused preferences, thereby expanding their flexibility with each other and with users. It is vital to note that the MBTI (and other assessments described here) are *not* predictors or indicators of success among computer programmers [Kerth et al., 1998] and should not be used to select people for participation on a project or team.

Welcome generalists and geeks. In today's development environment, a diverse team of functional specialists, analysts, programmers, architects, and administrators may be required to support multiple projects. In addition to a strong technical skills mix, a mix of communication, political, and interpersonal skills can also balance the strengths and weakness of a team.

IT managers should look for both technical and nontechnical gifts in each team member and utilize them in different project roles. It is tempting to hire those with the sharpest technical training and who share similar characteristics with other team members. Resist this urge by striving for balance, diversity — and even a bit of eccentricity. Klein et al. [2002] suggest that there are three unique perspectives that can support the development of an IT team: technical (project focused), end user (user focused), and sociopolitical (organizational system focused). Encouraging all three can mitigate risk and positively impact overall project success.

Understand dynamics of control and clarity. Faced with the complexity of a large development effort, many managers naturally respond by implementing control mechanisms to manage the process. In fact, most of the improvement models described in the previous section are designed for the goal of controlling process, so that it can be tracked, documented, and managed. This regulation comes at a cost. Most IT professionals report a low desire for wanted control on the FIRO-B (i.e., they dislike having others exert power and structure over them) and want more personal autonomy (i.e., individual decision making and self-sufficiency) than currently experienced. Furthermore, teams with control needs incompatible with the manager's (e.g., manager has high expressed control needs over a team with low wanted control needs) are more likely to report themselves as in turmoil. Conversely, IT professionals report wanting a significantly higher level of clarity in their work than currently experienced. This means that they want to know what to expect, and they want policies to be more explicitly communicated than they currently are.

Many managers have a difficult time separating the concepts of structure and policy from the concept of control, because there is a fine line between telling someone *what* needs to be done in an informative way and telling somehow *how* it shall be accomplished in a directive way. The first provides data to the team, whereas the second provides a decision. The distinction is not always obvious, particularly when the manager has a personality preference for Judging, which means that he or she naturally typically expresses both data and decisions in a closed-ended way. Judges, as they are called, often sound like they are giving decisions and direction, when they may just be offering an opinion or impression. In this case, clarity may sound like control, even if the message is unintentional.

IT managers should consider the balance between *delineating* the road forward, describing all of its roadblocks and speed traps, and *directing* the team on how to drive in order to avoid them. For most managers, this requires a commitment to self-exploration and management, as well as requests from team members for frequent feedback on this issue.

Encourage healthy tension between the temperaments. Section 47.2.3.1 described the two most prevalent temperaments (i.e., behavioral preferences) among IT professionals: the Intuitive Thinking (NT) and Sensing Judging (SJ) temperaments, comprising 75% of the IT professionals surveyed. Tension between SJ and NT constituencies is common in organizations. Groups valuing the SJ approach may value established, “tried and true” policies and procedures, proven standards, chain of command accountability, and respect for organizational history and tradition. These groups may see the NTs as disrespectful of tradition, irreverent, and simply trying to stir up the pot by constantly reinventing the wheel. Groups valuing the NT approach may value systems that reward future-focused, innovative thinking and loose structure with minimal formal procedures and policies. These groups may see the SJs as the “ball and chain” traditionalists, who stifle creativity by their inability to think outside the box [Kroeger et al., 2002].

The temperament in power may drive which of these two approaches is more valued in the organization or team. At the IT team level, a manager who understands temperament and its impacts can apply both to the project’s advantage. For example, SJs on the team may excel as administrators of systems requiring precision and organization, and prefer to focus on the specifics required for the work to be done today. On the other hand, NTs offer the challenge of questioning the established ways of doing things, with driving insights into the underlying principles of systems. Leveraging both should result in a better system overall, as different perspectives are considered during the process.

Engage users in the development process. A recurring theme in this chapter has been the need to work more effectively with users in the system development process. This discussion has focused on the level of the individual conversation, but it is also useful to review some of the structured methods by which this developer–user interaction can be encouraged [Maguire, 2001]:

User requirements interviews — Elicit individual views from a variety of users

Focus groups — Bring together stakeholder groups to discuss requirements

Task and process mapping — Defines the “as is” and “to be” states associated with envisioned system

Scenario visioning exercises — Help users to articulate what success looks like, leading to more definitive requirements and use cases

With effective planning and outreach, the IT manager can exert significant influence over the level of user involvement in system development efforts. Managers should consider introducing the methods described here as part of the work breakdown structure for development projects.

47.3.3 IT Educators

So far, this chapter has been primarily directed toward practicing IT professionals and managers, rather than the educators who prepare them for their profession. Here, we introduce suggestions for ways in which educators may introduce human dynamics into a range of educational programs, regardless of whether those programs are targeted toward computer science, systems engineering, or IT management.

Incorporate human uncertainty into assignments. Many educators use simulated exercises to allow programmers to practice programming skills. One common approach is to provide a team with an electronic kit containing both physical moving parts and a computer interface. The students are provided with specifications and must use their skills to program the robot to complete specific tasks.

We use a similar approach to investigate how IT teams approach ambiguous requirements [DAU, 2003]. We provide teams with a Lego Mindstorm Robot Kit and the following specifications: “Construct a robot that moves around a circle within 30 seconds, reverses, and moves around the circle in the opposite direction, also within 30 seconds. Creativity and elegance of design count.” We purposely limit the time period allowed, so that a programmed automated solution is not possible. Instead, to be successful, the team must explore the terms *robot* and *moves around*. If the team agrees that the robot could be nonautomated (since we did not give them a better definition) and manually moves any object around the circle and back, they generally consider themselves successful. If they assume the term *robot* means *automated*, they generally make little headway. Usually, this exercise leads to interesting learning by the team with respect to the assumptions being made in the requirements process.

Introducing this type of requirements uncertainty at the beginning of an educational exercise offers the chance to explore this human dynamic of the development process. Educators should look for opportunities in the classroom to discuss IT professional–user interaction and to develop critical thinking skills in the face of ambiguity.

Encourage a broad curriculum. Students only have a short time to learn the skills required for success in today’s IT environment. Furthermore, when a student leaves the educational setting, he or she may find a niche in programming, engineering, or management. As practitioners, we encourage educators to consider the following in planning a broad curriculum, focused on critical thinking and analysis:

Human and team dynamics — include as part of a well rounded software or computer engineering curriculum. Helping students to develop the habits of self-awareness and introspection will serve them well in any professional setting.

Functional areas outside the computer science and engineering disciplines — encourage students to explore. Students with an introduction to other subject areas may have more empathy for the challenges facing their end users. This also exposes them to different ways to approach the world.

Teach students to write — as practitioners, we have seen too many gifted programmers with underdeveloped writing skills. It is likely that students will eventually be required to write a strategic plan, document a technical architecture, write a requirements document, or write a critical analysis or product evaluation. Their education should include analytical writing skills. Again, this is a talent that will serve them well in any setting.

Balance theory and practice. Personality type theorists argue that the data-gathering function (assessed by the Sensing–Intuition scale of the MBTI) is the most important in determining how people learn. Intuitives tend to learn best when given a theoretical framework within which to place new information. Sensors, conversely, often learn best when presented with practical applications or when they are able to interact with tools that allow practice and interaction with the new knowledge. This difference is particularly important in higher education, where it is estimated that 70% of all professors are Intuitive. On the other hand, the general population is only 30% Intuitive, with 70% Sensors. The result is an overrepresentation of Intuitive professors at the college level, teaching theory to classrooms filled predominantly with Sensors. Given this imbalance, educators should attempt to balance the emphasis between theory and practice in the classroom [Kroeger and Thuesen, 1988].

Continue research on the human dynamics of the IT profession. Research helps to support the work of practitioners by providing insight into the industry and its process. Given the subject of this chapter, we encourage more cross-disciplinary research to bridge the existing gaps between computer science and the social sciences. We also encourage educators to engage in collaborative research efforts with industry, to help unite today’s curriculum with the industry challenges of tomorrow.

47.4 Research Issues and Summary

As practitioners, we approach the question of research direction from an applied viewpoint, searching for answers that will help us be better IT managers and professionals. Here, we suggest areas for consideration developed not only from our experience, but based on our applied research with IT teams:

We are intrigued by the finding that IT team members have a closer agreement about how the work setting or social climate *could be* than about what it actually is. Our research shows us that *not only* do IT professionals desire a greater degree of peer cohesion, task involvement, clarity, and physical comfort, but they also have more shared agreement as to what the ideal should look like than the reality currently experienced. If we can investigate these ideal views and the gaps that lie between here and there, we should be able to introduce improvements that will help to keep IT professionals working happily within their organizations, instead of moving on to perceived greener pastures. We selected proven psychological instruments (e.g., MBTI, FIRO-B, WES), popular and well documented in many other professional settings, for our research with IT teams. These instruments allow us to paint a broad portrait of IT teams. However, other areas were

not addressed and deserve investigation. IT organizations can be quirky places, with casual dress as the rule, foosball tables in the break room, and 4:00 A.M. working sessions the norm. What impacts do these nontraditional workplace practices have on the team's success and productivity? There may be ways to capture these dynamics, and they may have direct influences on stress, creativity, and innovation. One promising tool in working with this population is the Apter motivational style profile (AMSP), based on *reversal theory*, a broad theory of personality, emotion, and motivation that emphasizes changeability and inconsistency of behavior [Apter, 2001]. Focused on four pairs of opposing motivational states, the AMSP helps explain, for example, why individuals who have been focused and "in the groove" of intense productivity suddenly need to shift into periods of playtime (this is the foosball effect). These issues of motivation, and the associated emotion, are areas ripe for research in the IT environment.

More empirical research is required to solidify the connection between effective human dynamics, communication, and conflict management and team/project success. DeMarco and Lister [1999], in particular, note success stories of the "jelled team." We believe that effective teams deliver results that exceed the traditional measures of time, quality, and cost; however, a broad range of evidence is currently lacking within the IT community. Future research should include benchmarking to assess before and after profiles of team and project success when human dynamics and communication training are actively introduced within the organization.

The fields of organizational development and information technology remain worlds far apart. There is a broad array of tools and training available from the organizational development community, but the translation of these into the IT setting can be difficult. If forced to attend "touchy-feely" training at all, IT professionals want it to be applicable to the work they do and the problems they face. As such, we recommend research into ways that IT-oriented applications and lessons learned can be integrated within the typically more generic programs currently offered by the organizational development and training communities, ones that provide objective evidence of the positive impacts such work will have on team effectiveness.

The IT landscape has shifted over the past decade. Today, IT professionals face faster development times, a broad range of skill requirements and development models, an increased emphasis on teams, and an increasingly IT-knowledgeable user base. These shifts signal the need for a new set of skills and tools for IT professionals themselves — skills that are less technical and more interpersonal in nature. In this chapter, we have described the fundamental paradigm shifts in human dynamics at work in the IT industry, suggested possible best practices for addressing them, and proposed areas for future work.

Every human endeavor involving more than one person is initiated with a single conversation between individuals. System development is no different. The tools and knowledge to build better conversations are available; they must be used by the next generation of IT professionals in order to improve the systems and applications they develop in the future.

Acknowledgment

The research for this chapter was assisted by contributions and support from Patrick Peck and Phyllis Griggs at Booz Allen Hamilton; Hile Rutledge at Otto Kroeger Associates (OKA); Dr. Philippe Gwet; and researchers at the Institute for Scientific Research (ISR): Rebecca Giorcelli, David Harris, Amy Jacquez, Anita Meinig, Robert Morgan, and Anthony Yancey. The authors are grateful for their contributions. We also extend special thanks to Congressman Alan B. Mollohan for his vision and support.

48.1 Introduction*

Almost as long as there have been user interfaces, there have been special software systems and tools to help design and implement the user interface software. Many of these tools have demonstrated significant productivity gains for programmers and have become important commercial products. Others have proved less successful at supporting the kinds of user interfaces people want to build. Virtually all applications today are built using some form of **user interface tool** [Myers 2000].

User interface (UI) software is often large, complex, and difficult to implement, debug, and modify. As interfaces become easier to use, they become harder to create [Myers 1994]. Today, direct-manipulation interfaces (also called GUIs for **graphical user interfaces**) are almost universal. These interfaces require that the programmer deal with elaborate graphics, multiple ways of giving the same command, multiple asynchronous input devices (usually a keyboard and a pointing device such as a mouse), a mode-free interface where the user can give any command at virtually any time, and rapid “semantic feedback” where determining the appropriate response to user actions requires specialized information about the objects in the program. Interfaces on handheld devices, such as a Palm organizer or a Microsoft PocketPC device, use similar metaphors and implementation strategies. Tomorrow’s user interfaces will provide speech

*This chapter is revised from an earlier version: Brad A. Myers. 1995. “User Interface Software Tools,” *ACM Transactions on Computer–Human Interaction*. 2(1): 64–103.

recognition, vision from cameras, 3-D, intelligent agents, and integrated multimedia, and will probably be even more difficult to create. Furthermore, because user interface design is so difficult, the only reliable way to get good interfaces is to iteratively redesign (and therefore reimplement) the interfaces after user testing, which makes the implementation task even harder.

Fortunately, there has been significant progress in software tools to help with creating user interfaces. Today, virtually all user interface software is created using tools that make the implementation easier. For example, the MacApp system from Apple, one of the first GUI frameworks, was reported to reduce development time by a factor of four or five [Wilson 1990]. A study commissioned by NeXT claimed that the average application programmed using the NeXTStep environment wrote 83% fewer lines of code and took one-half the time, compared to applications written using less advanced tools, and some applications were completed in one-tenth the time. Over three million programmers use Microsoft's Visual Basic tool because it allows them to create GUIs for Windows significantly more quickly.

This chapter surveys UI software tools and explains the different types and classifications. However, it is now impossible to discuss all UI tools, because there are so many, and new research tools are reported every year at conferences such as the annual ACM User Interface Software and Technology Symposium (UIST) (see <http://www.acm.org/uist/>) and the ACM SIGCHI conference (see <http://www.acm.org/sigchi/>). There are also about three Ph.D. theses on UI tools every year. This article provides an overview of the most popular approaches, rather than an exhaustive survey. It has been updated from previous versions (e.g., [Myers 1995]).

48.2 Importance of User Interface Tools

There are many advantages to using user interface software tools. These can be classified into two main groups. First, the *quality* of the resulting user interfaces might be higher, for the following reasons:

- Designs can be rapidly prototyped and implemented, possibly even before the application code is written. This, in turn, enables more rapid prototyping and therefore more iterations of iterative design, which is a crucial component of achieving high-quality user interfaces [Nielsen 1993b].

- The reliability of the user interface will be higher, because the code for the user interface is created automatically from a higher-level specification.

- Different applications are more likely to have consistent user interfaces if they are created using the same UI tool.

- It will be easier for a variety of specialists to be involved in designing the user interface, rather than having the user interface created entirely by programmers. Graphic artists, cognitive psychologists, and usability specialists may all be involved. In particular, professional user interface designers, who may not be programmers, can be in charge of the overall design.

- More effort can be expended on the tool than may be practical on any single user interface, because the tool will be used with many different applications.

- Undo, Help, and other features are more likely to be available because the tools might support them.

Second, the UI code might be *easier and more economical* to create and maintain. This is because of the following:

- Interface specifications can be represented, validated, and evaluated more easily.

- There will be less code to write, because much is supplied by the tools.

- There will be better modularization, due to the separation of the UI component from the application.

 - This should allow the user interface to change without affecting the application, and a large class of changes to the application (such as changing the internal algorithms) should be possible without affecting the user interface.

- The level of programming expertise of the interface designers and implementers can be lower, because the tools hide much of the complexity of the underlying system.

- It will be easier to port an application to different hardware and software environments because the device dependencies are isolated in the UI tool.

FIGURE 48.1 The components of user interface software.

48.2.1 Overview of User Interface Software Tools

Because user interface software is so difficult to create, it is not surprising that people have been working for a long time to create tools to help with it. Today, many of these tools and ideas have progressed from research into commercial systems, and their effectiveness has been amply demonstrated. Research systems also continue to evolve quickly, and the models that were popular five years ago have been made obsolete by more effective tools, changes in the computer market, and the emergence of new styles of user interfaces, such as handheld computing and multimedia.

48.2.1.1 Components of User Interface Software

As shown in Figure 48.1, UI software may be divided into various layers: the **windowing system**, the **toolkit**, and higher-level tools. Of course, many practical systems span multiple layers.

The windowing system supports the separation of the screen into different (usually rectangular) regions, called **windows**. The X system [Scheifler 1986] divides window functionality into two layers: the window system, which is the functional or programming interface, and the **window manager**, which is the user interface. Thus, the window system provides procedures that allow the application to draw pictures on the screen and get input from the user; the window manager allows the end user to move windows around and is responsible for displaying the title lines, borders, and **icons** around the windows. However, many people and systems use the name “window manager” to refer to both layers, because systems such as the Macintosh and Microsoft Windows do not separate them. This article will use the X terminology, and use the term *windowing system* to refer to both layers.

Note that Microsoft confusingly calls its entire system *Windows* (for example, *Windows 98* or *Windows XP*). This includes many different functions that here are differentiated into the operating system part (which supports memory management, file access, networking, etc.), the windowing system, and higher-level tools.

On top of the windowing system is the toolkit, which contains many commonly used **widgets** (also called *controls*) such as menus, buttons, scroll bars, and text input fields. On top of the toolkit might be higher-level tools, which help the designer to use the toolkit widgets. The following sections discuss each of these components in more detail.

48.2.1.2 Windowing Systems

A windowing system is a software package that helps the user monitor and control different contexts by separating them physically onto different parts of one or more display screens [Myers 1988b]. Although most of today’s systems provide toolkits on top of the windowing systems, as will be explained later, toolkits generally only address the drawing of widgets such as buttons, menus, and scroll bars. Thus, when the programmer wants to draw application-specific parts of the interface and allow the user to manipulate these, the window system interface must be used directly. Therefore, the windowing system’s programming interface has significant impact on most user interface programmers.

The first windowing systems were implemented as part of a single program or system. For example, the EMACs text editor [Stallman 1979], Smalltalk [Tesler 1981], and DLISP [Teitelman 1979] programming environments had their own windowing systems. Later systems implemented the windowing system as an

FIGURE 48.2 The windowing system can be divided into two layers, called the base (or window system) layer and the user interface (or window manager) layer. Each of these can be divided into parts that handle output and input.

integral part of the operating system, such as Sapphire for PERQs [Myers 1984], SunView for Suns, and the Macintosh and Microsoft Windows systems. In order to allow different windowing systems to operate on the same operating system, some windowing systems, such as X and Sun's NeWS [Gosling 1986], operate as a separate process and use the operating system's interprocess communication mechanism to connect to application programs.

48.2.1.2.1 Structure of Windowing Systems

A windowing system can be logically divided into two layers, each of which has two parts (see Figure 48.2). The window system, or base layer, implements the basic functionality of the windowing system. The two parts of this layer handle the display of graphics in windows (the output model) and the access to the various input devices (the input model), which usually includes a keyboard and a pointing device such as a mouse. The primary interface of the base layer is procedural and is called the windowing system's application programmer interface (API).

The other layer of windowing system is the window manager or user interface. This includes all aspects that are visible to the user. The two parts of the user interface layer are the presentation, which comprises the pictures that the window manager displays, and the commands, which are how the user manipulates the windows and their contents.

48.2.1.2.2 Base Layer

The base layer is the procedural interface to the windowing system. In the 1970s and early 1980s, there were a large number of different windowing systems, each with a different procedural interface (at least one for each hardware platform). People writing software found this to be unacceptable because they wanted to be able to run their software on different platforms, but they would have to rewrite significant amounts of code to convert from one window system to another. The X windowing system [Scheifler 1986] was created to solve this problem by providing a hardware-independent interface to windowing. X has been quite successful at this, and it drove all other windowing systems out of the workstation hardware market. X continues to be popular as the windowing system for Linux and all other UNIX implementations. In the rest of the computer market, most machines use some version of Microsoft Windows, with the Apple Macintosh computers having their own windowing system.

48.2.1.2.3 Output Model

The output model is the set of procedures that an application can use to draw pictures on the screen. It is important that all output be directed through the window system so that the graphics primitives can be clipped to the window's borders. For example, if a program draws a line that would extend beyond a window's borders, it must be clipped so that the contents of other, independent, windows are not overwritten. Most computers provide graphics hardware that is optimized to work efficiently with the window system.

In early windowing systems, such as Smalltalk [Tesler 1981] and Sapphire [Myers 1986], the primary output operation was BitBlt (also called RasterOp, and now sometimes CopyArea or CopyRectangle). These early systems primarily supported monochrome screens (each pixel is either black or white). BitBlt takes

a rectangle of pixels from one part of the screen and copies it to another part. Various Boolean operations can be specified for combining the pixel values of the source and destination rectangles. For example, the source rectangle can simply replace the destination, or it might be XORed with the destination. BitBlt can be used to draw solid rectangles in either black or white, display text, scroll windows, and perform many other effects [Tesler 1981]. The only additional drawing operation typically supported by these early systems was drawing straight lines.

Later windowing systems, such as the Macintosh and X, added a full set of drawing operations, such as filled and unfilled polygons, text, lines, arcs, etc. These cannot be implemented using the BitBlt operator. With the growing popularity of color screens and nonrectangular primitives (such as rounded rectangles), the use of BitBlt has significantly decreased. Now, it is primarily used for scrolling and copying off-screen pictures onto the screen (e.g., to implement double-buffering).

A few windowing systems allowed the full PostScript imaging model [Adobe Systems Inc. 1985] to be used to create images on the screen. PostScript provides device-independent coordinate systems and arbitrary rotations and scaling for all objects, including text. Another advantage of using PostScript for the screen is that the same language can be used to print the windows on paper (because many printers accept PostScript). Sun created a version used in the NeWS windowing system, and then Adobe (the creator of PostScript) came out with an official version called Display PostScript, which was used in the NeXT windowing system. A similar imaging model is provided by Java 2-D [Sun Microsystems 2002], which works on top of (and hides) the underlying windowing system's output model.

All of the standard output models only contain drawing operations for two-dimensional objects. Extensions to support 3-D objects include PEX, OpenGL, and Direct3-D. PEX [Gaskins 1992] is an extension to the X windowing system that incorporates much of the PHIGS graphics standard. OpenGL [Silicon Graphics Inc. 1993] is based on the GL programming interface that has been used for many years on Silicon Graphics machines. OpenGL provides some machine independence for 3-D because it is available for various X and Windows platforms. Microsoft supplies its own 3-D graphics model, called Direct3-D, as part of Windows.

As shown in Figure 48.3, the earlier windowing systems assumed that a graphics package would be implemented using the windowing system. See Figure 48.3a. For example, the CORE graphics package was implemented on top of the SunView windowing system. Next, systems such as the Macintosh, X, NeWS, NeXT, and Microsoft Windows implemented a sophisticated graphics system as part of the windowing system. See Figure 48.3b and Figure 48.3c. Now, with Java2-D and Java3-D, as well as Web-based graphics systems such as VRML for 3-D programming on the Web [Web3-D Consortium 1997], we are seeing a return to a model similar to the one shown in Figure 48.3a, with the graphics on top of the windowing system. See Figure 48.3-D.

48.2.1.2.4 Input Model

The early graphics standards, such as CORE and PHIGS, provided an input model that does not support the modern, direct-manipulation style of interfaces. In those standards, the programmer calls a routine to request the value of a virtual device, such as a locator (pointing device position), string (edited text string), choice (selection from a menu), or pick (selection of a graphical object). The program would then pause, waiting for the user to take action. This is clearly at odds with the direct-manipulation mode-free style, in which the user can decide whether to make a menu choice, select an object, or type something.

With the advent of modern windowing systems, a new model was provided: a stream of event records is sent to the window that is currently accepting input. The user can select which window is getting events using various commands, described subsequently. Each event record typically contains the type and value of the event (e.g., which key was pressed), the window to which the event was directed, a timestamp, and the *x* and *y* coordinates of the mouse. The windowing system queues keyboard events, mouse button events, and mouse movement events together (along with other special events), and programs must dequeue the events and process them. It is somewhat surprising that, although there has been substantial progress in the output model for windowing systems (from BitBlt to complex 2-D primitives to 3-D), input is still

FIGURE 48.3 Various organizations that have been used by windowing systems. Boxes with extra borders represent systems that can be replaced by users. Early systems (a) tightly coupled the window manager and the window system, and assumed that sophisticated graphics and toolkits would be built on top. The next step in designs (b) was to incorporate into the windowing system the graphics and toolkits, so that the window manager itself could have a more sophisticated look and feel, and so applications would be more consistent. Other systems (c) allow different window managers and different toolkits, while still embedding sophisticated graphics packages. Newer systems (d) hark back to the original design (a) and implement the graphics and toolkit on top of the window system.

handled in essentially the same way today as it was in the original windowing systems, even though there are some well-known, unsolved problems with this model:

There is no provision for special stop-output (Ctrl+S) or abort (Ctrl+C, command-dot) events, so these will be queued with the other input events.

The same event mechanism is used to pass special messages from the windowing system to the application. When a window gets larger or becomes uncovered, the application must usually be notified

so it can adjust or redraw the picture in the window. Most window systems communicate this by queuing special events into the event stream, which the program must then handle.

The application must always be willing to accept events in order to process aborts and redrawing requests. If not, then long operations cannot be aborted, and the screen may have blank areas while they are being processed.

The model is device-dependent, because the event record has fixed fields for the expected incoming events. If a 3-D pointing device or one with more than the standard number of buttons is used instead of a mouse, then the standard event mechanism cannot handle it.

Because the events are handled asynchronously, there are many race conditions that can cause programs to get out of synchronization with the window system. For example, in the X windowing system, if you press inside a window and release outside, under certain conditions the program will think that the mouse button is still depressed. Another example is that refresh requests from the windowing system specify a rectangle for the window that needs to be redrawn, but if the program is changing the contents of the window, the wrong area may be redrawn by the time the event is processed. This problem can occur when the window is scrolled.

Although these problems have been known for a long time, there has been little research on new input models (an exception is the Garnet Interactors model [Myers 1990b]).

48.2.1.2.5 Communication

In the X windowing system and NeWS, all communication between applications and the window system uses interprocess communication through a network protocol. This means that the application program can be on a different computer from its windows. In all other windowing systems, operations are implemented by directly calling the window manager procedures or through special traps into the operating system. The primary advantage of the X mechanism is that it makes it easier for a person to utilize multiple machines with all their windows appearing on a single machine. Another advantage is that it is easier to provide interfaces for different programming languages: for example, the C interface (called xlib) and the Lisp interface (called CLX) send the appropriate messages through the network protocol. The primary disadvantage is efficiency, because each window request will typically be encoded, passed to the transport layer, and then decoded, even when the computation and windows are on the same machine.

48.2.1.2.6 User Interface Layer

The user interface of the windowing system allows the user to control the windows. In X, the user can easily switch user interfaces, by killing one window manager and starting another. Some of the original window managers under X included uwm (with no title lines and borders), twm, mwm (the Motif window manager), and olwm (the OpenLook window manager). Newer choices include complete desktop environments that combine a window manager with a file browser and other GUI utilities (to better match the capabilities found in Windows and the Macintosh). Two popular desktop environments are KDE (K Desktop Environment — <http://www.kde.org>) with its window manager KWin, and Gnome (<http://www.gnome.org>), which provides a variety of window manager choices. X provides a standard protocol through which programs and the base layer communicate to the window manager, so that all programs continue to run without change when the window manager is switched. It is possible, for example, to run applications that use Motif widgets inside the windows controlled by the KWin window manager.

A discussion of the options for the user interfaces of window managers was previously published [Myers 1988b]. Also, the video *All the Widgets* [Myers 1990a] has a 30-minute segment showing many different forms of window manager user interfaces.

Some parts of the user interface of a windowing system, which is sometimes called its *look and feel*, can apparently be copyrighted and patented. Which parts is a highly complex issue, and the status changes with decisions in various court cases [Samuelson 1993].

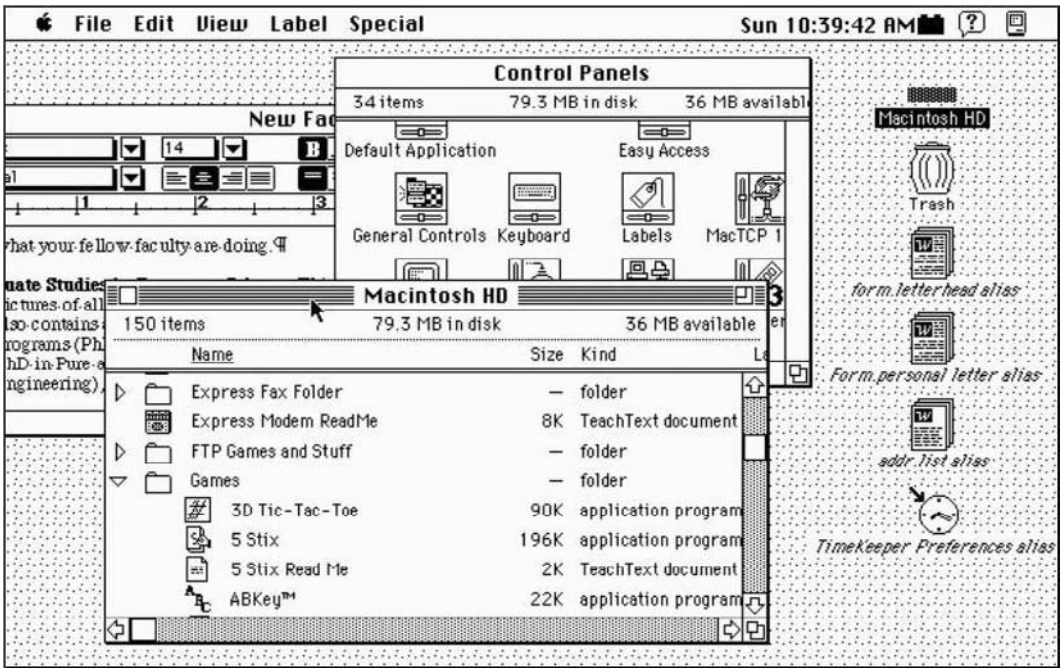

FIGURE 48.4 A screen from the original Macintosh showing three windows covering each other and some icons along the right margin.

48.2.1.2.7 Presentation

The presentation of the windows defines how the screen looks. One very important aspect of the presentation of windows is whether or not they can overlap. Overlapping windows, sometimes called covered windows, allow one window to be partially or totally on top of another window, as shown in Figure 48.4. This is also sometimes called the desktop metaphor, because windows can cover each other as pieces of paper can cover each other on a desk. There are usually other aspects to the desktop metaphor, however, such as presenting file operations in a way that mimics office operations, as originated in the Star office workstation [Smith 1982]. The alternative is tiled windows, which means that windows are not allowed to cover each other. Obviously, a window manager that supports covered windows can also allow them to be side by side, but not vice versa. Therefore, a window manager is classified as “covered” if it allows windows to overlap. The tiled style was popular for a while and was used by Cedar [Swinehart 1986] and by early versions of Star [Smith 1982], Andrew [Palay 1988], and even Microsoft Windows. A study even suggested that using tiled windows was more efficient for users [Bly 1986]. However, today tiled windows are rarely seen on conventional window systems, because users generally prefer overlapping.

Modern browsers for the World Wide Web, such as Netscape and Microsoft’s Internet Explorer, provide a windowing environment inside the computer’s main windowing system. Newer versions of browsers support frames containing multiple scrollable panes, which are a form of tiled window. In addition, if an application written in Java is downloaded (see Section 48.2.1.3.4), it can create multiple, overlapping windows like conventional GUI applications.

Another important aspect of the presentation of windows is the use of icons. These are small pictures that represent windows (or sometimes files). They are used because there would otherwise be too many windows to fit conveniently on the screen and to manage. Sapphire was the first window manager to group the icons into a window [Myers 1984], a format which was picked up by the Motif window manager. Now, the taskbar provides the icons and names of running and available processes in Windows and other modern window managers. Other aspects of the presentation include whether or not the window has a

title line, what the background (where there are no windows) looks like, and whether the title and borders have control areas for performing window operations.

48.2.1.2.8 *Commands*

Because computers typically have multiple windows and only one mouse and keyboard, there must be a way for the user to control which window is getting keyboard input. This window is called the input (or keyboard) focus. Another term is the listener, because it is listening to the user's typing. Some systems called the focus the active window or current window, but these are poor terms because, in a multiprocessing system, many windows can be actively outputting information at the same time. Window managers provide various ways to specify and show which window is the listener. The most important options are the following:

Click-to-type — This means that the user must click the mouse button in a window before typing to it. This is used by the Macintosh and Microsoft Windows.

Move-to-type — This means that the mouse only has to move over a window to allow typing to it. This is usually faster for the user, but it may cause input to go to the wrong window if the user accidentally knocks the mouse.

Some X window managers (including the Motif window manager, mwm) allow the user to choose the desired method. However, the choice can have significant impact on the user interface of applications. For example, because the Macintosh requires click-to-type, it can provide a single menu bar at the top, and the commands can always operate on the focused window. With move-to-type, the user might have to pass through various windows (thus giving them the focus) on the way to the top of the screen. Therefore, Motif applications must have a menubar in each window so the commands will know which window to operate on.

All covered window systems allow the user to bring a window to the top (not covered by other windows), and some allow sending a window to the bottom (covered by all other windows). Other commands allow windows to be changed in size, moved, shrunk to an icon, made full-size, and destroyed.

48.2.1.3 *Toolkits*

A toolkit is a library of widgets that can be called by application programs. As mentioned previously, a widget (also called a control) is a way of using a physical input device to input a certain type of value. Typically, widgets in toolkits include menus, buttons, scroll bars, text type-in fields, etc. [Figure 48.5](#) shows some examples of widgets. Creating an interface using a toolkit can only be done by programmers, because toolkits only have a procedural interface.

Using a toolkit has the advantage that the final UI will look and act similarly to other UIs created using the same toolkit, and each application does not have to rewrite the standard functions, such as menus. A problem with toolkits is that the styles of interaction are limited to those provided. For example, it is difficult to create a single slider that contains two indicators, which might be useful to input the upper and lower bounds of a range. In addition, the toolkits themselves are often expensive to create: "The primitives never seem complex in principle, but the programs that implement them are surprisingly intricate" [Cardelli 1985, p. 199]. Another problem with toolkits is that they are often difficult to use: they may contain hundreds of procedures, and it is often not clear how to use the procedures to create a desired interface.

As with the graphics package, the toolkit can be implemented either using or being used by the windowing system (see [Figure 48.3](#)). Early systems provided only minimal widgets (e.g., just a menu) and expected applications to provide others, as shown in [Figure 48.3a](#). In the Macintosh and in Microsoft Windows, the toolkit is at a low level, and the window manager user interface is built using it. The advantage of this is that the window manager can then use the same sophisticated toolkit routines for its user interface. See [Figure 48.3b](#). When the X system was being developed, the developers could not agree on a single toolkit, so they left the toolkit to be on top of the windowing system. In X, programmers can use a variety of toolkits (for example, the Motif, InterViews [Linton 1989], Amulet [Myers 1997], tcl/tk

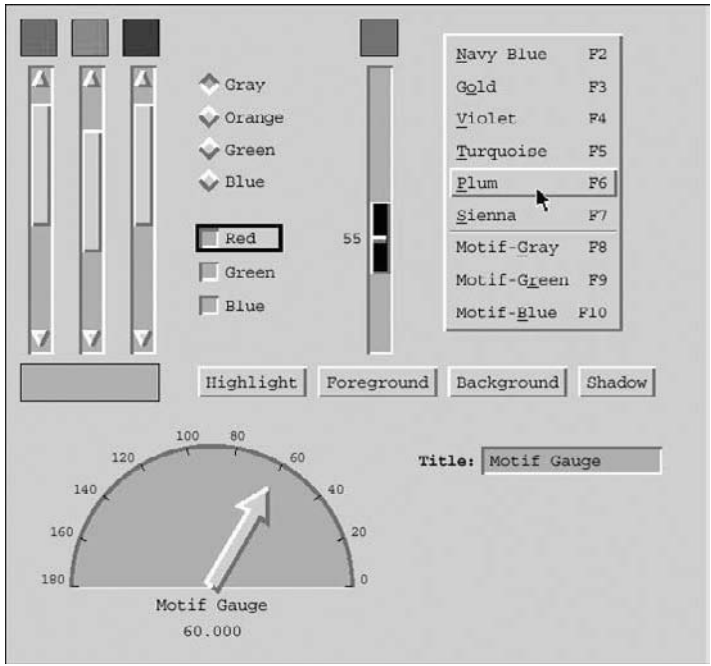

FIGURE 48.5 Some of the widgets with a Motif look and feel provided by the Garnet toolkit.

FIGURE 48.6 (a) At least three different widget sets that have different looks and feels were implemented on top of the Xt intrinsics. (b) The Motif look and feel has been implemented on many different intrinsics.

[Ousterhout 1991], and Gnome GTK+ [GNOME 2002] toolkits can be used on top of X), but the window manager must usually implement its user interface without using the toolkit, as in Figure 48.3c. The Java Swing toolkit is implemented on top of the Java 2-D graphics package, which in turn is on top of the windowing system. See Figure 48.3d.

Because the designers of X could not agree on a single look and feel, they created an **intrinsic** layer on which to build different widget sets, which they called Xt [McCormack 1988]. This layer provides the common services, such as techniques for object-oriented programming and layout control. The widget set layer is the collection of widgets implemented using the intrinsics. Multiple widget sets with different looks and feels can be implemented on top of the same intrinsic layer (Figure 48.6a), or else the same look and feel can be implemented on top of different intrinsics (Figure 48.6b).

48.2.1.3.1 Toolkit Intrinsic

Toolkits come in two basic varieties. The most conventional is simply a collection of procedures that can be called by application programs. Examples of this style include the SunTools toolkit for the SunView windowing system, and the original Macintosh Toolbox [Apple Computer Inc. 1985]. The second variety uses an object-oriented programming style that makes it easier for the designer to customize the interaction techniques. Examples include Smalltalk [Tesler 1981], Andrew [Palay 1988], InterViews [Linton 1989],

Xt [McCormack 1988], Amulet [Myers 1997], the Java Swing toolkit [Sun Microsystems 2003], and Gnome's GTK+ [GNOME 2002].

The advantages of using object-oriented intrinsics are that it is a natural way to think about widgets (the menus and buttons on the screen *seem* like objects), the widget objects can handle some of the chores that otherwise would be left to the programmer (such as refresh), and it is easier to create custom widgets (by subclassing an existing widget). The advantages of the older, procedural style are that it is easier to implement, no special object-oriented system is needed, and it is easier to interface to multiple programming languages.

To implement the objects, the toolkit might invent its own object system, as was done with Xt, Andrew, Amulet and GTK+, or it might use an existing object system, as was done in InterViews [Linton 1989], which uses C++; NeXTStep from NeXT, which uses Objective-C; and Swing, which uses Java.

The usual way that object-oriented toolkits interface with application programs is through the use of **call-back procedures**. These are procedures defined by the application programmer which are called when a widget is operated by the end user. For example, the programmer might supply a procedure to be called when the user selects a menu item. Experience has shown that real interfaces often contain hundreds of call-backs, which makes the code harder to modify and maintain [Myers 1992c]. In addition, different toolkits, even when implemented on the same intrinsics like Motif and OpenLook, have different call-back protocols. This means that code for one toolkit is difficult to port to a different toolkit. Therefore, research has been directed at reducing the number of call-backs in UI software [Myers 1991b].

Some research toolkits have added novel features to the toolkit intrinsics. For example, Garnet [Myers 1990d], Rendezvous [Hill 1994], Amulet [Myers 1997], and SubArctic [Hudson 1996] allow the objects to be connected using **constraints**, which are relationships that are declared once and then maintained automatically by the system. For example, the designer can specify that the color of a rectangle is constrained to be the value of a slider, and then the system will automatically update the color if the user moves the slider.

Many toolkits include a related capability for handling graphical layouts in a declarative manner. This is often called **geometry management**. Widgets can be specified to stay at the sides or the center of a container or to expand to fill up a specified space. This is particularly important when the size of objects might change, for example, in systems that can run on multiple architectures. An early example of this was in InterViews [Linton 1989], and layout managers are important parts of Motif and Java Swing.

48.2.1.3.2 *Widget Set*

Typically, the intrinsics layer is look and feel-independent, which means that the widgets built on top of it can have any desired appearance and behavior. However, a particular widget set must pick a look and feel. The video *All the Widgets* shows many examples of widgets that have been designed over the years [Myers 1990a]. For example, it shows 35 different kinds of menus. Like window manager UIs, the widgets' look and feel can be copyrighted and patented [Samuelson 1993].

As mentioned earlier, different widget sets (with different looks and feels) can be implemented on top of the same intrinsics. In addition, the same look and feel can be implemented on top of different intrinsics. For example, there are Motif look-and-feel widgets on top of the Xt, InterViews, and Amulet intrinsics. See [Figure 48.6b](#). Although they all look and operate the same (and so would be indistinguishable to the end user), they are implemented quite differently and have completely different procedural interfaces for the programmer.

48.2.1.3.3 *Specialized Toolkits*

A number of toolkits have been developed to support specific kinds of applications or specific classes of programmers. For example, the SUIT system [Pausch 1992] (which contains a toolkit and an **interface builder**) is specifically designed to be easy to learn and is aimed at classroom instruction. Its successor, Alice [Pausch 1995], provides an easy way to program 3-D graphics and animation. Amulet [Myers 1997] provides high-level support for graphical, direct-manipulation interfaces and handles input as hierarchical command objects, making Undo easier to implement [Myers 1996a]. Rendezvous [Hill 1994], Visual Obliq

[Bharat 1994], and GroupKit [Roseman 1996] are designed to make it easier to create applications that support multiple users on multiple machines operating synchronously. Whereas most toolkits provide only 2-D interaction techniques, the Brown 3-D toolkit [Stevens 1994] and Silicon Graphics' Inventor toolkit [Wernecke 1994] provide preprogrammed 3-D widgets and a framework for creating others. Special support for animations has been added to Artkit [Hudson 1993], Amulet [Myers 1996b], and Alice [Pausch 1995]. Tk [Ousterhout 1991] is a popular toolkit for the X window system (and also for Windows) because it can be attached to a variety of interpretive languages, including the original, called tcl, Perl, and Python, which makes it possible to change the user interface dynamically. Tcl supports the UNIX style of programming, in which many small programs are glued together.

48.2.1.3.4 Virtual Toolkits

Although there are many small differences among the various toolkits, much remains the same. For example, all have some type of menu, button, scroll bar, text input field, etc. Although there are fewer windowing systems and toolkits than there were ten years ago, people are still finding it a lot of work to port software so that it works on the Macintosh, Microsoft Windows, and X on Linux.

Therefore, a number of systems, called **virtual toolkits**, have been developed that try to hide the differences among the various toolkits, by providing virtual widgets that can be mapped into the widgets of each toolkit. Another name for these tools is cross-platform development systems. The programmer writes the code once, using the virtual toolkit, and the code will run without change on different platforms and still look like it was designed with that platform's widgets. For example, the virtual toolkit might provide a single menu routine, which always has the same programmer interface but connects to a Motif menu, a Macintosh menu, or a Windows menu, depending on which machine the application is run on.

There are two styles of virtual toolkits. In the first, the virtual toolkit links to the different actual toolkits on the host machine. For example, XVT [XVT Software Inc. 1997] provides a C or C++ interface that links to the actual Motif, Macintosh, MS-Windows, and OS/2-PM toolkits (and also character terminals) and hides their differences. The Java AWT toolkit also works in this way and uses the underlying widget sets. The second style of virtual toolkit reimplements the widgets in each style. For example, Galaxy [Visix Software Inc. 1997], Amulet [Myers 1997], and Java Swing provide libraries of widgets that look like those on the various platforms. The advantage of the first style is that the user interface is more likely to be look and feel conformant (since it uses the real widgets). The disadvantage is that the virtual toolkit must still provide an interface to the graphical drawing primitives on the platforms. Furthermore, virtual toolkits tend only to provide functions that appear in all toolkits. Many of the virtual toolkits that take the second approach, for example, Java Swing, provide a sophisticated graphics package and complete sets of widgets on all platforms. However, with the second approach, there must always be a large run-time library, because in addition to the built-in widgets that are native to the machine, there is the reimplementations of these same widgets in the virtual toolkit's library.

All of the toolkits that work on multiple platforms can be considered virtual toolkits of the second type. For example, SUIT [Pausch 1992] and Garnet [Myers 1990d] work on X, Macintosh, and Windows. However, these use the same look and feel on all platforms (and therefore do not look the same as the other applications on that platform), so they are not classified as virtual toolkits.

48.2.1.4 Higher-Level Tools

Because programming at the toolkit level is quite difficult, there is a tremendous interest in higher-level tools that will make the UI software production process easier. These are discussed next.

48.2.1.4.1 Phases

Many higher-level tools have components that operate at different times. The design-time component helps the UI designer to design the user interface. For example, this might be a graphical editor that can lay out the interface, or a compiler to process a UI specification language. The next phase is when the end user is using the program. Here, the run-time component of the tool is used. This usually includes a toolkit but may also include additional software specifically for the tool. Because the run-time component

is “managing” the user interface, the term **user interface management system** (UIMS) seems appropriate for tools with a significant run-time component.

There also may be an after-run-time component that helps with the evaluation and debugging of the user interface. Unfortunately, very few UI tools have an after-run-time component. This is partially because tools that have tried, such as MIKE [Olsen 1988], discovered that there are very few metrics that can be applied by computers. Some tools try to evaluate how people will interact with interfaces by automatically creating cognitive models from high-level descriptions of the user interface. For example, the GLEAN system generates quantitative predictions of a system’s performance from a GOMS model [Kieras 1995].

48.2.1.4.2 Specification Styles

High-level UI tools come in a large variety of forms. One important way in which they can be classified is by the designer’s specification of what the interface should be. Some tools require the programmer to program in a special-purpose language, some provide an **application framework** to guide the programming, some automatically generate the interface from a high-level model or specification, and others allow the interface to be designed interactively. Each of these types is discussed in the following sections. Of course, some tools use different techniques for specifying different parts of the user interface. These are classified by their predominant or most interesting feature.

48.2.1.4.3 Language-Based

With most of the older UI tools, the designer specifies the user interface in a special-purpose language. This language can take many forms, including context-free grammars, state transition diagrams, declarative languages, event languages, etc. The language is usually used to specify the syntax of the user interface, that is, the legal sequences of input and output actions. This is sometimes called the dialogue. Green [1986] provides an extensive comparison of grammars, state transition diagrams, and event languages, and Olsen [1992] surveys various older UIMS techniques.

48.2.1.4.3.1 State Transition Networks

Because many parts of user interfaces involve handling a sequence of input events, it is natural to think of using a state transition network to code the interface. A transition network consists of a set of states, with arcs out of each state labeled with the input tokens that will cause a transition to the state at the other end of the arc. In addition to input tokens, calls to application procedures and the output to display can also be put on the arcs in some systems. In 1968, Newman implemented a simple tool using finite state machines [Newman 1968] that handled textual input. This was apparently the first user interface tool. Many of the assumptions and techniques used in modern systems were present in Newman’s tool: different languages for defining the user interface and the semantics (the semantic routines were coded in a normal programming language), a table-driven syntax analyzer, and device independence.

State diagram tools are most useful for creating user interfaces in which the user interface has a large number of modes (each state is really a mode). For example, state diagrams are useful for describing the operation of low-level widgets (e.g., how a menu or scroll bar works) or the overall global flow of an application (e.g., this command will pop up a dialogue box, from which you can get to these two dialogue boxes, and then to this other window, etc.). However, most highly interactive systems attempt to be mostly mode-free, which means that at each point, the user has a wide variety of choices of what to do. This requires a large number of arcs out of each state, so state diagram tools have not been successful for these interfaces. In addition, state diagrams cannot handle interfaces where the user can operate on multiple objects at the same time. Another problem is that they can be very confusing for large interfaces, because they get to be a “maze of wires,” and off-page (or off-screen) arcs can be hard to follow.

Recognizing these problems, but still trying to retain the perspicuity of state transition diagrams, Jacob [1986] invented a new formalism, which is a combination of state diagrams and a form of event languages. There can be multiple diagrams active at the same time and flow of control transfers from one to another in a coroutine fashion. The system can create various forms of direct-manipulation interfaces. VAPS is

a commercial system that uses the state transition model, and it eliminates the maze-of-wires problem by providing a spreadsheetlike table in which the states, events, and actions are specified [eNGENUITY 2002]. Transition networks have been thoroughly researched but have not proved particularly successful or useful, either as a research or a commercial approach.

48.2.1.4.3.2 *Context-Free Grammars*

Many grammar-based systems are based on parser generators used in compiler development. For example, the designer might specify the UI syntax using some form of BNF. Examples of grammar-based systems are Syngraph [Olsen 1983] and parsers built with YACC and LEX in UNIX.

Grammar-based tools, like state diagram tools, are not appropriate for specifying highly interactive interfaces, because they are oriented toward batch processing of strings with a complex syntactic structure. These systems are best for textual command languages; they have been mostly abandoned for user interfaces by researchers and commercial developers.

48.2.1.4.3.3 *Event Languages*

With event languages, the input tokens are considered to be events that are sent to individual event handlers. Each handler will have a condition clause that determines what types of events it will handle and when it is active. The body of the handler can cause output events, change the internal state of the system (which might enable other event handlers), or call application routines.

Sassafras [Hill 1986] is an event language in which the user interface is programmed as a set of small event handlers. The Elements-Events and Transitions (EET) language provides elaborate control over when the various event handlers are fired [Frank 1995]. In these earlier systems, the event handlers were global. In more modern systems, the event handlers are specific to particular objects. For example, the HyperTalk language, which is part of HyperCard for the Apple Macintosh, can be considered an event language. Microsoft's Visual Basic also contains event-language features; code is written to handle the response to events on objects.

The advantages of event languages are that they can handle multiple input devices active at the same time, and supporting nonmodal interfaces, where the user can operate on any widget or object, is straightforward. The main disadvantage is that it can be very difficult to create correct code, especially as the system gets larger, because the flow of control is not localized and small changes in one part can affect many different pieces of the program. It is also typically difficult for the designer to understand the code once it reaches a nontrivial size. However, the success of HyperTalk, Visual Basic, and similar tools shows that this approach is appropriate for small to medium-sized programs. The style of programming used by Java Swing and related systems, in which the programmer overrides methods that are called when events happen, is similar to the event style.

48.2.1.4.3.4 *Declarative Languages*

Another approach is to try to define a language that is declarative (stating what should happen) rather than procedural (stating how to make it happen). Cousin [Hayes 1985] and HP/Apollo's Open-Dialogue [Schulert 1985] both allow the designer to specify user interfaces in this manner. The user interfaces supported are basically forms, in which fields can be text that is typed by the user, or options selected using menus or buttons. There are also graphic output areas that the application can use in whatever manner is desired. The application program is connected to the user interface through variables, which can be set and accessed by both. As researchers have extended this idea to support more sophisticated interactions, the specification has grown into full application models, and newer systems are described in [Section 48.2.1.4.5](#).

The layout description languages that come with many toolkits are also a type of declarative language. For example, Motif's user interface language (UIL) allows the layout of widgets to be defined. Because the UIL is interpreted when an application starts, users can (in theory) edit the UIL code to customize the interface. UIL is not a complete language, however, in the sense that the designer still must write C code for many parts of the interface, including any areas containing dynamic graphics and any widgets that change.

The advantage of using declarative languages is that the UI designer does not have to worry about the time sequence of events and can concentrate on the information that needs to be passed back and forth. The

disadvantage is that only certain types of interfaces can be provided this way, and the rest must be programmed by hand in the “graphic areas” provided to application programs. The kinds of interactions available are preprogrammed and fixed. In particular, these systems provide no support for such things as dragging graphical objects, rubber-band lines, drawing new graphical objects, or even dynamically changing the items in a menu based on the application mode or context. However, these languages have been used as intermediate languages describing the layout of widgets (such as UIL) that are generated by interactive tools.

48.2.1.4.3.5 *Constraint Languages*

A number of UI tools allow the programmer to use constraints to define the user interface [Borning 1986b]. Early constraint systems include Sketchpad [Sutherland 1963], which pioneered the use of graphical constraints in a drawing editor, and Thinglab [Borning 1981], which used constraints for graphical simulation. Subsequently, Thinglab was extended to aid in the generation of user interfaces [Borning 1986b].

The previous discussion of toolkits mentions the use of constraints as part of the intrinsics of a toolkit. A number of research toolkits now supply constraints as an integral part of the object system (e.g., Garnet [Myers 1990d], Amulet [Myers 1997], and SubArctic [Hudson 1996]). In addition, some systems have provided higher-level interfaces to constraints. Graphical Thinglab [Borning 1986a] allows the designer to create constraints by wiring icons together, and NoPump [Wilde 1990] and C32 [Myers 1991a] allow constraints to be defined using a spreadsheet-like interface.

The advantage of constraints is that they are a natural way to express many kinds of relationships that arise frequently in user interfaces. For example, lines should stay attached to boxes; labels should stay centered within boxes, etc. A disadvantage with constraints is that they require a sophisticated run-time system to solve them efficiently, and it can be difficult for programmers to specify and debug constraint systems correctly. As yet, there are no commercial UI tools using general-purpose constraint solvers.

48.2.1.4.3.6 *Database Interfaces*

A very important class of commercial tools supports form-based or GUI-based access to databases. Major database vendors such as Oracle [Oracle Tools 1995] provide tools that allow designers to define the user interface for accessing and setting data. Often, these tools include interactive form editors (which are essentially interface builders) and special database languages. Fourth-generation languages (4GLs), which support defining the interactive forms for accessing and entering data, also fall into this category.

48.2.1.4.3.7 *Visual Programming*

Visual programs use graphics and 2-D (or more) layout as part of the program specification [Myers 1990c]. Many different approaches to using **visual programming** to specify user interfaces have been investigated. Most systems that support state transition networks use a visual representation. Another popular technique is to use dataflow languages. In these, icons represent processing steps, and the data flow along the connecting wires. The user interface is usually constructed directly by laying out prebuilt widgets, in the style of interface builders. Examples of visual programming systems for creating user interfaces include Labview [National Instruments 2003], which is specialized for controlling laboratory instruments, and Prograph [Pictorius 2002]. Using a visual language seems to make it easier for novice programmers, but large programs still suffer from the familiar maze-of-wires problem. Other papers (e.g., Myers [1990c]) have analyzed the strengths and weaknesses of visual programming in detail.

Another popular language is Visual Basic from Microsoft. However, this is more of a structure editor for Basic combined with an interface builder (see [Section 48.2.1.4.6.3](#)), and therefore does not really count as a visual language.

48.2.1.4.3.8 *Summary of Language Approaches*

In summary, many different types of languages have been designed for specifying user interfaces. One problem with all of these is that they can only be used by professional programmers. Some programmers have objected to the requirement of learning a new language for programming just the UI portion [Olsen 1987]. This has been confirmed by market research [X Business Group 1994]. Furthermore, it seems more

natural to define the graphical part of a user interface using a graphical editor. However, it is clear that for the foreseeable future, much of the user interface must still be created by writing programs, so it is appropriate to continue investigations into the best language to use for this. Indeed, an entire book is devoted to investigating the languages for programming user interfaces [Myers 1992b].

48.2.1.4.4 Application Frameworks

After the Macintosh Toolbox had been available for a little while, Apple discovered that programmers had a difficult time figuring out how to call the various toolkit functions and how to ensure that the resulting interface met the Apple guidelines. They therefore created a software system that provides an overall application framework to guide programmers. This was called MacApp [Wilson 1990] and used the object-oriented language Object Pascal. Classes are provided for the important parts of an application, such as the main windows, the commands, etc. The programmer specializes these classes to provide the application-specific details, such as what is actually drawn in the windows and which commands are provided. MacApp was very successful at simplifying the writing of Macintosh applications. Today, there are multiple frameworks to help build applications for most major platforms, including the Microsoft Foundation Classes (MFC) for Windows and the portable Java Swing framework. A framework is a software architecture, often object-oriented, that guides the programmer so that implementing UI software is easier.

The Amulet framework [Myers 1997] is aimed at graphical applications, but due to its graphical data model, many of the built-in routines can be used without change (the programmer usually does not need to write methods for subclasses). Newer frameworks aim to help implement applications that take advantage of ubiquitous computing (also called pervasive computing) [Weiser 1993], multiple users (also called computer-supported cooperative work[CSCW]), various sensors that tell the computer where it is and who is around (called context-aware computing [Moran 2001]), and user interfaces that span multiple computers (called multicomputer user interfaces [Myers 2001]). For example, the BEACH framework [Tandler 2001] provides facilities to handle all of these kinds of user interfaces.

The component approach aims to replace today's large, monolithic applications with smaller pieces that attach together. For example, you might buy a separate text editor, ruler, paragraph formatter, spell checker, and drawing program, and have them all work together seamlessly. This approach was invented by the Andrew environment [Palay 1988], which provides an object-oriented document model that supports the embedding of different kinds of data inside other documents. These insets are unlike data that is cut and pasted in systems like the Macintosh, because they bring along the programs that edit them; therefore, they can always be edited in place. Furthermore, the container document does not need to know how to display or print the inset data because the original program that created it is always available. The designer creating a new inset writes subclasses that adhere to a standard protocol, so the system knows how to pass input events to the appropriate editor. Microsoft OLE [Petzold 1991], Apple's OpenDoc [Curbow 1995], and JavaBeans [JavaSoft 1996] use this approach. The Microsoft .Net initiative provides a component architecture for Web services.

All of these frameworks require the designer to write code, typically by creating application-specific subclasses of the standard classes provided as part of the framework.

48.2.1.4.5 Model-Based Automatic Generation

A problem with all of the language-based tools is that the designer must specify a great deal about the placement, format, and design of the user interfaces. To solve this problem, some tools use automatic generation so that the tool makes many of these choices from a much higher-level specification. Many of these tools, such as Mickey [Olsen 1989], Jade [Vander Zanden 1990], and DON [Kim 1993] have concentrated on creating menus and dialogue boxes. Jade allows the designer to use a graphical editor to edit the generated interface if it is not good enough. DON has the most sophisticated layout mechanisms and takes into account the desired window size, balance, symmetry, grouping, etc. Creating dialogue boxes automatically has been very thoroughly researched, but there are still no commercial tools that do this.

The **user interface design environment** (UIDE) [Sukaviriya 1993] requires that the semantics of the application be defined in a special-purpose language, and therefore might be included with the

language-based tools. It is placed here instead because the language is used to describe the functions that the application supports and not the desired interface. UIDE is classified as a model-based approach because the specification serves as a high-level, sophisticated model of the **application semantics**. In UIDE, the description includes pre- and post-conditions of the operations, and the system uses these to reason about the operations, to automatically generate an interface, and to automatically generate help [Sukaviriya 1990].

The ITS system [Wiecha 1990] also uses rules to generate an interface. ITS was used to create the visitor information system for the EXPO 1992 World's Fair in Seville, Spain. Unlike the other rule-based systems, the designer using ITS is expected to write many of the rules, rather than just writing a specification on which the rules work. In particular, the design philosophy of ITS is that all design decisions should be codified as rules so that they can be used by subsequent designers, which hopefully will mean that interface designs will become easier and better as more rules are entered. As a result, the designer should never use graphical editing to improve the design, because then the system cannot capture the reason that the generated design was not sufficient.

Recently, there has been a resurgence of interest in model-based interfaces to try to provide interfaces that work on the many kinds of handheld devices. For example, the wireless access protocol (WAP) contains high-level descriptions of the information to be displayed, which the handhelds must convert to use specific layouts and interaction techniques. Research continues on ways to convert high-level specifications of appliances and other devices into appropriate remote control interfaces for handhelds, for use in "smart rooms" [Ponnekanti 2001], by the disabled [Zimmerman 2002], and for home appliances [Banavar 2000], [Nichols 2002].

48.2.1.4.6 Direct Graphical Specification

The tools described next allow the user interface to be defined, at least partially, by placing objects on the screen using a pointing device. This is motivated by the observation that the visual presentation of the user interface is of primary importance in graphical user interfaces, and a graphical tool seems to be the most appropriate way to specify the graphical appearance. Another advantage of this technique is that it is usually much easier for the designer to use. Many of these systems can be used by nonprogrammers. Therefore, psychologists, graphic designers, and UI specialists can more easily be involved in the UI design process when these tools are used.

These tools can be distinguished from those that use visual programming because with direct graphical specification, the actual user interface (or a part of it) is drawn, rather than being generated indirectly from a visual program. Thus, direct graphical specification tools have been called direct-manipulation programming, because the user is directly manipulating the UI widgets and other elements.

The tools that support graphical specification can be classified into four categories: prototyping tools, those that support a sequence of cards, interface builders, and editors for application-specific graphics.

48.2.1.4.6.1 Prototyping Tools

The goal of **prototyping tools** is to allow the designer to mock up quickly some examples of what the screens in the program will look like. Sometimes, these tools cannot be used to create the real user interface of the program; they just show how some aspects will look. This is the chief factor that distinguishes them from other high-level tools. Many parts of the interface may not be operative, and some of the things that look like widgets may just be static pictures. In many prototypers, no real toolkit widgets are used, which means that the designer must draw simulations that look like the widgets that will appear in the interface. The normal use is that the designer would spend a few days or weeks trying out different designs with the tool, and then completely reimplement the final design in a separate system. Most prototyping tools can be used without programming, so they can, for example, be used by graphic designers.

Note that this use of the term *prototyping* is different from the general phrase *rapid prototyping*, which has become a marketing buzzword. Advertisements for just about all UI tools claim that they support rapid prototyping, by which they mean that the tool helps create the UI software more quickly. In this chapter, the term *prototyping* is being used in a much more specific manner.

The first prototyping tool was probably Dan Bricklin's Demo program. This is a program for an IBM PC that allows the designer to create sample screens composed of characters and character graphics (where the fixed-size character cells can contain a graphic, such as a horizontal, vertical, or diagonal line). The designer can easily create the various screens for the application. It is also relatively easy to specify the actions (mouse or keyboard) that cause transitions from one screen to another. However, it is difficult to define other behaviors. In general, there may be some support for type-in fields and menus in prototyping tools, but there is little ability to process or test the results.

For GUIs, designers often use tools like Macromedia's Director [Macromedia 2003a], which is actually an animation tool. The designer can draw example screens and then specify that when the mouse is pressed in a particular place, an animation should start or a different screen should be displayed. Components of the picture can be reused in different screens, but again the ability to show behavior is limited. HyperCard and Visual Basic are also often used as prototyping tools. Research tools such as SILK [Landay 1995] and DENIM [Lin 2002] provide a quick sketching interface and then convert the sketches into actual interfaces.

The primary disadvantage of these prototyping tools is that sometimes the application must be recoded in a "real" language before the application is delivered. There is also the risk that the programmers who implement the real user interface will ignore the prototype.

48.2.1.4.6.2 *Cards*

Many graphical programs are limited to user interfaces that can be presented as a sequence of mostly static pages, sometimes called frames, cards, or forms. Each page contains a set of widgets, some of which cause transfer to other pages. There is usually a fixed set of widgets to choose from, which have been coded by hand.

An early example of this is Menulay [Buxton 1983a], which allows the designer to place text, graphical potentiometers, iconic pictures, and light buttons on the screen and see exactly what the end user will see when the application is run. The designer does not need to be a programmer to use Menulay.

Probably the most famous example of a card-based system is HyperCard from Apple. There are many similar programs, such as GUIDE [Owl International Inc. 1991], and ToolBook [Click2learn 1995]. In all of these, the designer can easily create cards containing text fields, buttons, etc., along with various graphic decorations. The buttons cause transfers to other cards. These programs provide a scripting language to offer more flexibility for buttons. HyperCard's scripting language is called HyperTalk and, as mentioned previously, is really an event language, because the programmer writes short pieces of code that are executed when input events occur. In its usual instantiation, the World Wide Web was represented as a sequence of pages, which were like cards, with embedded links that transfer to other pages that replace the previous page.

48.2.1.4.6.3 *Interface Builders*

An interface builder allows the designer to create dialogue boxes, menus, and windows that are to be part of a larger user interface. These are also called interface development tools (IDTs) or GUI builders. Interface builders allow the designer to select from a predefined library of widgets and place them on the screen using a mouse. Other properties of the widgets can be set using property sheets. Usually, there is also some support for sequencing, such as bringing up subdialogues when a particular button is hit. The Steamer project at BBN Technologies demonstrated many of the ideas later incorporated into interface builders and was probably the first object-oriented graphics system [Stevens 1983]. Other examples of research interface builders are DialogEditor [Cardelli 1988] and Gilt [Myers 1991b]. There are hundreds of commercial interface builders, including the resource editors that come with professional development environments such as Metrowerks CodeWarrior. Microsoft's Visual Basic is essentially an interface builder coupled with an editor for an interpreted language. Many of the tools discussed previously, such as the virtual toolkits, visual languages, and application frameworks, also contain interface builders.

Interface builders use the actual widgets from a toolkit, so they can be used to build parts of real applications. Most will generate C or C++ code templates that can be compiled along with the application code. Others generate a description of the interface in a language that can be read at run-time. It is sometimes important that the programmers not edit the output of the tools (such as the generated C code), or else the tool can no longer be used for later modifications.

Although interface builders make laying out the dialogue boxes and menus easier, this is only part of the UI design problem. These tools provide little guidance toward creating good user interfaces, because they give designers significant freedom. Another problem is that for any kind of program with a graphics area (such as drawing programs, CAD, visual language editors, etc.), interface builders do not help with the contents of the graphics pane. Also, they cannot handle widgets that change dynamically. For example, if the contents of a menu or the layout of a dialogue box changes based on program state, this must be programmed by writing code.

48.2.1.4.6.4 *Data Visualization Tools*

An important commercial category of tools is dynamic data visualization systems. These tools, which tend to be quite expensive, emphasize the display of dynamically changing data on a computer and are used as front ends for simulations, process control, system monitoring, network management, and data analysis. The interface to the designer is usually quite similar to an interface builder, with a palette of gauges, graphers, knobs, and switches that can be placed interactively. However, these controls usually are not from a toolkit and are supplied by the tool. Example tools in this category include DataViews [DataViews 2001] and SL-GMS [SL Corp. 2002].

48.2.1.4.6.5 *Editors for Application-Specific Graphics*

When an application has custom graphics, it would be useful if the designer could draw pictures of what the graphics should look like rather than having to write code for this. The problem is that the graphic objects usually need to change at run-time, based on the actual data and the end user's actions. Therefore, the designer can only draw an example of the desired display, which will be modified at run-time, and so these tools use demonstrational programming [Myers 1992a]. This distinguishes these programs from the graphical tools of the previous three sections, with which the full picture can be specified at design time. As a result of the generalization task of converting the example objects into parameterized prototypes that can change at run-time, these systems are still in the research phase.

Peridot [Myers 1988a] allows new, custom widgets to be created. The primitives, which the designer manipulates with the mouse, are rectangles, circles, text, and lines. The system generalizes from the designer's actions to create parameterized, object-oriented procedures such as those that might be found in toolkits. Experiments showed that Peridot could be used by nonprogrammers. Lapidary [Vander Zanden 1995] extends the ideas of Peridot to allow general application-specific objects to be drawn. For example, the designer can draw the nodes and arcs for a graph program. The DEMO system [Fisher 1992] allows some dynamic, run-time properties of the objects to be demonstrated, such as how objects are created. The Marquise tool [Myers 1993] allows the designer to demonstrate when various behaviors should happen and supports palettes that control the behaviors. With Pavlov [Wolber 1997], the user can demonstrate how widgets should control a car's movement in a driving game. Gamut [McDaniel 1999] has the user give hints to help the system infer sophisticated behaviors for games-style applications. Research continues on making these ideas practical.

48.2.1.4.6.6 *Specialized Tools*

For some application domains, there are customized tools that provide significant high-level support. These tend to be quite expensive, however (i.e., \$20,000 to \$50,000). For example, in the aeronautics and real-time control areas, there are a number of high-level tools, such as InterMAPhics [Gallium 1991].

48.2.2 **Tools for the World Wide Web**

Implementing user interfaces for the World Wide Web generally uses quite different tools than building GUIs and is covered in depth in other chapters of this volume. Furthermore, the technology and tools are changing quite rapidly. Therefore, this section just provides a brief overview.

Simple Web pages may be composed of static text and graphics with embedded links, and these can be authored by directly writing the underlying hypertext markup language (HTML). Alternatively, the author

can use interactive tools, such as Microsoft FrontPage, which therefore serves as a kind of interface builder. FrontPage can also author pages that contain forms for filling in information (text fields, buttons, etc.). More dynamic pages can use a scripting language embedded in the HTML, such as JavaScript or VBScript (Visual Basic Script). Alternatively, a specialized animation language can be used, such as Macromedia's Flash language, which might be authored using an interactive tool such as Dreamweaver [Macromedia 2003b].

In all cases, the back-end that provides the pages, processes any input provided in form fields, and delivers new pages as a result, must be implemented using some kind of server-side scripting or database tool, which is typically quite different from the tools used to author the client-side pages that the user sees.

48.3 Models of User Interface Software

Because creating UI software is so difficult, there have been a number of efforts to describe the software organization at a very abstract level, by creating models of the software. The earliest attempts used the same levels that had been defined for compilers and talked about the semantic, syntactic, and lexical parts of the user interface, but this proved to be useful mostly for parser-based implementations [Buxton 1983b]. Another early model is the **Seeheim model** [Pfaff 1985], which separates the presentation aspects (output) from the dialogue management (what happens in what order, based on what input) from the application interface model (what the resulting changes in data are). This model does not work well with GUIs, because they deemphasize dialogue in favor of mode-free interaction. The **model-view-controller** concept [Krasner 1988] was first used by Smalltalk, and separates the output handling (view) from the input handling (controller). Both of these are separated from the underlying data (the model). Later systems, such as InterViews [Linton 1989], found it difficult to separate the view from the controller, and therefore used a simpler model-view organization, in which the view includes the controller. A new model for software organization — which tries to handle the various aspects required for multiple users, distributed processing and ubiquitous computing — is being developed as part of BEACH [Tandler 2002].

48.4 Technology Transfer

User interface tools are an area where research has had a tremendous impact on the current practice of software development [Myers 1998]. Of course, window managers and the resulting GUI style come from the seminal research at the Stanford Research Institute, Xerox Palo Alto Research Center (PARC), and MIT in the 1970s. Interface builders and card programs like HyperCard were invented in research laboratories at BBN, the University of Toronto, Xerox PARC, and others. Now, interface builders are widely used for commercial software development. Event languages, widely used in HyperTalk and Visual Basic, were first investigated in research laboratories. The current generation of environments, such as OLE and JavaBeans, are based on the component architecture that was developed in the Andrew environment from Carnegie Mellon University. Thus, whereas some early UIMS approaches, such as transition networks and grammars, may not have been successful, overall, UI tool research has changed the way that software is developed.

48.5 Research Issues

Although there are many UI tools, there are plenty of areas in which further research is needed. Previous reports discuss future research ideas for UI tools at length [Myers 2000, Olsen 1993]. Here, a few of the important ones are summarized.

48.5.1 New Programming Languages

The built-in input/output primitives in today's programming languages, such as printf/scanf or cout/cin, support a textual question-and-answer style of user interface that is modal and well known to be poor. Most of today's tools use libraries and interactive programs that are separate from programming languages.

However, many of the techniques, such as object-oriented programming, multiple-processing, and constraints, are best provided as part of the programming language. Even new languages, such as Java, make much of the user interface harder to program by leaving it in separate libraries. Furthermore, an integrated environment, where the graphical parts of an application can be specified graphically and the rest textually, would make the generation of applications much easier. How programming languages can be improved to better support UI software is the topic of a book by Myers [1992b].

48.5.2 Increased Depth

Many researchers are trying to create tools that will cover more of the user interface, such as application-specific graphics and behaviors. The challenge here is to allow flexibility to application developers while still providing a high level of support. Tools should also be able to support Help, Undo, and Aborting of operations.

Today's UI tools mostly help with the *generation* of the code of the interface, and assume that the fundamental UI design is complete. Also needed are tools to help with the generation, specification, and analysis of the *design* of the interface. For example, an important first step in UI design is task analysis, in which the designer identifies the particular tasks that the end user will need to perform. Research should be directed at creating tools to support these methods and techniques. These might eventually be integrated with the code generation tools, so that the information generated during early design can be fed into automatic generation tools, possibly to produce an interface directly from the early analyses. The information might also be used to generate documentation and run-time help automatically.

Another approach is to allow the designer to specify the design in an appropriate notation, and then provide tools to convert that notation into interfaces. For example, the UAN [Hartson 1990] is a notation for expressing the end user's actions and the system's responses.

Finally, much work is needed in ways for tools to help evaluate interface designs. Initial attempts, such as MIKE [Olsen 1988], have highlighted the need for better models and metrics against which to evaluate user interfaces. Research in this area by cognitive psychologists and other user interface researchers (e.g., Kieras [1995]) is continuing.

48.5.3 Increased Breadth

We can expect the user interfaces of tomorrow to be different from the conventional window-and-mouse interfaces of today, and tools will have to change to support the new styles. For example, already we are seeing tiny digital pagers and phones with embedded computers and displays, palm-sized computers such as the PalmOS devices, notebook-sized panel computers such as Microsoft's TabletPCs, and wall-sized displays. Furthermore, computing is appearing in more and more devices around the home and office. An important next wave will appear when the devices can all easily communicate with each other, probably using wireless radio technologies like 802.11 (Wi-Fi) or Bluetooth [Haartsen 1998]. Sound, video, and animations will increasingly be incorporated into user interfaces. New input devices and techniques will probably replace the conventional mouse and menu styles. For example, there will be substantially more use of techniques such as gestures, handwriting, and speech input and output. These are called recognition-based because they require software to interpret the input stream from the user to identify the content. In these "non-WIMP" applications [Nielsen 1993a] (WIMP stands for windows, icons, menus, and pointing devices), designers will also need better control over the timing of the interface, to support animations and various new media such as video. Although a few tools are directed at multiple-user applications, there are no direct graphical specification tools, and the current tools are limited in the styles of applications they support. A further problem is supporting *multiple* interfaces for the same application, so the application can run on small and large devices in a consistent manner. Also, sometimes a person might be using multiple devices *at the same time*, such as a PalmOS device *and* a big display screen [Myers 2001].

Another concern is supporting interfaces that can be moved from one natural language to another (like English to French). Internationalizing an interface is much more difficult than simply translating the text

strings, and it includes different number, date, and time formats; new input methods; redesigned layouts; different color schemes; and new icons [Russo 1993]. How can future tools help with this process?

48.5.4 End User Programming and Customization

One of the most successful computer programs of all time is the spreadsheet. The primary reason for its success is that end users can program it (by writing formulas and macros). However, end-user programming is rare in other applications. Where it exists, it usually requires learning conventional programming. For example, AutoCAD provides Lisp for customization, and many Microsoft applications use Visual Basic. More effective mechanisms for users to customize existing applications and to create new ones are needed [Myers 1992b]. However, these should not be built into individual applications, as is done today, because this means that the user must learn a different programming technique for each application. Instead, the facilities should be provided at the system level, and therefore part of the underlying toolkit. Naturally, because this is aimed at end users, it will not be like programming in C, but rather at some higher level.

48.5.5 Application and User Interface Separation

One of the fundamental goals of UI tools is to allow better modularization and separation of UI code from application code. However, a survey reported that conventional toolkits actually make this separation more difficult, due to the large number of call-back procedures required [Myers 1992c]. Therefore, further research is needed into ways to better modularize the code and how tools can support this.

48.5.6 Tools for the Tools

It is very difficult to create the kinds of tools described in this chapter. Each one takes an enormous effort. Therefore, work is needed in ways to make the tools themselves easier to create. For example, the Garnet toolkit explored mechanisms specifically designed to make high-level graphical tools easier to create [Myers 1992d]. The Unidraw framework has also proved useful for creating interface builders [Vlissides 1991]. However, more work is needed.

48.6 Conclusions

Generally, research and innovation in *tools* trail innovation in user interface *design*, because it only makes sense to develop tools when you know what kinds of interfaces you are building tools for. Given the consolidation of the UI interaction style in the last 15 years, it is not surprising that tools have matured to the point where commercial tools have fairly successfully covered the important aspects of user interface construction. It is clear that the research on UI software tools has had enormous impact on the process of software development. Now, UI design is poised for a radical change, primarily brought on by the rise of the World Wide Web, ubiquitous computing, recognition-based user interfaces, handheld devices, wireless communication, and other technologies. Therefore, we expect to see a resurgence of interest in and research on UI software tools in order to support the new user interface styles.

Defining Terms

Application or application semantics: The part of the software that is *not* the user interface.

Application framework: A software architecture, often object-oriented, that guides the programmer so that implementing user interface software is easier.

Call-back procedures: Procedures defined by the application programmer that are called when a widget is operated by the end user.

Constraints: Relationships that are declared once and then maintained automatically by the system.

Geometry management: Part of the toolkit intrinsics that handles the placement and size of widgets.

Graphical user interface (GUI): A form of user interface that makes significant use of the direct-manipulation style using pointing with a mouse.

Icons: Small pictures that represent windows (or sometimes files) in window managers.

Interface builder: Interactive tool that lays out widgets to create dialog boxes, menus, and windows that are to be part of a larger user interface. These are also called interface development tools and GUI builders.

Intrinsics: The layer of a toolkit on which different widgets are implemented.

Model-view-controller: Model of how user interface software might be organized, separating the application data (model), presentation (view), and input handling (controller) aspects.

Prototyping tools: These allow the designer to mock up quickly some examples of what the screens in the program will look like. Often, these tools cannot be used to create the real user interface of the program; they just show how some aspects will look.

Seeheim model: Model of how user interface software might be organized, separating the presentation, dialogue, and application aspects.

Toolkit: A library of widgets that can be called by application programs.

User interface (UI): The part of the software that handles the output to the display and the input from the person using the program.

User interface design environment (UIDE): General term for comprehensive user interface tools.

User interface management system (UIMS): An older term, not much used now. Sometimes used to cover all user interface tools, but usually limited to tools that handle the sequencing of operations (what happens after each event from the user).

User interface tool: Any software that helps to create user interfaces.

Virtual toolkits: Also called cross-platform development systems, these are programming interfaces to multiple toolkits that allow code to be easily ported to Macintosh, Microsoft Windows, and Unix environments.

Visual programming: Using graphics and two- (or more) dimensional layout as part of the program specification.

Widget: A way of using a physical input device to input a certain type of value. Typically, widgets in toolkits include menus, buttons, scroll bars, text type-in fields, etc.

Window: Region of the screen (usually rectangular) that can be independently manipulated by a program and/or user.

Window manager: The user interface of the windowing system. Can also refer to the entire windowing system.

Windowing system: Software that separates different processes into different rectangular regions (windows) on the screen.

49.1 Introduction: Media and Multimedia Interfaces

In order to communicate information to other human beings, we must disturb the environment around us in such a way that the disturbances can be detected by the people with whom we wish to communicate. Furthermore, we must have previously agreed upon the meanings of such disturbances so that the messages can be understood. In other words, we must establish *a medium of communication* between ourselves and our target audience. It is in this sense that computer designers talk about *media*.

Some media of communication are very simple in nature — for example, the doorbell of a house. At this simple level, a ring means there is only one message: “Someone is at the door.” However, one could imagine this medium being developed further in certain circumstances. For example, one ring could mean person A is at the door, two rings could indicate person B, etc. One could even transmit quite complex messages through the doorbell using Morse code. Why anyone would want to do this is not immediately obvious, but such a system might be useful for someone who was severely disabled and could not easily get to the door.

This simple example illustrates the essential components of a medium:

Basic tokens or symbols (such as the ringing of the bell)

Agreed-upon structures built from these elements (such as the number of consecutive soundings of the bell, the length of silences, the maximum number of rings in a structure)

Assigned meaning to the different structural elements (e.g., Morse code)

These three components are often termed the symbols (or lexicon), syntax (or structural rules), and semantics (meaning) of the medium. The parallel with language is obvious, and complex media are essentially a form of communication language. The fourth element of language, pragmatics, is also often present. Pragmatics are concerned with conventions and common usage (e.g., in the doorbell example, all communications might start with two rapid bells to gain attention).

The preceding doorbell example also illustrates multiple uses of media. The huge leap in communicative power that is released when the bell is used for Morse code results from developing a mapping between the simple bell and another very powerful medium of communication: our spoken or written language. The system is, in one sense, illustrating the use of multiple media because it can be used to alert the householder, to transmit a more complex message, or to do both at the same time.

Multimedia communication is the simultaneous (or sequential) use of more than one medium of communication to transmit information. For human beings, using multiple media is the normal way to communicate. A human being will usually, in parallel, employ spoken language, body language, gesture, and touch to transmit a message to another person. If they are constrained (e.g., by having their hands tied), human beings often find it more difficult to communicate. It is interesting to note that when people are observed talking on the telephone, they still use extensive gestures, even though no one is observing them.

Just as human beings need media to communicate, so computers (or the designers who write the programs) must employ media to communicate with their users. This is done through the human–computer interface (HCI). To communicate with users, *output media* are employed. These media must be comprehended by human beings and often involve words, pictures, or sounds. To interpret what the users are communicating to the computer system, *input media* are used. Such media often require special skills (such as typing skills) to be employed effectively. A medium is therefore a specific way of presenting information to a user or presenting information to a computer.

The simultaneous use of media to communicate with users on the human–computer interface is termed a *multimedia interface* and can refer to the input media, the output media, or both. Coupling media can often result in the creation of new media. For example, the coupling of moving video and audio into films or television has created new entertainment media.

Multimedia interfaces are more than a set of interesting new ways to use new technology. Many people believe that such communication is natural and corresponds closely to how the brain has developed. Marmollin [1992] has described multimedia as exercising “the whole mind.” In this viewpoint, the human brain is seen as having evolved in a multisensory environment, where simultaneous input on different channels was essential for survival. Thus, the processing of the human brain has been fine-tuned to allow simultaneous sampling and comparison between different channels. When channels agree, a sense of safety and well-being is felt. When channels degrade, input from one channel can be used to compensate another. Thus, input channel redundancy (within limits) is thought to be desirable and is an agreeable experience.

It is important to realize that multimedia design is not just about choosing the most obvious medium for a particular communication requirement. Deliberately presenting information in an unusual medium can deliver new and interesting insights into a problem. For example, musical harmony is normally presented through the audio channel, yet new insights into harmonic progressions can be obtained by displaying harmony in a visual manner. A nice example of this is the HarmonySpace application of Holland [1994]. This tool offers both experts and beginners the opportunity to explore harmony by allowing them to use spatial attributes in their exploration (e.g., nearness, centrality, and shape similarity). Similarly, music can be used to assist in the understanding of computer algorithms or physical processes such as turbulence [Blattner et al., 1992].

One final and important point about multimedia interfaces is their significance for disabled users. The current high emphasis on visual output media can be severely disadvantaging to blind or partially sighted individuals. Designers should exploit the new presentation opportunities offered by the multimedia approach, but they must not forget that their interfaces may be used by someone unable to assimilate all the channels. Therefore, designers should allow sufficient redundancy on channels so that the partial loss of one medium does not fatally affect communication in other media. On the other hand, designers ought also to take advantage of the new aural media by offering specially adapted interfaces for the partially sighted. Some progress has already been made in this area. Edwards has created a word processor that uses musical tones and synthesized speech [Edwards, 1989]. The approach adapts visual interfaces so that blind users can use them. The system provides auditory windows, which signify their position by unique tones when the cursor enters them. Spoken menus are activated from these areas. The system, called Soundtrack, can be controlled solely through the audio channel. However, the interface also has a visual manifestation, and this redundancy can be utilized by a partially sighted person.

The importance of matching media appropriately with the capabilities or limitations of the user population is now high on the political agenda in many countries. Strong legislation is now either in force or due to come into force to ensure that designers take proper account of people's limitations so that sections of the community are not disadvantaged through the use of information technology. This has raised many questions with respect to the design and usability of multimedia interfaces. Here are some examples:

How can we design ubiquitous interfaces so that users with a range of disabilities can all use them effectively?

Are different combinations of media more effective for different user cognitive learning styles? For example, it is well known that users with dyslexia process information in different ways than nondyslexic users.

Can we exploit the properties of multimedia interfaces to overcome particular types of disabilities?

It is important that media designers acknowledge that they have a responsibility to think carefully about the usability of their interfaces for users with different types of disabilities.

49.2 Types of Media

As previously stated, media can be subdivided into input and output media. These can then be divided according to the sense used to detect them — visual, aural, and haptic (meaning touch) media — which can then be subdivided further, into language and graphics for visual output media, or into sound and music for aural media. Table 49.1, which is not intended to be exhaustive, gives some examples of common media.

TABLE 49.1 Some Common Media

	Aural	Visual	Haptic
Input Media	Natural sound	Video camera	Keyboard
	Spoken word	Text scan	Mouse
	Synthesized sound	Diagram scan	Trackball
		Gesture recognition	Data glove
		Eye tracking	Touch screen
		Foot pedal	
		Breathing tube	
Output Media	Natural sound	Written text	Data glove
	Music	Static graphics	Braille pad
	Synthesized sound	Animation	
	Spoken word	Still video	
		Moving video	

Currently, haptic media dominate the input media area, and visual media dominate the output media field. Aural media are still not fully exploited, particularly for input, where voice recognition could offer a flexible and natural interface.

In [Section 49.2.3](#), wearable and ubiquitous computers are discussed. Such developments considerably extend our conventional ideas about media.

49.2.1 Output Media

Many current output media are reasonably well tuned to human capabilities. They are based on media that have been used among human beings for many years: text, graphics, pictures, video, and sound. Although normal-sized VDU screens do not have quite the same properties as standard-sized office paper, the correspondence is close. Most users therefore have little trouble in understanding well designed visual or aural output media. The problems of designing effective output using these media are essentially the same as those in traditional media design (e.g., books, movies, or diagrams). This does not mean that designing such media is necessarily straightforward, but well known design techniques exist.

One output medium, however, which has still not been fully utilized in traditional computer applications, is the auditory medium. Although most computers can support quite sophisticated aural output (e.g., music), this is rarely exploited. It is now a number of years since Gaver [1986] suggested the use of *auditory icons* — well known, usually natural sounds with common associations (such as a police car's siren). Blattner et al. [1989] have further suggested the use of structured *earcons*, based on simple musical motifs. Such motifs (or jingles) are often used in public address systems to precede messages and alert listeners. Alty [1995] has investigated mappings between computer algorithms and music. The internal workings of an algorithm are mapped to musical structures. Thus, in an audiolization of the Bubble Sort Algorithm, moving up the list, the swapping of elements, and the current state of the list are all mapped into different instruments and rhythmic structures. Using stereo output further assists disambiguation. It appears that people can understand the algorithms from the musical output alone, but more work is needed on which types of musical mappings are most appropriate. Musical mappings have also been suggested to aid computer program debugging [Vickers and Alty, 2000a, 2000b, 2000c].

Traditional entertainment media usually consist of output media only (films and TV programs are examples of these). In computing applications, however, the user is normally able to interact and control the progress of the interaction. This is termed *interactive multimedia*. In interactive media environments, linking between different media and within media can both be very important, and there has been considerable recent research work on how to link different elements within the various media.

Output text has been transformed through the creation of *hypertext* structures [Nielsen, 1990]. Hypertext techniques transform traditional sequential text into a cross-linked structure. Certain words in the text are made “active” in that, when selected, they will transfer the reader to another section of text. In extreme cases, the sequential nature of the text is lost, and the text becomes a structure with many paths through it, selectable by the reader. Hypertext linkages across communication networks have now become commonplace, an obvious example being the World Wide Web. Most textual information on the Web is now retrieved as hypertext (using a language called HTML). Such Web text contains links to other systems on the Web, and exceedingly long and complex chains of linkages can be followed.

The term *hypermedia* is often used to describe the creation and support of linkages between different media. Elements of text may link to photographs, movies, or even sound sequences, either on local systems or across the communication network. One of the current problems in hypertext and hypermedia structures is navigation. Users can easily become lost in hypermedia space. Nondynamic links can also inhibit exploratory learning.

One area where media are now being extensively employed in new ways is virtual reality, where input and output media are used to create virtual environments. For output media, this involves creating an impression of *immersion*. A key aspect of immersion is to avoid the current interface situation, where the interface is a small part of the visual or aural field. Thus, the whole field (visual or auditory) is completely filled. Visually, this can be done in two ways. First, very large curved screens (or even domes) can be

used to fill the field of vision. Second, the user can wear glasses, which consist of two small computer output screens. Distinct presentations to the two screens can give an impression of immersive 3-D. The second technique is clearly less expensive and is economical in space usage. However, it requires more software effort to create the 3-D effects and to maintain stability in the environment when the head moves.

A related output medium, which has potential but is underexploited, is 3-D vision. The problem is, of course, the present requirement for special glasses. The third dimension has obvious applications in displaying 3-D molecules or architectural structures, but it can also be used to improve presentation of other data. Three-dimensional presentation has also been used in displaying information in databases. Because 3-D display is usually essential in virtual reality systems, it is expected that rapid developments will take place in this area.

49.2.2 Input Media

Current input media, in comparison with output media, are cumbersome and unnatural. They require skills (such as keyboard skills) to be used effectively. Furthermore, input media are unusual in the fact that they must be coupled with some form of output medium to be useful. For example, keyboard input is not effective unless the user receives simultaneous output of what is being typed. In a similar manner, input using a mouse requires visual feedback to be effective. This complicates the analysis of input media.

Recently, there has been more active research on new input media. Developments have been reported in voice recognition (now beginning to reach acceptable levels of performance), gesture and pointing (where the actual visual gestures are tracked by video cameras and interpreted), eye movement (the actual movement of the eye is tracked and can be used as a selection device), lip motion (to assist in speech recognition), facial expression, and handwriting. The research is driven by the current primitive state of input media in contrast to human-human communication.

An interesting feature of many input media is their impreciseness. Voice recognition is often a difficult process because of other extraneous noise; gesture is often vague and ambiguous; lip motion is not read accurately by most human beings. Human beings process such media effectively because they are usually processed in parallel with other media (e.g., gesture and lip movement usually accompany speech). The human processing system exploits the redundancy across these channels, comparing input from different channels for confirmation or seeking support for the interpretation of one channel from another input channel. Some experiments have even suggested that human beings combine acoustic and visual information before classifying them separately [Braidai, 1991]. In other words, separate channel decisions are not made on each input. It is not surprising that much recent input media research work has been concerned with investigating the simultaneous use of a number of input media, and experiments have been carried out to see whether recognition can be improved through the simultaneous use of touch, speech input, and gesture.

Experiments on input media have been reported that involve the combination of speech recognition with lip reading, gesture with speech, and speech with handwriting [Waibel et al., 1995]. One experiment concerned the simultaneous input of lip reading and voice. The acoustic input performance was measured in clean and noisy environments. When the acoustic input was clean, word accuracies in excess of 90% were attained. The lip-reading performance, on its own, varied between 32% and 47% accuracy, and, when used in parallel with the acoustic input, had minimal effect on overall accuracy. When the noisy acoustic input was used, acoustic recognition on its own fell to around 50%, but with lip reading added in parallel, performance improved to over 70%. Thus, adding the lip-reading input (which had a relatively poor recognition rate on its own) boosted the recognition rates of acoustic input in noisy environments.

Waibel et al. [1995] also examined gestural input in some detail. Their input gestures were created by stylus moves on a 2-D graphics tablet. They report on the great variability in the way users make gestures: "No matter how many tokens we put in the training database to cover the different gestures used that mean 'delete text' for example, there may always be totally different gestures that are not yet

part of the gesture vocabulary.” Bordegoni and Hemmje [1993] have constructed a “dynamic gesture machine,” providing graphical feedback in a 3-D interface. The system is based on a simple gesture language.

More novel input devices have been reported. Bordegoni and Hemmje [1993] report on the use of a “force-input” device. This device replaces the mouse in a 3-D virtual environment and is based on a space trackball, which not only can act as a normal trackball but, in addition, can detect the pressure exerted on the ball for providing 3-D movement. A data glove is used, in addition, to detect the position of the hand. Data gloves on their own offer interesting new possibilities, particularly in virtual reality applications [Zimmermann et al., 1987].

49.2.3 Wearable Computers and Ubiquitous Computing

These two concepts are in one sense quite different and in another rather similar. *Ubiquitous computing* involves the embedding of computers into everyday objects such as desks, tables, chairs, and walls. When users move around in this environment, they are (perhaps unconsciously) interacting with these embedded computers, which might then respond. For example, a so-called “smart” room might keep track of the people in it by reading identification tags, and the configuration of the room might change depending on those currently present. The heating might be reduced when no one is in the room and air circulation increased as the room population increases. Laptop computers might automatically link up with each other and also with some central room computer when in the same room. There have already been a number of experiments using badge readers [Want et al., 1992]. A major issue is that of privacy.

Wearable computers start at the other end of the spectrum from ubiquitous computing [Mann, 1996, 1997]. The body of the user carries the computing elements and all the sensors. In the extreme, this should be all that is necessary, because human beings have been able to work this way effectively for a long time! Wearable computers and ubiquitous computers both have been used to maintain personal diaries, where the privacy issue is likely to be less of a problem.

Wearable computers have their own constraints. They must be comfortable (ideally not noticeable). This was a problem for the first generation of wearables. They clearly must be portable. They must have a large number of sensors with extensive communication facilities and be switched on all the time. They should ideally allow the user to operate hands-free and eyes-free when possible; otherwise, the presence of the wearable will seriously intrude on the user’s activities. Network connections will enable the user to retrieve data and perhaps to compare it with the world currently in view.

The wearables concept challenges our ideas of media. For example, most of our current input media are simply not suitable. One proposed input device is the *twiddler* — a one-handed, chorded keyboard and mouse with over 4000 combinations. It is claimed that up to 60 words a minute can be input using the twiddler, but this requires extensive training. Speeds of up to 10 words per minute can be learned during a weekend. Video input typically uses a tiny LED screen (720 × 280 monochrome pixels), viewable by one eye through a reflector, enabling the outside world to be seen at the same time. It looks like a normal 15-inch display viewed from about 2 feet away.

Ultimately, of course, the objective will be to make direct connections between the brain, the nervous system, and the computing systems. At present, this may sound a little futuristic, but already some progress has been reported. StartleCam [Healey and Picard, 1998] is a wearable system with a video camera, which is partially controlled by inputs from the body’s physiological system. A skin conductivity sensor detects what is termed a *startled* response. The skin conductivity is measured by applying a small voltage, and this is continuously monitored. The palms of the hands and soles of the feet are preferred sites for the sensors. The startled response is a typical survival response, although it is also triggered by less threatening events, such as a light being turned on or an expression of anxiety. At the time of writing, such research is in its infancy, but if success is achieved, most of our ideas about media will need significant revision.

49.3 Multimedia Hardware Requirements

Multimedia systems inevitably require considerable hardware resources. Such systems need large amounts of memory (both primary and secondary), and any transmission of multimedia data over a network usually requires high bandwidths.

The most common multimedia platforms currently in use are based upon Sun workstations, PCs, or Apple Macintosh systems. Minimum multimedia enhancements will include a sound board, a super VGA graphics card, a CD read/write device, and a DVD reader.

49.3.1 Compact Disc Secondary Storage Technology

Optical storage media, as typified by the CD-ROM, have provided the much needed increased storage capability required for multimedia applications. The CD-ROM is rather like a traditional long-playing record but, in contrast to the traditional record player, the track is read at a constant linear velocity. This means that the rotation speed must change, depending upon the position of the track relative to the center. The data are divided into blocks to provide some direct access capability. The approach allows high data volumes to be stored, but it reduces direct access possibilities because the data are stored in a long spiral, starting at the inside. Originally, CD-ROMs were read-only. However, they are now available in two different technologies — CD-R (CD-recordable) and CD-RW (CD-rewritable). CD-R discs used to be called WORM drives (**w**rite **o**nce, **r**ead **m**any times). Today, cheap CD recorders are available for writing either CD-R or CD-RW discs. They are not identical to the traditional CD (mass produced and bought in shops), and there may be problems in playing recordable media in older CD drives. Most recent CD players will, however, play all media types. For example, audio CDs can be created on a CD-R and then read on a car CD.

The time required to burn a CD depends on the speed of the drive and the amount of data to be stored. The base line is 75 minutes for 650 MB of data on a 1× drive, but this would reduce to about 19 minutes on a 4× speed drive.

The CD-ROM was developed from the audio CD (CD technologies are defined in colored books: audio technology is in the Red book, data CD technology is in the Yellow book, and recordable CD technology is defined in the Orange book). These standards define the basic hardware and storage mechanisms. However, there is also a need to standardize the ways in which operating systems access the information. The *ISO 9660* standard (originally known as *High Sierra*) achieves this and allows different operating systems to access the same CD-ROM. One improvement provided by the ISO standard is the concept of a *session*. A CD-ROM may be built up progressively as sessions are added. When the disc is read, by default, the last session is accessed. This session can access data written in previous sessions or prevent that information from being accessed (e.g., an update). This allows the designer to write information to the disk in different sessions (i.e., at different times) and to update earlier data.

CD-ROM technology stores data in a manner similar to normal filing systems, using a directory structure to locate the contents. A typical CD-ROM can store up to 650 MB of data, which corresponds to 250,000 pages of A4 text, 7,000 full-screen images, 72 minutes of full-bandwidth animation or full-screen video, or 75 minutes of uncompressed high-quality audio. It is important to realize that the high-volume storage capability of CD-ROM discs (> 600 MB) is achieved at the expense of access times (the worst case is about 150 KB/s, although it is proportionally higher on 2× or 4 × drives, etc.). The amount of data contained on a CD-ROM is large, and the data must be properly managed. Although careful placement of files can be used to improve efficiency, most management takes place outside the CD-ROM.

The introduction of low-cost write-read CD-ROM creation systems has revolutionized the production process for CD-ROMs. Previously, a designer had to create a binary image of the CD-ROM on magnetic media and deliver this to a CD-ROM manufacturer. From the binary file, a master disc was made, from which multiple discs were then pressed. This made low-volume production uneconomical. Now, a designer can buy cheap CD recorders, which can be attached to a PC and can master individual discs. The availability

of this new hardware has expanded the application areas for CDs. They are now commonly used as removable media to back up files.

49.3.2 Video Storage and Manipulation

Handling video data places very high demands on the multimedia computer system. A typical full-screen still picture requires about 1 to 2 MB of memory. If this were to form part of a movie, the system would need to transfer about 30 MB/s to give the illusion of motion. Thus, one minute of video could occupy nearly a gigabyte of storage. In addition, huge transfer rates would be required to refresh the memory with new picture. In the previous decade, hard disk transfer rates were a limiting factor. Although transfer rates from the latest hard disks are now approaching these speeds, it is still vital to compress information in order to ensure cost-effective delivery over broadcast networks and the Internet.

One of the most common video compression systems used for still images is Joint Photographic Experts Group (JPEG). It can usually achieve compression ratios of about 30:1 without loss. This means that the 30 MB/s transfer rate reduces to 1 MB/sec — well within the capabilities of present hard disk drives — and an image can be stored in about 40 kilobytes. The compression speeds are high.

For moving pictures, the Moving Picture Experts Group (MPEG-2) compression technique is used. This achieves compression ratios of about 50:1 without degradation, and the compression and decompression can occur in real time. Using MPEG-2, a movie can be played from a CD-ROM. Higher compression is possible, but this results in a loss of image quality. MPEG-2 is also used for digital television and DVDs. Work continues on more efficient video compression; for example, MPEG-4 is currently mainly aimed at low-data streaming applications but could be used for future DVDs. A new compression standard, JVT/H.26L, can reduce bit rates by a further factor of 3 compared to MPEG-2, and similar results are achieved using the latest Microsoft Media Player.

The DVD (digital video disc, but now usually just called DVD) has provided dramatically improved levels of data storage. DVDs were specifically aimed at the home entertainment market and are now fully established in the marketplace. At present, most DVDs are read-only, but DVD writers are now available and are reducing in price. They store over two hours of high-quality video and audio data and with additional features, such as double-sides or dual layers, this can be increased to over eight hours. They can hold eight tracks of digital audio, providing multilanguage tracks, subtitles, and simple interactive features. The resultant video is much better than CD quality (though, of course, the quality depends upon the compression techniques used — MPEG-2 is essential). At the time of writing, the discs are still quite expensive, about \$20, but this should slowly reduce. DVDs are now available for audio only (DVD-audio). The discs are actually available in two sizes, 12 cm and 8 cm, with a storage ratio of about 3:1. Capacity varies from an 8 cm single-sided/single-layer DVD (1.36 GB) to 12 cm double-sided/double-layer DVD (15.9 GB). With compression, these can store from half an hour of video to eight hours of video.

Many discs contain *regional codes*, and players are designed so that they will only play discs that correspond to their regional code. One of the main reasons for these codes is to control the release of DVDs in different countries. There are eight regional codes that span the world (Japan, USA/Canada, Australasia, Europe, etc.). Furthermore, DVDs are recorded in two incompatible formats corresponding to the two main TV formats (PAL and NTSC). Most PAL players can read and perform conversion on NTSC DVDs, but the reverse is not true.

In the short term, DVDs are likely to replace CD-ROMs; in the longer term, they will replace video recorders.

49.3.3 Animations

Animation covers any *related artificially created* moving images on the screen, not movement or change itself. So, screen changes are not animation, but moving banners and moving images of animals, cartoon characters, or human shapes clearly are. Movies are not animations because they are not artificially created, although some very specialized movies might be thought of as animations. There are also gray areas. For example, are mouse-over images animations?

Animations are important because the human physiological system is tuned to picking up movement, particularly peripheral movement. The evolutionary reasons are obvious — anything moving poses a threat (or could be food). Our visual system is therefore tuned to almost involuntary response to moving images, and movement will affect anything else we are doing at the time. Thus, animation provides two challenges to human–computer interaction:

Movement can be used to direct the attention of the user.

Irrelevant movement can seriously distract a user from the current task.

We should therefore exploit the former and minimize the latter. However the interface is designed, animation should add content or assist the user in using the interface by directing his or her attention.

There are a number of ways in which animations can be created using software:

A set of GIF (or JPEG) images can be created. Such images are essentially bit-mapped pictures with each succeeding picture slightly changed — like the pages of a flipbook. A good aspect of this approach is that it is not browser-dependent. However, the files created are very large, so download times are a problem. Because of the size, GIF animation can be rather jerky.

The alternative is to use vector graphics (the main product on the market being FLASH .swf files). These are relatively small (requiring one-tenth the memory of a GIF), but files are browser-dependent and require a plug-in. Another problem with using FLASH is that many browser functions are suspended (e.g., Stop). However, it has been estimated that 200 million people are equipped to view it. Shockwave vector graphics incorporates FLASH, 3-D, XML, and other data types.

JavaScript animation gives complete control over animation. A common use is JavaScript rollover on buttons.

Good animation, particularly when accompanied by voice-over explanations, can be very effective. It can also be used to direct and control what the user is looking at. When flashing or blinking items are on the screen, users are forced to direct attention toward the moving images. However, animation is often improperly used, particularly in Web pages, where irrelevant animations frequently distract and annoy users.

49.3.4 Audio Technology – Digital Audio and the Musical Instrument Digital Interface

Much of the audio activity in multimedia applications is concerned with sound, rather than with speech. Most books on multimedia applications hardly mention speech synthesis or voice recognition at all. Voice recognition is not discussed because it is still at a fairly early stage of development and is not usually reliable enough for many existing applications. Voice synthesis, on the other hand, works reasonably well and is considered straightforward. Most personal computers offer standard voice synthesis packages, which use text strings as a source.

Sound is stored in computer systems as digitized audio. Any sounds can be digitized: music, the singing voice, or natural sounds. The input analog signal is sampled at a regular rate and stored. Sampling frequencies vary from 11 to 48 KHz, and the sample size can be 8 or 16 bits. Audio quality requires a sampling rate of 48 KHz, whereas 22 KHz will store speech effectively. Sound editors are available which can work on the digitized waveform. In this way, the designer can add reverberation and chorus effects, fade in and out, and alter parameters such as volume.

Digital audio, at an appropriate sampling rate (about four times the maximum required audio frequency), stores a nearly faithful representation of the analog waveform. The musical instrument digital interface (MIDI) system, on the other hand, offers quite distinct facilities [Moog, 1986]. In contrast to digital audio, this system stores descriptions of a musical score and communicates this information along logical channels to other MIDI devices. Thus, a MIDI keyboard will record note-on and note-off actions, the note value, the pressure on the key, as well as other control signals which alter volume, define the timbre (instrument), and define the stereo profile. These signals can then be sent to a MIDI synthesizer, which will reproduce the analog signals necessary to play the score. Each MIDI instrument usually has MIDI-in, MIDI-thru, and MIDI-out ports. A typical MIDI setup is shown in [Figure 49.1](#).

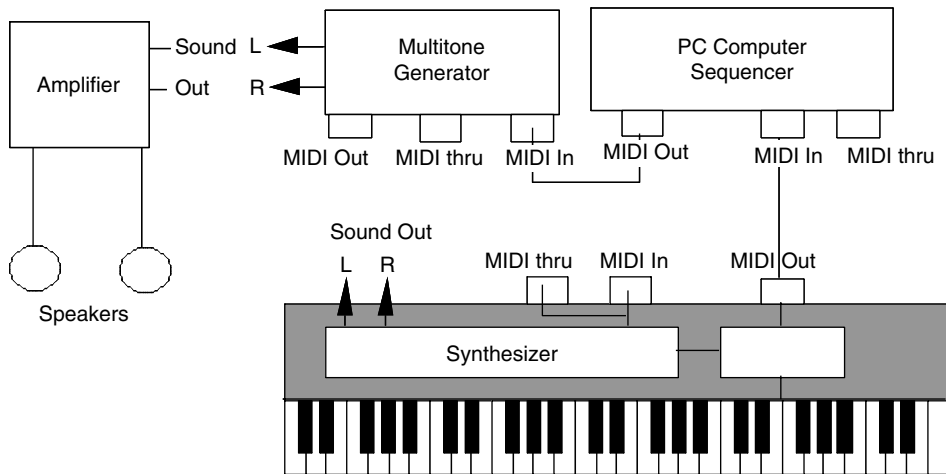

FIGURE 49.1 Typical MIDI connections.

The keyboard can be used to create basic MIDI instructions (note-on, note-off, etc.), in which case the output is taken from MIDI-out port and processed elsewhere. Alternatively, the internal synthesizer of the keyboard can be used to create sounds from the MIDI signals created by the keyboard. This results in audio output signals from sound out. The MIDI-in port can also be used by another keyboard, which would send in MIDI signals to be synthesized by the internal synthesizer.

If the MIDI-out port is used from the keyboard, this can either go directly into the MIDI-in port of the multitone generator to produce sounds at the sound out (in this case, simply using the multitone generator as a synthesizer instead of the internal synthesizer of the keyboard; connection not shown in diagram). Or it could be fed into the MIDI-in port of a PC that is running a MIDI sequencing software package. The resultant MIDI combined output will be stored on the disk of the PC and can then be played at any time, sending the output through the MIDI-out port of the PC to the MIDI-in port of the multitone generator, which will simultaneously create the necessary sounds at sound out. Finally, these sounds will be amplified and sent to stereo speakers in the normal way.

The MIDI-thru ports are used to connect to multiple devices. They allow the signals at a MIDI-in port to be presented elsewhere at the same time. For example, the MIDI-thru port on the multitone generator could be connected to the MIDI-in port of the keyboard to give an extra sound (but more likely to a different multitone generator).

It is important to note that MIDI signals are not digitized sounds; they are a sort of musical shorthand. As a result, MIDI files are far more compact — as much as 1000 times more compact — than digital audio files. The MIDI system can support up to 16 distinct channels simultaneously. Each channel can be assigned to a different instrument, and the signals can then be sent, in parallel, to a multitimbral tone generator that recreates the analog sounds. The sounds can be created in a sequencer, that is, a software system that allows a composer to build up the parallel descriptions of each part. Extensive editing facilities are available, and actual musical scores can be produced automatically from the MIDI description.

There are now a number of effective sequencing systems in the marketplace, such as Cubase [Steinberg, 2002] and Sibelius 2 [Sibelius, 2002]. Sibelius differs from Cubase in that the score is the “heart” of the system. To use it effectively, the user must be familiar with musical scoring notation. Cubase also provides a score, but creation and manipulation can also be carried out through a “piano roll”-type interface. Both packages offer professional-level music creation and manipulation facilities.

Using a system such as Cubase or Sibelius 2, the composer of the multimedia soundtrack can build up the separate channels and control instrument selection, volume, panning, and special effects. The timing of MIDI compositions can be accurately controlled so that they can be synchronized with other media, such as video. Cubase also offers extensive audio signal processing capabilities.

TABLE 49.2 Some General MIDI Sound Assignments

Identifier	Sound or Instrument
1	Acoustic grand piano
14	Xylophone
25	Acoustic electric guitar
41	Violin
61	French horn
72	Clarinet
98	Soundtrack
125	Telephone ring
128	Gunshot

Provided a standard mapping is used, the composer can also expect the desired instruments to be selected on playback in another MIDI device. There are a number of standard mappings, one of which is the general instrument sound map (general MIDI level 1), a small portion of which is given in Table 49.2.

Note that not only musical sounds are capable of being reproduced. Other general MIDI sounds include laughing, screaming, heartbeat, door slam, siren, dog, rain, thunder, wind, seashore, bubbles, and many others.

There are now a huge number of devices on the market for creating and manipulating sound. Auditory signals can be captured in digitized formats, such as .wav files. These can then be manipulated and edited in many ways. MIDI techniques can be used with digital files. For example, samplers can capture original sounds in a digitized format. These can then be stored on the hard disk for later use. Samplers exist that enable the user to buy CD-ROM collections of sampled sounds and load them into memory. These samples can then be assigned to MIDI channels and used to create the output from a sequencer. The result is very realistic sound. CD-ROMs are available that will provide, for example, samples from a complete orchestra playing string sounds, sampled over the complete chromatic scale and using different string techniques such as pizzicato, tremolo, and spicato. Mixers can then be used to adjust the final mix of sounds for performance and the final composition written to CD-ROM. The trend now is toward computer-based (i.e., software-driven) devices rather than stand-alone hardware.

49.3.5 Other Input, Output, or Combination Devices

In addition to the usual input devices (keyboard, mouse, tablet, etc.) multimedia systems may additionally have color scanners, voice input/output, and 3-D trackers (e.g., data gloves). Some of these devices combine input with feedback.

The flatbed scanner is like a photocopying machine. It is essential for adding artwork to multimedia presentations. The picture to be scanned is placed, face down, on a glass screen and is then scanned. Color scanners are normally used in multimedia work. They use three 8-bit values for each RGB component, providing a 24-bit image. As well as color resolution, a scanner has an optical resolution, measured in dots per inch (dpi). Typical values for optical resolution are 300, 400, or 600 dpi. Scanners require software to support them, which enables the user to process the image (e.g., to adjust brightness and contrast).

Three-dimensional trackers can be used to measure the absolute position and orientation of a sensor in space. The tracking is accomplished either by magnetic means or by acoustic means. The yaw, pitch, and roll may also be determined. Such measurements are important if human gesture is to be correctly interpreted. Trackers are often mounted on clothing, such as data gloves, helmets, or even body suits. The data glove worn on the hand can provide input data on hand position, finger movement, etc. Data gloves are particularly useful in virtual reality environments, where they can be used to select virtual objects by touch or grasping. An output feedback system can also be placed in the glove, which provides a sensation of pressure, making the grasping almost lifelike. An interesting example of such an application is the GROPE system [Brooks et al., 1990]. The GROPE system uses a device with force feedback to allow scientists to fit molecules into other molecules. The user can manipulate the computer-created objects and actually

feel the molecules. Some improvement in performance was noted, and users reported that they obtained a better understanding of the physical process of the docking of molecules.

49.4 Distinct Application of Multimedia Techniques

Because media are at the heart of all human–computer interaction, an extreme viewpoint would regard all computer interfaces as multimedia interfaces, with single media interfaces (such as command languages) being special limiting cases. However, we will restrict the term *multimedia interface* to interfaces that employ two or more media: in series, in parallel, or both.

There is a major division in the way multimedia techniques are applied. First, the techniques can be used to front-end any computer application using the most appropriate media to transmit the required information to the user. Thus, different media might be used to improve a spreadsheet application, a database front-end retrieval system, an aircraft control panel, or the control desks of a large process control application. On the other hand, multimedia techniques have also created new types of computer application, particularly in educational and promotional areas. In the front-ending instances, multimedia techniques are enhancing existing interfaces, whereas in the latter fields, applications are being developed which were not previously viable. For example, educational programs analyzing aspects of Picasso's art or Beethoven's music were simply not possible with command-line interfaces. These new applications are quite distinct from more conventional interfaces. They have design problems that are more closely associated with those of movie or television production.

In both application areas, there is a real and serious lack of guidelines for how best to apply multimedia techniques. Just as very fast computers allowed programmers to make mistakes more quickly, so can the indiscriminate use of multiple media confuse users more effectively. The key issues related to the application of multimedia technology are therefore more concerned with design than with the technology per se. The past decade has been characterized more by bad design than by good design. There is no doubt, however, that good design practice will emerge eventually.

It is not difficult to understand why design will be a major issue. The early human–computer interfaces relied almost exclusively on text. Text has been with the human race for a few hundred years. We are all brought up on it, and we have all practiced communicating with it. When new graphics technology allowed programmers to expand their repertoire, the use of diagrams was not a large step, either. Human beings were already used to communicating in this way. When color became available, however, the first problems began to occur. Most human beings can appreciate a fine design which uses color in a clever manner. Few would, however, be able to create such a design. Thus, most human beings are not skilled in using color to communicate, so when programmers tried to add color to their repertoire, things went badly wrong. Many gaudy, overcolored interfaces were created before the advice of graphics designers was sought. More recently, the poor quality of most home video productions has shown that new skills are required in using video in interfaces. Such interfaces will require a whole new set of skills, which the average programmer does not currently possess.

49.5 The ISO Multimedia Design Standard

The International Organization for Standardization (ISO) has drafted a standard for multimedia user interface, ISO 14915, which consists at present of three parts:

- Part 1** — Design principles and frameworks
- Part 2** — Multimedia navigation and control
- Part 3** — Media selection and combination

Specifications for these can be obtained from the ISO Web site [ISO, 2003] for a small cost. Media are classified first according to the sense used to detect them (auditory or visual), then by their realism (realistic or nonrealistic), then by their dynamism, (still or moving), and finally by their language base (verbal/nonverbal).

The standard develops media-neutral descriptions of information, which can then be mapped to media. Examples of information types include causal, descriptive, discrete action, event, physical, and relationship types (there are many more).

Mappings can then be made. For example, the audible click of an on-off switch can be mapped to audio (discrete action); graphs are nonrealistic still images (relationship); and a movie of a storm is a realistic moving image (physical).

The text of the ISO standard contains many interesting examples, and readers are encouraged to examine the standard.

49.6 Theories about Cognition and Multiple Media

49.6.1 The Technology Debate

Can the use of a technology such as multimedia enhance a student's learning experience? This is a question that has taxed the teaching profession for the last 50 years. There have been many discussions and false dawns in the application of technology to learning. For example, the initial introductions of radio and television were supposed to revolutionize teaching. More recently, the same claims are being made about the use of computer-based multiple media in the classroom. The stance of the antitechnology school was summed up in contributions by Clark [1983], who argued repeatedly in the 1980s and 1990s against the concentration of education research on technology and media. He claimed that pedagogy and teaching style were the main variables to be examined and that a concentration on media and their effects was a distraction.

For example, Clark wrote, "There is no cognitive learning theory that I have encountered where any media, media attribute, or any symbol system are included as variables that are related to learning" [Clark, 1983]. Clark's point was that many media are equally capable of delivering any instruction, so media choices are about cost and efficiency, but not about cognition and learning. However, Cobb has pointed out that "there may be no unique medium for any job, but this does not mean that one medium is not better than another, or that determining which is better is not an empirical question" [Cobb, 1997].

Cobb's argument shifts attention to cognitive efficiency and how choice of medium affects such efficiency. Clark's point is almost certainly valid in that the teacher and the pedagogy used should be the main focus. However, it is surely also true that, although any reasonable combination of media can be used to transfer knowledge, some media require more cognitive effort on the part of the learner than others. Musical appreciation can be taught using just musical scores. Actually being able to hear the music, as well, does make the task easier. The point is that appropriate choice of media can reduce the cognitive work required by the user, which might otherwise get in the way of the learning process.

49.6.2 Theories of Cognition

Although cognitive scientists would readily admit that they do not fully understand how human memory operates, they do have some useful models, which can be taken as reasonable approximations of particular aspects of memory behavior. Such models tend to be generalizations, but they can be used in a predictive manner. First, it is generally accepted that memory can be divided (at least logically) into a number of distinct units, two of which are often called working memory and long-term memory. Much of the initial evidence for the existence of some form of working memory was eloquently stated in Miller's well known paper [Miller, 1956]. Working memory provides a temporary store, which seems to be necessary for many cognitive skills. A great deal of experimental evidence has been collected to support the basic concept of working memory. There is also memory in the sensory devices themselves (eyes, etc.), but these are of very short duration.

Long-term memory is where all our durable memories are stored. It is durable and very large in size. In contrast, working memory is very limited in size and has been described as having a capacity of 7 ± 2 "chunks." Working memory is where human beings seem to make the connection between a stimulus from the outside world and the content of long-term memory. The word *forest* might trigger a picture of a forest

we have read about in a book, the memory of a real forest with which we are familiar, or some stylized or prototypical generalization. This might then trigger a previous view or a journey that involved a forest and that we can actually “replay” in the mind.

There is also strong evidence that memories in both working memory and long-term memory exist in a number of forms that are similar to their original sensory stimulus — haptic, audio, and visual stimulations [Paivio, 1986]. In this view, music would be assumed to be stored as an auditory experience and a picture as a visual experience. Memories in long-term memory are much more than simple memories of faces, names, etc. They are thought to include structures called *schemas*, descriptive structures that can be triggered by particular external stimuli. For example, when a person walks into a shop, the “shopping” schema is immediately triggered. This creates expectations about what will happen and puts into context many other external inputs. However, if some external stimulus does not fit into the shopping schema pattern (say some goods fall off the shelf), the person suddenly becomes conscious of effort in working memory to resolve the situation.

Paivio [1986] has proposed what is called *dual coding theory*. In this theory (which has been extensively verified experimentally), items in memory are stored in the same modality as they were experienced (for a recent text, see Sadoski and Paivio [2001]). Thus, music is stored as some form of musical sequence (auditory) and pictures as visual representations. This view contrasts with other theories of memory, which claim that all sensory experiences are recoded into some common coding scheme. Furthermore, Paivio distinguishes between two distinct types of stored structure: *imagens* and *logogens*. *Imagens* and *logogens* can exist in any sensory form — visual, auditory, or haptic. For example, verbal utterances (*logogens*) can be stored as audio (words), written text (visual), or carvings in stone (haptic). *Imagens* can have auditory, visual, or haptic forms. There are strong referential connections between equivalent *logogens* and *imagens*. So, the *logogen* “table” can invoke the *imagen* “table,” and vice versa.

Figure 49.2 illustrates the main aspects of the theory. The two subsystems exist to process the verbal and image representations independently. The *imagens* are quite different structures from the *logogens*, but there are referential links between them. Associative links also exist within each subsystem.

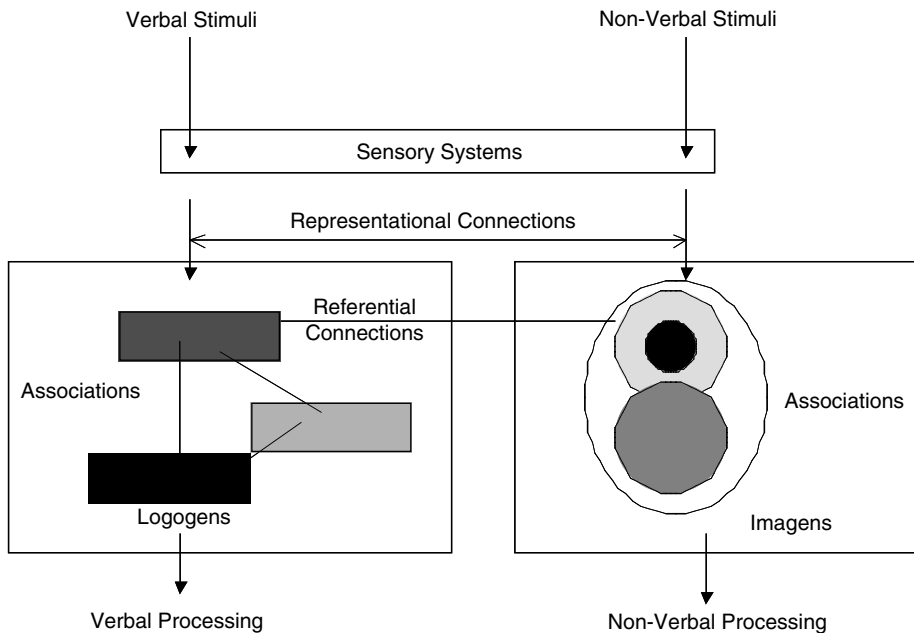

FIGURE 49.2 Processing in the dual coding theory.

Paivio suggests that the two types of storage are processed in fundamentally different ways. Imagens can be processed in parallel and from any viewpoint. Imagine your living room. You can view it in your mind, at will, from any angle. When you think of a face, you do not think of it as successively decomposed into lips, eyes, nose, nostrils, etc. This suggests that imagens are simultaneous structures. On the other hand, it is not easy to break into the middle of a logogen (e.g., a poem). It is very difficult to start in the middle and work backwards, because, Paivio argues, the structure in memory, a logogen, is essentially sequential. Music is more likely to be stored as a logogen than an imagen. For example, Minsky [1989] suggested that “[w]hen we enter a room, we seem to see it all at once: we are not permitted this illusion when listening to a symphony . . . hearing has to thread a serial path through time, while sight embraces a space all at once.”

The ideas of working memory and dual coding theory can now be connected. When a person sees an image, hears a word, or reads a set of words with which they are familiar, processing and recognition are almost instantaneous. This is called *automatic processing*. The incoming stimulus seems to trigger the right structure or schema in long-term memory. If an unusual image or new word is encountered, or if a set of words is read which is not understood, the automatic processing stops, and conscious processing is entered. There is a feeling of having to do work to understand the stimulus.

Rich schemas are what probably distinguish experts from novices, because an expert will have more higher-level schema to trigger. Novices, in contrast, must process unfamiliar schemas using their working memory, with a resultant high cognitive load. Sweller et al. [1998] have termed the procedure of connecting with an internal schema “automatic processing”; they call the process of converting a structure in working memory into a schema in long-term memory “schema acquisition.” Schema acquisition puts a high load on working memory, which in itself is very limited. However, schema acquisition is rapid.

These theories can offer predictions about the use of multiple media. For example, Beacham et al. [2002] have presented similar material in three different forms to students and have measured the amount of material learned. Material was presented

- As a voice-over with diagrams (Sound + D)
- As written text with diagrams (Text + D)
- As text only

Four different modules on statistical material were presented over four days to three groups of students. The student groups were given different presentation styles each day, to avoid any group bias effect. The Sound + D presentation style resulted in significantly higher recall than either of the other two methods for all four modules, even though the material was quite different in nature. For example, the first module (on the null hypothesis) was very discursive, whereas the modules on binomial probability distribution and normal distributions were highly mathematical in nature. The results of the recall of material for all four modules (presented on different days) are shown in Figure 49.3.

FIGURE 49.3 Recall of material for the three presentation styles.

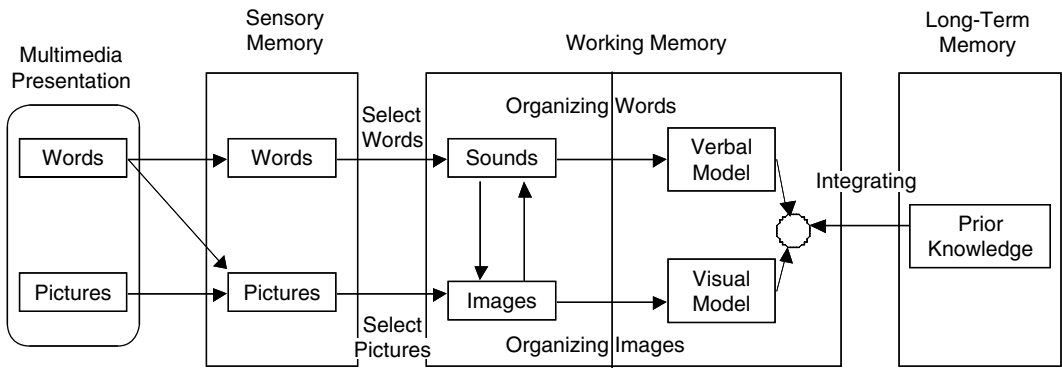

FIGURE 49.4 Mayer's cognitive theory of multimedia learning [Mayer, 2000].

Mayer [2000] has developed a cognitive theory of multimedia learning based on the work of Miller, Paivio, and Sweller. A diagrammatic version of Mayer's approach is given in Figure 49.4.

The multimedia presentation is represented on the left of the figure. For a brief period of time, the sounds or images are held in sensory memories and a selection is made, transferring material to working memory. In working memory, seen words can be converted to sounds and other correspondences made. The right-hand side corresponds to the dual coding approach, in which images and logogens are created and stored, being integrated with existing images and logogens in long-term memory.

The theory suggests a set of design principles:

The spatial contiguity principle — Place related words and pictures near each other.

The temporal contiguity principle — Present related words and pictures simultaneously, rather than separately.

The coherence principle — Exclude unnecessary or irrelevant words or pictures.

The modality principle — Present using different modalities. For example, animation is better supported by voice-overs than by text.

The reader is referred to Mayer [2000], which contains many references to experimental support.

49.7 Case Study — An Investigation into the Effects of Media on User Performance

The following case study is from the process control. This particular application area differs from the traditional computer system because process control systems are highly dynamic and will usually continue whether or not the user intervenes (sometimes with serious consequences). The operator's task in such systems is to ensure that the process continues to operate safely within a predefined economic envelope.

The main task of the interface designer is to present the activities of the dynamic process in such a way that the operators can readily control the process, identify deviations from the norm in good time, and be provided with guidance about how to return the system to the normal state. Usually, there are two goals associated with handling problem conditions:

First, to move the system into a safe (possibly suboptimal) state

Second, to return the system to its optimal state

The PROMISE project was a large international project, funded by the European Commission, which investigated whether multimedia techniques could assist in the control of such dynamic processes. A multimedia toolset was built and a series of experiments carried out to examine the effects of different media on operator performance. Some experiments were performed in the laboratory and others in a live

FIGURE 49.5 Crossman's water bath.

chemical plant. Only the laboratory data will be reported here. Space precludes a complete analysis, so any reader interested in additional information is referred to Alty [1999] for the laboratory work and Alty et al. [1995] for the plant results.

49.7.1 The Laboratory Task

Process control tasks are characterized by having thousands of variables, so one of the main problems encountered when setting up process control laboratory studies is choosing a task that is reasonably representative of the domain under investigation, yet is reasonably straightforward to set up. It also must be learned relatively easily by subjects.

A task already existed that has these characteristics, and for which operator behavior had already been extensively studied. This task is Crossman's water bath [Crossman and Cooke, 1974], which has been studied on numerous occasions [Sanderson et al., 1989; Moray and Rotenberg, 1989]. The task is deceptively simple (see Figure 49.5).

Crossman's water bath is a simulated hydraulic system. A simple bath contains water, the *Level* of which can be altered by adding water through the in-valve *Vin* increasing the *Outflow* by opening the out-valve *Vout*, or both. At any time, there will be an outflow (*Outflow*) from the bath, which could be zero if *Vout* is closed. The bath is heated (*Heat*). Inside the bath is a further container with a fixed amount of water in it, whose temperature is continuously measured by *Temp*. Thus, changes to *Vin*, *Vout*, and *Heat* (the independent variables) cause changes to *Temp*, *Level*, and *Outflow* (the dependent variables). The subject is given the system in a particular state and asked to stabilize it at a new state (a set of limits within which the variables must lie after stabilization).

More than 50 engineering students used as subjects were given a brief introduction to the system. The task and the controls were explained, but without giving any principles of the underlying system. Each session consisted of two halves. In the first half, the subject had to complete 21 tasks of increasing difficulty (but all the tasks were relatively easy). In the second half, subjects had to complete a set of more difficult tasks, involving larger moves in the state space and narrower stabilization limits. Tasks were characterized by their *compatibility*, a task descriptor defined by Sanderson et al. [1989]. Tasks had a compatibility of 1 (easy) to 3 (most difficult). In the break between the two halves of the experiment, subjects were tested for their understanding of the state variables. This test was repeated at the end. All sessions were recorded, timing statistics were collected by the system, and subjects were asked to verbalize their current beliefs about the system and the reasons for their actions.

TABLE 49.3 The Basic Media Used in the Experiment

Medium	Description
Text only	Single text values of each dependent variable and the required limits were displayed. Subjects altered text values of the independent variables.
Graphics only	A graphical representation of the water bath, which reflected the current state, was displayed. Current values and limits of all variables were displayed graphically. Sliders altered independent variables.
Voice messages	A male or female voice gave warning messages.
Sound output	A variable sound of flowing water, which reflected the inflow rate, was presented.
Written messages	A written message gave warnings.
Scrolling text table	The last 20 values of all dependent variables were displayed in text with the current values at the base. The table continuously scrolled. The limits were shown as text. Subjects altered text values of independent variables.
Dynamic graph	A continuously scrolling graph showed the recent history of all the variables and the current state. Limits were shown as targets.

	Readings	Targets	
		Min	Max
Level (mm)	316	273	393
Temperature (°C)	25.44	10.0	34.61
Flow Rate (ml/sec)	1998	2204	3404

In Valve = 60	Out Valve = 75	Heater = 39
---------------	----------------	-------------

FIGURE 49.6 The text only interface.

49.7.2 The Media Investigated

A wide range of media were used to create different instances of the controlling interface. The basic media are outlined in Table 49.3.

An example of the text-only interface is given in Figure 49.6. The readings reflect the current state of the dependent variables. These can be compared with the targets. The user's task is to stabilize the system so that all the readings are within the target ranges. The values of the independent variables are at the base of the screen and can be changed by selection using the cursor. The scrolling text interface is shown in Figure 49.7, which also shows the sound outputs (these, and the written warnings, can be presented in any interface).

By comparing results from individual or combinations of elements, particular variables can be isolated. For example, a comparison of (text only and graphics only) with (text and sound and graphics and sound) can examine the effect of sound. The main measures taken during the experiment were as follows:

- Time to complete the task
- Total number of user actions
- Number of warning situations entered
- Subjective ratings of the interfaces by users

	Level (mm)	Temperature (C)	Flowrate (ml/sec)
	363	28.29	2350
	371	28.03	2409
	378	27.76	2463
	385	27.49	2512
	391	27.22	2557
	396	26.96	2598
	401	26.69	2635
Current	406	26.44	2669
Min:	345	10.00	1774
Max:	450	27.68	2974

FIGURE 49.7 The scrolling text interface.

49.7.3 The Effect of Warnings on Performance

Subjects showed no significant differences in performance as a result of receiving spoken or textual warnings, but they did rate spoken warnings as more important. A more detailed analysis of the data revealed that, although all subjects rated spoken warnings as important, this was not true for textual warnings. One group of users had rated them as more important than the other group. The group that rated textual warnings highly also found the tasks difficult. The other group found the tasks much easier. Written warnings require additional processing in comparison with verbal ones (because a switch must be made from the visual task at hand), and they can easily be missed. Therefore, it was likely that subjects who found the tasks difficult tended to check the written messages carefully and, therefore, rated them as more important. Spoken messages, on the other hand, could be processed in parallel with the visual perception of the screen and were rarely missed.

49.7.4 The Effects of Sound

The effects of the presence or absence of sound are shown in Figure 49.8, which again shows completion times, number of actions, and the number of warning situations entered. What is immediately striking about these results is an apparent detrimental effect of sound. Every effect deteriorates when sound is present — the task takes longer, there are more actions, and the number of warning situations entered is increased. A more careful analysis, separating the performance on the three different levels of task compatibility, however, reveals a much more interesting result. These results are shown in Figure 49.9.

A clear pattern emerges from these graphs, although the result does not reach significance. Sound appears to have an increasing effect with increasing task complexity, and one might speculate why this may be so. The moves in state space for category-3 tasks were much greater than for the other two. Thus, in general, larger changes occurred in the flowrate of category-3 tasks than for the simpler tasks. These large changes resulted in larger sound volume shifts, so that the sound volume may then have been more obvious and usable for category-3 tasks. In the easy tasks, the volume changes were not distinct enough to be useful.

It is obviously important to use media that can signal the required differences the human operator needs for successful control. In the case of sound, this was not happening in the easy tasks.

FIGURE 49.8 Effect of sound on performance.

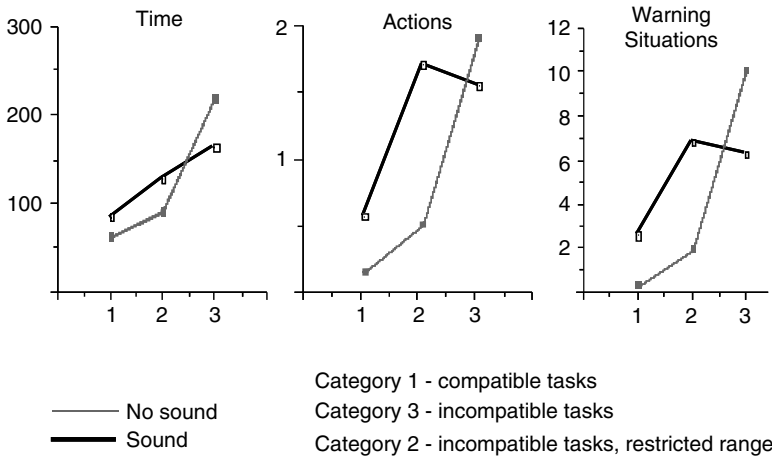

FIGURE 49.9 Effect of task compatibility and sound.

49.7.5 Effects of Mental Coding

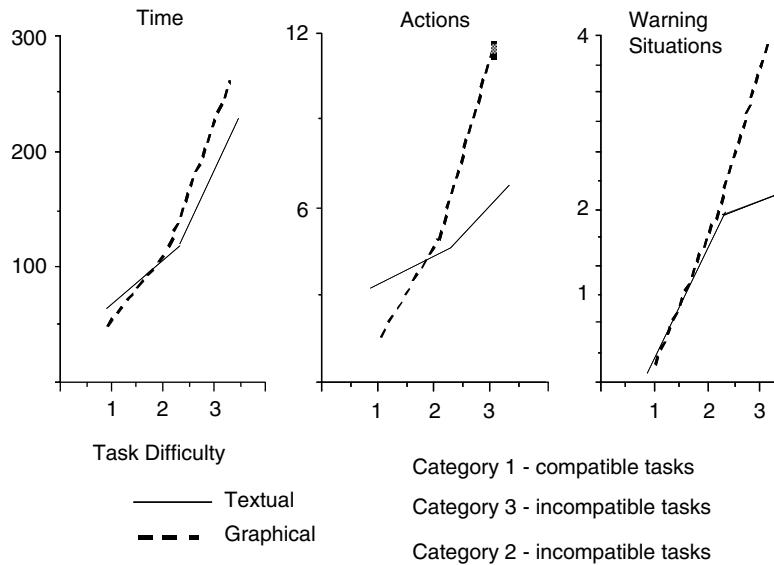

Finally, the performance of subjects in the graphical conditions, compared with the textual conditions, was examined. Received wisdom would imply that subjects ought to perform better on spatial tasks when presented with information in graphical form. The independent variable being examined here is mental processing code (See Table 49.4).

The table shows that, from an efficiency point of view, the graphical interfaces yielded better performance than the textual ones. Only the difference in the number of actions approached significance, however ($p < 0.03$). The effect of graphical interfaces become more interesting when one analyzes the results again in terms of task difficulty. Figure 49.10 (similar to Figure 49.9) illustrates this point.

The trend is significant for both the number of actions ($p < 0.003$) and the warning situations ($p < 0.03$). There is therefore an indication that the graphical interfaces provided better information in a more appropriate form, particularly for more complex tasks. Thus, although the graphical representation might provide too much information for simple tasks, resulting in a low signal-to-noise ratio, as the task becomes more complex, the information provided becomes more relevant and essential to the task.

TABLE 49.4 Effect of Mental Processing Code on Performance

Condition	Completion Time	Number of Actions	Number of Warning Situations
Graphical	97	4.13	0.96
Textual	107	5.46	1.476

**FIGURE 49.10** Effect of task compatibility and mental processing code.

49.7.6 Do Multimedia Interfaces Improve Operator Performance?

A basic assumption of multimedia designers is that multimedia interfaces do indeed make a difference to operator performance. But does presentation affect the way information is picked up and consequently reasoned about? [Figure 49.11](#) illustrates the results from the knowledge questionnaires for users who had experienced the different multimedia interfaces.

The figure shows the results from the knowledge questionnaire for the six variables, broken down by medium type: text (T), graphics (G), graphics with warnings (GSP + GW), text multimedia (TMM), and graphics multimedia (GMM). A statistical analysis shows that, in the cases of *Outflow* and *Vout*, the result is highly significant ($p < 0.01$ in both cases). The other four variables, however, failed to yield a significant result. Thus, the type of medium chosen did affect comprehension in the cases of these two variables (although the analysis does not tell us how).

The figure exhibits some interesting features. Three of the variables have very high levels of comprehension — temperature, in-valve, and heater — and a fourth is reasonably well understood. The effect of the different media seems to be greatest when understanding is lowest (e.g., in the cases of outflow and out-valve).

The concepts of heater, temperature, in-valve, and level are easy to understand. The heater is increased, and the bath heats up. The in-valve is opened, and the flow into the bath increases. The inflow rate is directly proportional to the setting of the valve. The level variable is a little harder to understand, because it depends on the settings of both the in-valve and out-valve, but users seemed to be able to grasp the basic principles. The outflow and out-valve settings, however, are much harder to understand, and the reasons are in the physics. Although the out-valve may be set at a particular value, this does not result in a fixed outflow value. This is because the actual flowrate will depend on the setting of the out-valve *and* the

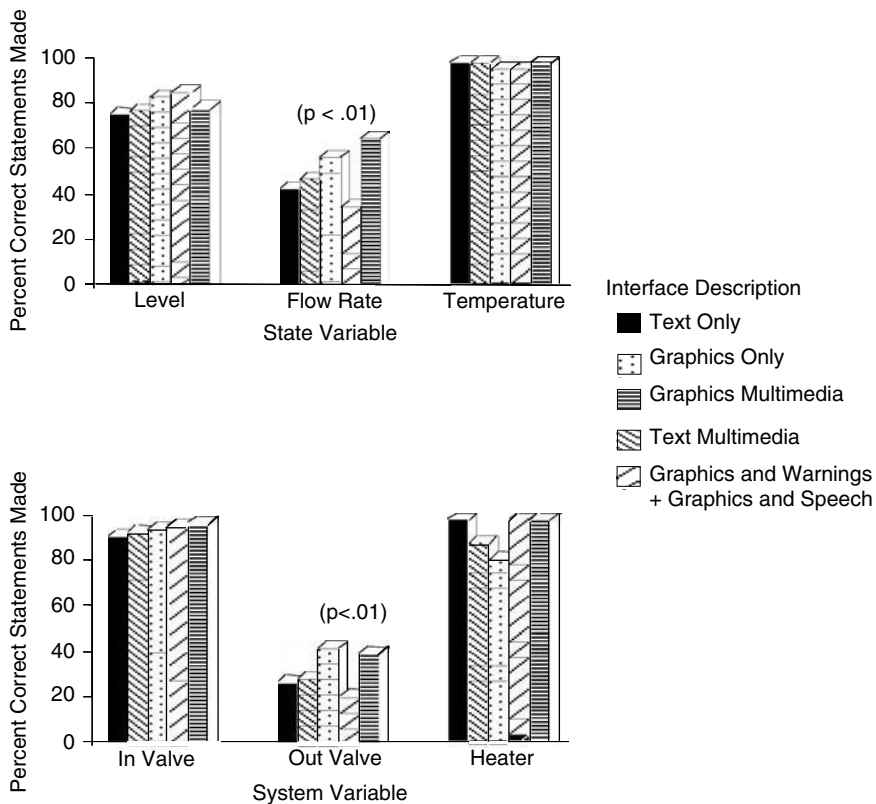

FIGURE 49.11 Overall effect of media on comprehension.

level in the bath (i.e., the pressure). Thus, setting the out-valve to a particular value does not guarantee a certain outflow rate. Moreover, this outflow rate will change as the bath empties or fills. The level of comprehension was quite low for both outflow (about 50%) and out-valve (about 30%).

Here is a possible explanation. The concepts of heater, temperature, level, and in-valve are well understood (probably even before the experiment). Thus, it does not matter what medium is used to portray their actions. Provided the basic information is exchanged, the users will understand. If the opposite extreme of this situation is considered, where the concepts being portrayed are not understood at all by the users (this condition was not present in this experiment), then one might reasonably postulate that it would not matter what medium was used to show their operation; the users would have great difficulty in understanding what was going on. In other words, the medium would not seriously affect comprehension, because there would be no point of contact. The intermediate situation is the interesting one. What if the users understand the basic elements of the domain but are operating on the edge of their understanding? In the cases of the outflow and the out-valve, the users did understand some aspects, but not all (they did not get zero marks in the comprehension test). In such cases, it appears that medium choice does make the difference in understanding.

If this explanation is true, it is an important result and is a strong argument for the appropriate use of multimedia elements in interface design. The intermediate area of understanding just described is an important one. In process control, it represents that area where the operators are trying to understand abnormal conditions in the behavior of the plant, or where users of computer applications are exploring new features. In more traditional applications, it represents the situation during initial exposure to the system or when users are exploring more advanced features of the applications.

49.8 Authoring Software for Multimedia Systems

In the case of promotional software, educational software, or games, the creation of a multimedia application strongly resembles the production of a film or television program, and one talks of multimedia productions. All the different aspects of the production, such as scanned photographs, movie sequences, musical sequences, and text, must be put together into a meaningful whole, all correctly synchronized. For such applications, software to organize and assist in bringing together the contributions from the different media is essential. Such software is often called *authoring software*. In addition, other software is required to create the components that make up the complete applications, such as sound sequences, animations, etc. Like most emerging software environments, the situation can change quite rapidly, and there are many options. However, there are now a number of reasonably well established tools on the market.

In the case of sound composition, tools like Cubase and Sibelius 2 have already been mentioned. These are sophisticated tools for creating sequences, orchestrations, and musical scores. In addition, Cubase can provide extensive digital wave editing and manipulation. There are still many hardware-based tools for sound recording and manipulation, but the trend is now rapidly moving toward computer- or software-based solutions.

For still pictures and animations, there are a number of highly developed packages. In the case of still pictures, packages like Photoshop [Adobe, 2002] offer full picture manipulation and editing. For animation and graphics, there are two basic techniques: raster and vector graphics. *Raster graphics* (or bit-maps) are composed of sets of individual pixels. The resolution is measured in dots per inch (dpi). *Vector graphics* are based on a totally different principle — line representations of images. This means that the components of a vector graphics-based image are calculated using mathematics. This has major implications for the size of the stored image, the processing power required to manipulate it, and its scalability. For example, a bit-map does not scale easily.

Authoring software enables the designer to create and edit different media, and then put them together in a desired sequence. As with most interface tools, different metaphors are used to ease the design task. One example of a common metaphor used is the timeline, in which all the events are laid out across the screen in a time sequence. Using a configurable time frame (usually about 1/30th of a second), elements are positioned on parallel time lines, and other events are cued along the timeline. These representations have tended to replace the card metaphor, rather like a card address file, in which a stack of cards formed the basis of the design. A second type of authoring tool is an existing visual programming environment, such as Visual Basic. Finally, other tools are icon based (similar to visual programming).

There are a number of authoring systems on the market. The situation is changing rapidly, so any detailed comments about tool facilities must be read with caution. The general principles, however, will apply. Tool-based systems include Visual Basic; timeline products include Macromedia Director, FLASH, Adobe Premiere, Action, and Animation Works; and an example of an icon-based authoring tool is Authorware.

All these are proprietary packages. In contrast, the synchronized multimedia integration language (SMIL) enables simple authoring of interactive audio-visual presentations. Using SMIL, a multimedia presentation is captured as a standardized XML application. Various graphical tools are appearing in the marketplace to create and manipulate SMIL presentations. A number of proprietary players can now also play SMIL presentations.

Which package to choose depends on how ambitious the planned multimedia project is. The icon-based tools are the easiest to use, and the timeline tools are probably the most complex. The tool-based systems may not provide all the facilities needed and may require further effort in mastering the tool itself. There are many tools on the market. A recent listing of multimedia products covered more than 90 different offerings, although not all of these are authoring tools. Prices for authoring tools vary from a few hundred dollars to over \$20,000. As one might expect, the buyer often gets what has been paid for.

49.9 The Future of Multimedia Systems

It is clear that multimedia technology is already available that can greatly augment the choices open to the user interface designer. These choices will also be available for systems of all sizes, as computational speeds increase and hardware costs fall. A corollary of this is the ubiquity of high-bandwidth, worldwide networks capable of transmitting information in a variety of representational forms via multicast or point-to-point connections. For example, the use of the multimedia HTTP transfer protocol (as used in the World Wide Web) gives an interesting, albeit haphazard, view of multimedia interfaces of the future.

However, the lack of prevalent and wide-ranging design criteria still makes multimedia user interface design an ill defined and empirically lacking discipline. To counter this, user-centered, rather than technology-centered, research is focusing on the following areas:

- Examining the effect of different media on human cognitive representations, particularly the construction of mental models of represented domains [Faraday, 1995; Williams, 1996]
- Classifying media in linguistic terms by virtue of their expressiveness [Stenning and Oberlander, 1995]
- Matching media to task descriptions [Maybury, 1993]
- Developing cognitively based approaches to design [Mayer, 2000]

There is no doubt that if user interface designers are to fully utilize the technology on offer, suitable design methodologies must be developed. These must encompass both the cognitive and the goal-oriented aspects of the human-computer system. Without them, multimedia will remain a pragmatic area of HCI application, or worse, will only be fit for use in entertainment systems.

50.1 Introduction

The development of networked computing and the globalization of industry have dramatically increased the importance of what is called computer-supported collaborative work (CSCW). The Web has made geographically distributed collaborative systems feasible in a manner that was previously impossible [Deek and McHugh, 2003]. This chapter surveys various factors that affect collaboration, with an emphasis on the media characteristics of distributed computer systems, process management techniques, the information processing characteristics of groups, and the impact of organizational context on the use of collaborative systems.

We begin by considering, in [Section 50.2](#), the effect of media characteristics of an interaction environment on collaboration under a variety of interaction modalities. Because remote groups lack physical copresence, computer-supported communication serves as a surrogate for a broad variety of physical factors, like visual and behavioral cues. These factors are fundamental to understanding the kind of infrastructure that computer-supported environments approximate, supplement, or substitute for.

[Section 50.3](#) focuses on how computer mediation affects group productivity, and how productivity may be enhanced by appropriate computer-supported processes and by effectively structuring interactions. The view is based on the premise that group productivity is determined by the task to be solved, the resources available to the group, and the processes used to solve the task. The characteristics of these processes can increase or decrease group productivity. We consider several process-related effects that affect

productivity, including production blocking, anonymous communication, and evaluation apprehension. We also consider techniques for structuring group interactions to make them more effective, such as interaction and task structuring techniques like templates and voting. Information exchange is a defining characteristic distinguishing individual and group problem solving.

Section 50.4 looks at factors that affect how groups handle information, including the availability characteristics of information, such as whether it is initially common, unique, or partially shared among its members, and issues related to opinion formation, like the role of information influence and normative influence. Section 50.5 focuses on impediments to organizational acceptance and issues that groupware developers should be alert to when determining the kinds of functionality appropriate to groupware and the effect of design presuppositions on groupware functionality.

50.2 Media Factors in Collaboration

The media we use to communicate profoundly influence the nature of those communications. This section focuses on the diverse and subtle impacts of the media characteristics of an **interaction environment** on collaboration. We consider a variety of interaction modalities: face-to-face, video-supported, audio-only, and synchronous and asynchronous computer-supported communication. We consider the characteristics of **collocated work**, environmental factors that affect the ability to establish a shared understanding of a problem, and the role of visual and auditory cues in communication. Although the cues in copresent collaboration are different from those in computer-supported communication, they can help us understand the characteristics of communicative exchanges in general. This knowledge can then be brought to bear on issues that arise in computer-supported collaboration. We compare video-mediated and audio-only communications, especially in the context of consensus generation, and consider the impact of so-called proxemic effects. We consider how conversational exchanges can be modeled and how interaction environments affect social context cues, leading to changes in behavior, as has been argued for the case of deindividuation and **group polarization**. We briefly consider which media environments may be preferred for different purposes, such as managerial or organizational objectives, and discuss the effects of I/O and asynchrony.

50.2.1 Environmental Factors Affecting Collaboration

The *interaction environment* for collaboration is defined as the modality or mechanism through which the group interaction occurs. In face-to-face collaboration, the interaction environment is the physical world. In computer-supported collaboration, the interaction environment is the computerized interface that supports the interaction [Whitworth et al., 2000]. A fundamental difference between face-to-face and computer-supported interactions is that the latter provide fewer of the cueing factors that facilitate shared cognitive attention, factors like gesturing, **deictic reference**, and nonverbal expression. A rich cueing environment makes it easier for a group to attain a common understanding or shared context for its discussions, letting everyone in a group be on the same page. The relative scarcity of such cues in computer-supported interactions represents a **process loss**, that is, an inefficiency associated with a process or environment which decreases the productivity of the process.

However, computer-supported interactions also exhibit **process gains**, that is, efficiencies that increase the productivity of the process. For example, computer-supported interactions are more documentable, more reviewable, and may be more precise than their face-to-face counterparts [Nunamaker et al., 1991a]. Some of the current technological limitations on the cueing characteristics of computer-supported environments will be mitigated over time by advances in technology, but other limitations are intrinsic to remote communication.

We begin by examining the simplest model of collaboration, collocated work, which refers to collaboration where participants are located at a common site, with workspaces separated by at most a short walk, say less than 30 meters, and where the work is done synchronously. We assume that there is a common or shared space where group members can meet and that all group members have convenient access to

shared static media like blackboards, bulletin boards, boards for posting materials, etc. This kind of interactive environment is also referred to as *proximal interaction* [Olson and Olson, 2000]. Simple collocation and physical proximity are well known to have a strong positive effect on the initiation of collaboration [Kraut et al., 1990]. The interactions that can occur in a collocated synchronous work environment are characterized by the following factors:

- Rapid feedback (allowing for quick correction)
- Multiple information channels (vocal, facial, postural, gestural)
- Coreference (such as deictic reference by gaze)
- Spatiality of reference (participants are in the same physical space)
- Opportunistic information exchange
- Shared local context
- Implicit cues
- Easily nuanced information exchange

The discretized communication represented by text cannot match the continuum of nuances that occur in a proximal context. All the participants share the same local context, including the same time of day and circadian state. Having the same spatial frame of reference, so-called *coreference*, simplifies deictic reference, which refers to pointing to objects by gesturing and the ability to use the words *this* or *that* as references. There is also substantial individual control, with members able to focus discussion readily.

Most of these characteristics of collocated work derive from the shared spatiality of reference, which embeds in a single space both the individuals and the work products and artifacts they are working on. Each of these features of a collocated workspace has certain positive implications for collaboration. For example, the rapid, real-time feedback makes it easy to nip misunderstandings and errors in the bud. The instant personal identification of sources makes it easier to evaluate the information in the context of its source. The availability of spontaneous, unplanned interactions, which are less likely in a computer-supported context, permits opportunistic exchange of information and facilitates individual and group cohesion [Olson and Olson, 2000]. This is not to imply, however, that face-to-face interactions automatically always represent a gold standard for interactions [Olson and Olson, 2000], because remote collaborations may sometimes be more suitable.

Several factors facilitate collaboration and effective communication, the first being what is called **common ground** [Olson and Olson, 2000]. Common ground refers to the environmental factors or characteristics that facilitate or make possible a shared collaborative experience. Common ground characteristics include factors that enhance cueing, such as the copresence of participants, mutual visibility of participants, audibility, contemporality (which allows immediate reception of communications or messages), simultaneity (which allows participants to send and/or receive messages simultaneously), and sequentiality (which ensures speaker or communicator turns cannot get out of order). Other media characteristics relevant to common ground are factors that enhance the quality of communications or messages, including revisability of messages (messages can be revised by the sender before their final transmission) and reviewability of messages (messages from others can be reviewed after receipt) [Olson and Olson, 2000]. The richer the interaction environment or medium, the more cues it supports for establishing a commonly recognized, shared understanding. Copresence, for example, entails all the advantages that follow from convenient deictic reference.

Besides common ground, other factors that facilitate collaboration are the degree to which work is **tightly coupled**, the desire of participants to collaborate, and the technological preparedness of the group to work in a groupware environment. Another factor is the willingness of participants to collaborate remotely in the first place, which is tied to the incentive structure of the organization, defined as the system of rewards that encourage performance of an activity. Collaboratively sharing and seeking information from or with others requires an appropriate incentive structure. An example of an incentive structure hostile to collaboration (remotely or locally) is one that awards participants based on individual claims to ownership of ideas. In such a context, collaboration may cloud ownership and be perceived as contrary to an individual's benefit [Olson and Olson, 2000].

50.2.2 Visual and Auditory Cues in Face-to-Face Collaboration

Whittaker and O’Conaill [1997] give an overview of the role of visual cues in conversational communication and coordination. They observe that any communication, computer-supported or proximate, requires extensive coordination between speakers (senders) and listeners (receivers). First of all, there must be coordinating processes for initiating and terminating entire conversations (availability), as well as processes for coordinating how speakers and listeners alternate turns during an initiated conversation (turn-taking). In addition to process coordination, conversations also require content coordination, which refers to how participants in the conversation establish a shared understanding. The turn-taking process determines how transitions are negotiated and is remarkably fine-tuned. The process of recognizing availability concerns the initiation of entire conversations. Potential participants must identify when partners are available to converse and whether the moment is opportune to initiate a conversation. These processes require awareness and alertness by participants to cues signaling turn-taking and availability, including understanding the social protocols that signal readiness to begin a conversational process or to switch turns from speaker to listener.

Establishing shared understanding is more complex than merely navigating a conversation. For one thing, the literally expressed meaning of a communication underspecifies what the speaker fully intends to express. What is unspoken must be inferred by the listener from the discussion context, prior understandings, and contextual environmental cues in the physical environment. Some of this inferred understanding can be gathered from the preposited shared source called common ground. For example, common ground facilitates deictic reference, which lets participants easily identify artifacts in the environment. As part of establishing shared understanding, conversations require a feedback loop so speakers can confirm that listeners have correctly understood the intent of the communication [McGrath and Hollingshead, 1994]. The feedback loop helps maintain and extend the common ground or shared knowledge. In a proximate conversation, feedback information is generated on a real-time basis and occurs through a variety of cues. Whittaker and O’Conaill observe that in addition to informational exchange, participants must also be able to track dynamic changes in the affective states and interpersonal attitudes of conversational partners [Whittaker and O’Conaill, 1997].

Much of the information used to support conversations is based on visual cues available in face-to-face environments, including communicative cues about other participants in the interaction and cues about the shared environment itself. The communicative cues include gaze, facial expression, gestures, and posture. Communicative processes like turn-taking depend on information from multiple channels, such as gaze, gesture, and posture. It is worth emphasizing that “an important property of non-verbal signaling [is] that it can go on simultaneously with verbal communication without interrupting it” [Short et al., 1976]. The effects are subtle in terms of their impact on the conversational process. For example, a “negotiated mutual gaze” [Whittaker and O’Conaill, 1997] between the speaker and listener signals that the speaker is yielding the turn to the listener. Or the speaker can gaze at the listener to prompt attention on the listener’s part. Gaze has many nuances and can be modulated to indicate the speaker’s affective attitude to the listeners or the affective content of what the speaker is saying: trustworthy, sincere, skeptical, amicable, etc. The characteristics of a person’s gaze behavior are also revealing. For example, an individual who looks at a conversational partner only a small part of the time will be evaluated as evasive, while a person with the opposite behavior may be interpreted as friendly or sincere. Speakers tend to gaze more when they are attempting to be persuasive or deceptive. Facial expressions are an even richer source of communicative information and feedback than gaze and range from head nod frequency to cross-cultural expressions of affect. A glance is another useful visual behavior that can allow a participant to determine whether another person is available for conversation, not present, or engaged in another activity. Glances also serve as useful “prompts to the identity of a potential participant” [Daly-Jones et al., 1998]. It is worth noting from the point of view of computer-supported communication that visual recognition of identity is possible with low bandwidth and that “more can be remembered about a person when prompted by their face than by their name” [Daly-Jones et al., 1998].

In addition to visible behavior, the shared visible environment itself supports common ground. For example, the presence of others can be automatically inferred, though less effectively so the larger the group. Direct knowledge of the proximity or activities of others can be used to initiate conversations and also affects how interruptions are handled. Visible cues about the availability of a person can affect conversation initiation. Conversely, dyadic conversations may be terminated or altered in content or mode by the arrival of a third person.

50.2.3 Video vs. Audio-Only

Early studies on audio-only conversations [Reid, 1977] concluded that audio channels significantly improved performance on tasks involving simple, objective information exchange, but there was no particular advantage from additional visual access. These studies also showed that audio-only collaboration led to the exchange of considerably more messages than purely written exchanges when solving problems for which there was a single correct solution. Face-to-face communications similarly led to considerably more messages than audio-only [Short et al., 1976].

Interestingly, very slight delays in auditory transmissions, such as can occur over transmission links or Internet connections, can significantly affect the interpretation of verbal communications. The classic study by Krauss and Brickner observed that increases in delay led to an increase in words used [Krauss and Bricker, 1966]. The task used consisted in identifying scrambled, random graphic symbols; each of two participants had identical sets of symbols. One participant had to characterize a symbol verbally to the other participant, who then had to recognize which symbol was being described. The number of so-called *free-standing utterances* (speech by one partner that was immediately preceded and followed by speech by the other partner) was measured, as was the length of the utterances. Delays beyond 1.8 seconds led participants to characterize partners as less attentive, and there were noticeable gender-related effects. The task used here is called a *referential communication task* [Krauss and Fussell, 1990]. These usually consist of a visual stimulus which one of the participants must describe to the other, who then must select the described object from a list. The object (referent) may be a nonsense figure, and the list of choices is called the *nonreferent array*. Although the tasks are limited and unlike ordinary conversational exchanges, reference experiments are useful for testing the effects of an environment on deixis and its communicative effectiveness.

The cuelessness model of Rutter et al. [1981], who analyzed dyadic exchanges over an audio-only link, proposed that, in comparison with face-to-face communications, audio-only interactions were both more issue/task oriented and more depersonalized, because the absence of visual cues “forfeited the regulatory information of non-verbal signals” [Daly-Jones et al., 1998]. O’Malley et al. [1996] used a map interpretation task to compare video, audio-only, and face-to-face communications. Each participant received a slightly different map of an area, and one participant had to tell the other how to follow a route, despite slight differences between the maps. The results indicated that video and audio-only communications were more alike than either was to face-to-face communication. In particular, high-quality video “has only small effects on the process of conversation and low-quality video can actually impede communication” [Daly-Jones et al., 1998].

50.2.4 Proxemic Effects

Visual proxemic effects illustrate the extent to which a sense of personal immediacy can be conveyed through computer-supported video. *Proxemic effects* refer to the apparent distance of one individual from another [Grayson and Coventry, 1998] and are one of the most primitive components of nonverbal communication. Social protocols govern the proximity behavior of people when they interact, with the rules depending not only on the context and relation between the individuals but also on culture and personality. Hall [1963] classified proximity as intimate, personal, social, or public space, with corresponding interactions associated with each. Thus, “talking to a close friend may occur within personal space (18 inches to 4 feet), whereas talking to a stranger will usually occur with the social space (4 to 12 feet)”

[Grayson and Coventry, 1998]. It is known that close proximity may increase perceived persuasiveness, although too-close proximity decreases persuasive influence.

The fact that video communication appears to enhance communication in situations that require negotiation may be related to proxemic effects. Grayson and Coventry [1998] examined proxemic effects in video connections, using dialog analysis to provide a standard decomposition of the conversation into backchannels, turns, overlaps, and utterances or words. *Backchannel responses* refer to communications that signal whether a listener is satisfied or not, agrees or not, is paying attention or not, understands or does not understand the current state of the discussion. Backchannels do not directly disrupt the speaker's flow of speech. They include body language signals, like nods or furled brows, and are used for state correlation but otherwise lack content.

In the Grayson and Coventry experiment, participants whose perceived distance was closer, that is, where the video image appeared closer, interacted more, with more turns taken and more words spoken. Because increased conversational interaction aids understanding more than mere listening, perceived proximity may enhance understanding. The putative explanation is that "conversation involves participants trying to establish the mutual belief that the listener has understood what the speaker meant . . . a collaborative process called grounding" [Grayson and Coventry, 1998]. This mutual view of conversational understanding contrasts with the autonomous view, whereby "merely hearing and seeing all that happens and having the same background knowledge is sufficient to understanding fully" [Grayson and Coventry, 1998]. Apparently, video conferencing conveys proxemic information, though at an attenuated level compared to face-to-face interaction.

50.2.5 Dialog Structure

Conversational dialog is the prototypical interaction, so it is critical to understand its structure. Models of discourse, like the conversation analysis of Sacks et al. [1974] and the interactionist model of Clark and Schaeffer [1989], can help analyze the structure of conversations. The model of Sacks et al. takes a regulatory view of dialog, emphasizing the role of turn-taking during discussions and how often speakers overlap; the lengths of gaps between speakers; and the lengths of individual turns, interruptions, and breakdowns in the dialog. The model tends to interpret breakdowns in conversational flow as failures of communication and interprets a smooth flow in turn-taking as indicating conversational success. According to the interactionist model, on the other hand, the issue is not regulating turn-taking but attaining shared understanding. The interactionist model interprets interruptions and overlaps in speech not as disruptions of a normative smooth sequence of turns, but as necessary to produce a common ground of shared understanding, which is the real objective of the dialog.

As the discussion of cues per Whittaker and O'Conaill [1997] indicates, human interaction has several components, including making contact in the first place, turn-taking disciplines, attention monitoring, comprehension feedback, and various kinds of deixis to objects or persons. Each of these components can be mediated by auditory or visual cues. Initiating contact, for example, uses a cooperative process called a *summons-answer sequence* in which "the caller seeks the attention of a desired recipient who in turn signals their availability and so precipitates an interaction" [Daly-Jones et al., 1998]. Both parties can use auditory or visual signals, with visual signals apparently being more important the larger the number of participants. Similarly, turn-taking can use either visual or auditory cues, the latter including effects like changes in vocal pitch, which serve as turn regulators. Semantic structures in conversation, like requests for attention or explicit questions that signal "entry points into the conversation" [Daly-Jones et al., 1998], also facilitate turn-taking via audition.

50.2.6 Social Context Cues

Social context cues are generally attenuated in computer-supported systems. Sproul and Kiesler [1986] claimed that this tends to result in behavior which is "more extreme, more impulsive, and less socially differentiated" than in a face-to-face context. The negative behaviors exhibited purportedly ranged from

flaming to decreased inhibition about delivering bad news. They explain this behavior as resulting from reduced static and dynamic social cues. Static social cues refer to artifacts like a large desk (symbolizing elevated status) or appearance. Dynamic social cues refer to body expressions like nods of approval or frowns. Paper letters or memos reduce static cues to a minimum of “standardized format conventions” [Sproul and Kiesler, 1986] and provide no dynamic cues.

Spears and Lea present a very different analysis of the social ambience of computer-supported communications than is emphasized in the social cues and cuelessness approaches [Spears and Lea, 1992]. They claim that such communications are indeed more social, in the most fundamental sense of the word, than even face-to-face contact. Their use of the word *social* differs from that of theorists who emphasize social presence as the key manifestation of a social element. The latter tend to equate the social with interpersonal contact and immediacy, as mediated by the kind of social cues just described, and which are attenuated in a computer-supported environment. Spears and Lea use *social* in the sense of social identity theory, where it refers to the social categories or identities according to which individuals define themselves, with different categories being salient at different times and in different contexts.

The kind of information used to convey social cues in the interpersonal sense in a visual context are gestures, postures, backchannel signals, the tone of verbal exchanges, and so on. The kinds of cues used to communicate social information in the more fundamental sense defined in social identity theory include “information about the participants, [about] the context, and . . . relevant social category information” [Spears and Lea, 1992]. Interpersonal social cues are strongly affected by the communications media used. The categorical information required in the social identity sense is sparser and less dependent on the information-richness of the environment. Indeed, social categorical information “is often likely to be given or already inferred in the [computer-supported] context” [Spears and Lea, 1992]. Basic categorical information is of the type “generally supplied by message headers (e.g., name, giving cues to gender and ethnicity, organizational affiliation, distribution lists)” etc., [Spears and Lea, 1992]. In contrast, the understanding of social influence characteristic of the social cues line of research is strongly affected by the socio-emotional vs. task distinction proposed by Bales [1950]. While the gold standard for exchange of interpersonal information is the face-to-face environment, with the interpersonal taken as equivalent to the social, this interpersonal characterization of the social neglects the importance of “social categories, norms, and identifications which position communicators and define their relations to each other” [Spears and Lea, 1992].

Spears and Lea summarize the logic of the cuelessness, social presence, and reduced social cues models of interaction as basically asserting that fewer clues lead “to psychological distance, psychological distance leads to task-oriented and depersonalized content, and task-oriented depersonalized content leads in turn to a deliberate, unspontaneous style” [Spears and Lea, 1992]. Conversely, the richer face-to-face environment makes the interpersonal factor more salient. The impoverished social cue environment is then used to explain asocial behaviors in computer-supported groups, like decreased inhibition and group polarization. In fact, *group polarization* (or *risky shift*), which refers to the “tendency for the mean [in the sense of the average] attitudes or decisions of individuals to become more extreme in the direction of the already preferred pole of a given scale, as a result of discussion within a group” [Spears and Lea, 1992], is one of the most well-established characteristics of group behavior. The cuelessness model claims that computer-supported communications exacerbate group polarization because they “undermine the social and **normative influences** on individuals or groups, leading to a more deregulated and extreme (anti-normative) behavior” [Spears and Lea, 1992]. The classic explanation for this is that the egalitarian, uninhibited behavior of computer-supported groups increases the number of persuasive arguments supporting the general direction of the group opinion. Thus, the rationale offered by such models is that reduced social cues lead to more extensive exchanges of arguments and more extreme arguments.

Deindividuation and depersonalization also come into play. *Deindividuation*, defined as “the loss of identity and weakening of social norms and constraints associated with submergence in a group or crowd” [Spears and Lea, 1992], is encouraged by the **anonymity** and reduced feedback typical of computer-supported environments and which provoke less socially desirable behavior. *Depersonalization* occurs because the decrease in social cues redirects participant attention to the task or message context and away

from the social context. These combined effects allegedly make the group less interpersonally and more information oriented, and so more affected by persuasive arguments, leading to group polarization. Spears and Lea contend, on the contrary, that people are more likely to be affected by group influence “under de-individualizing conditions because the visual anonymity [provided by computer mediated environments] will further reduce perceived intra-group differences, thereby increasing the salience of the group” [Spears and Lea, 1992]. They explain group polarization not as a manifestation of a socially barren environment but, quite the opposite, as representing the convergence of the group “on an extremized group norm” [Spears and Lea, 1992]. The applicable social psychology concept is referent informational influence according to which “social influence reflects conformity to the norm of the relevant group with which one identifies” [Spears and Lea, 1992]. The computer-supported environment’s low information richness fosters the significance of social categorical information, decreasing the salience of interpersonal cues that undermine those social categories.

50.2.7 Managerial Behavior and Information Richness

Daft and Lengel [1984] introduced the concept of *richness* or *information richness*, defined as the “potential information-carrying capacity of data,” a seemingly redundant definition clarified in their work. Lee [1994] surveys and critiques the idea of information richness. From a managerial viewpoint, a medium is richer the more rapidly it allows participants using the medium to disambiguate lack of clarity. Information richness emphasizes the effectiveness of a medium for producing shared understanding in a timely manner and how this is related to the medium’s characteristics. Richness can also be thought of as a measure of the capacity of a medium to support learning. Consider how managers deal with the key issue of **equivocality**, which refers to uncertainty about the meaning of information when the information has multiple interpretations. Face-to-face communication, usually considered the standard for information richness, provides a broad range of cues to reduce equivocality. Whereas uncertainty about a situation (lack of information) can be reduced by obtaining additional information, equivocality is unaffected by further information and is only resolved or clarified through negotiation, which can be used to converge on a consensus interpretation that minimizes equivocality [Hohmann, 1997].

Negotiation seems to be facilitated by media richness [Dennis and Valacich, 1999]. The process of negotiation is highly social and interpersonal. As Kraut et al. [1990] observe, high equivocality leads decision makers into a fundamentally social interaction, because they are involved in a process of “generating shared interpretations of the problem, and enacting solutions based on those interpretations” [Kraut et al., 1990]. Indeed, Daft and Lengel [1984] (referring to Weick [1979]) claim organizations “are designed to reduce equivocality” and even that “organizations reduce equivocality through the use of sequentially less rich media down through the hierarchy.” This is consistent with the notion that nonrich computer-supported communications are better suited to reducing uncertainty (lack of information) than to reducing equivocality (existence of multiple interpretations of information).

50.2.8 Effects of I/O Rates and Asynchrony

The relative speeds of keyboard typing, text reading, speaking, and listening affect the amount of information available to a group, which in turn affects process gains and losses [Nunamaker et al., 1991a]. McGrath and Hollingshead [1994] observe an interesting media asymmetry between output and input rates: “Most people can talk much faster than even very skilled typists can type,” but “[m]ost people can read faster than they can listen, although the amount of that difference depends on type of material.” In other words, the output in face-to-face communication (by speaking) is faster than output in computer-supported environments (by typing), but input in face-to-face communication (by listening) is slower than input in computer-supported environments (by reading). Adrianson and Hjelmquist [1991] also remark on the differing delay characteristics of computer-supported environments and face-to-face environments and how these affect communication. Thus, computer-supported environments rely primarily on the production and perception of textual messages. These messages can be composed without the need for the kind

of relatively instantaneous generation required in a face-to-face environment. Furthermore, the messages can be reviewed and edited by the sender before transmission and reflected on by the receiver after reception. Dennis et al. [1990] also observe how the media difference characteristics of computer-supported environments can positively impact the efficiency of communications. For example, they may “dampen dysfunctional socializing and encourage people to be more succinct” [Dennis et al., 1990].

Another distinguishing characteristic of interaction environments is whether they are synchronous or asynchronous. Face-to-face communications are by nature synchronous, while computer-supported communications can be synchronous or asynchronous but are more often asynchronous. The different modes lead to distinct patterns of communication. McGrath and Hollingshead [1994] allude to various temporal effects of the different modes (also Hesse et al. [1990]). Synchronous communications are strongly constrained by temporal constraints, which tend to limit the length of communications, while asynchronous communication tends to encourage lengthier communications. This can lead to a greater number of simultaneous discussion topics in asynchronous exchanges and possibly more creative contributions, since asynchronous communications can be done over a longer period of time, rely on collective computer-retained memories of past discussions, and suffer no **production blocking** constraints (see Turoff [1984, 1991], Ocker et al. [1995], and Ocker [2001]).

The asynchronous mode may lead to coordination problems (for example, communications are subject to disruptions in sequence), but asynchrony also facilitates coordination. On the other hand, Hiltz et al. [2001] observe that in all their experiments, “even the most extreme asynchronous structures do not reduce the quality of the solutions when compared to the more classical coordination and group approaches.” It is important to appreciate that asynchronous computer-supported communication is not just a poor substitute for immediate contact. As Turoff [1991] observes, it is widely misunderstood that asynchronous communication “is a problem, because it is not the sequential process that people use in the face-to-face mode.” In fact, the real opportunities for improving group communications via asynchronous systems lie in capitalizing on the fact that such systems allow individuals to “deal with that part of the problem they can contribute to at a given time, regardless of where the other individuals are in the process” rather than trying “to maintain the sequential nature of the processes that groups go through in face-to-face settings” [Turoff, 1991].

50.3 Computer-Supported Processes and Productivity

Steiner’s classic work [1972] on group problem solving proposed that group productivity is determined by the task to be solved, the resources available to the group, and the processes used to solve the task. The characteristics of the processes can either increase or decrease group productivity. This section considers process-related effects that affect productivity, including production blocking, anonymous communication, and evaluation apprehension. It also looks at techniques that have been proposed for structuring group interactions to make them more effective.

50.3.1 Process Gains and Losses

Computer-supported collaborative environments have many characteristics that affect productivity. For example, they allow parallel, remote, and relatively instantaneous communications and support a digital group memory. Dennis and Valacich [1993] examined whether the communication among the members of a real group improves performance or detracts from it by contrasting *real group* performance with that of *nominal groups*. The latter are statistical constructs: sets of noninteracting individuals mathematically viewed as a group for purposes of statistical comparison with a real group. Nominal groups are groups in name only, whereas in a real group, the members actually interact.

Process gains may be defined as factors that increase performance in a collaborative environment or efficiencies associated with the intrinsic characteristics of a process. For example, process gains could include the synergies and learning that can occur in a group environment [Nunamaker et al., 1991a] or the advantages associated with parallelism in a computer-supported environment. *Process losses* are inefficiencies

associated with the intrinsic characteristics of a process or factors that decrease its performance [Dennis, 1996]. Nominal groups exhibit neither (communication) process gains nor losses, because there is no intermember communication. In contrast, there can be extensive communications among the members of a real group that can have positive or negative effects, leading to process gains or losses. Dennis and Valacich [1993] and Nunamaker et al. [1991b] focused on the gains and losses associated with communication and identified literally dozens of potential process losses. The most prominent of these process effects are production blocking, evaluation apprehension, and **free-riding**, each of which we examine in this section.

50.3.2 Production Blocking

Production blocking is the process loss that occurs in a face-to-face environment when more than one participant wishes to speak concurrently. Speaking requires mutually exclusive access to the floor, so only one person can speak at a time. Allocation of this air-time resource is managed by various social protocols. The delay caused by the associated access contention and its cognitive side-effects is a key source of productivity loss in face-to-face group problem solving. Computer-supported communications ameliorate this kind of production blocking by allowing simultaneous or parallel communication. The blocking is alleviated by a combination of parallel communications, which enable more than one participant to communicate at a time, and extensive logging of communications, which enables later access to these communications. Logged communications also provide a group memory, which reduces the need for members to keep abreast of and remember exchanges, reduces the cognitive effort required by listening, and facilitates reflection on what has been said.

Production blocking has many implications for group interaction. For example, participants who are not allowed to speak at a given point may subsequently forget what they were going to say when they are finally able to speak. Furthermore, after listening to subsequent discussion, participants may conclude that what they had intended to say is now less relevant, less original, or less compelling. The participant may not be accurate in this assessment, but in any case, the group does not know what they were thinking. This could in turn affect how the overall group discussion proceeds. Another effect of blocking is that individuals who are waiting to express an idea must concentrate on what they are about to say instead of listening to what others are saying or thinking productively about the problem. They may waste their cognitive resources trying to remember the idea rather than generating new ideas. Additionally, the act of listening to others speak may block individuals from generating alternatives [Nunamaker et al., 1991a]. Despite its benefits, there are also complications and costs associated with the parallel, synchronous, or asynchronous communications that alleviate production blocking. McGrath and Hollingshead [1994] observe that there is a potentially high cognitive load and possible sequencing complications to discourse caused by these communications, with the result that elimination of blocking can lead to information overload.

50.3.3 Anonymity and Free-Riding

Another phenomenon that affects the productivity of group communications is *evaluation apprehension*, a psychological and socially based effect, unlike production blocking, which is a physical effect based on the mutual exclusion required for speaking. Evaluation apprehension is the fear of being criticized for an opinion one expresses, causing an obvious process loss [Dennis and Valacich, 1993]. It especially affects timid or low-status individuals.

A simple **process structure** proposed to decrease evaluation apprehension is to impose a moratorium on criticism at points where individuals propose opinions, a policy that can easily be implemented in face-to-face and computer-supported environments. A standard mechanism for reducing evaluation apprehension is anonymity or anonymous communication. Anonymity allows individuals to present their ideas without fear of being openly embarrassed by critical comments and without having to challenge openly the opinions of others. The risk of embarrassment or even retaliation in an organizational environment is substantially decreased if no one can be sure who made a comment. Anonymity is straightforward to implement in

a computer-supported environment, although there may be technical issues (related to system security and the trustworthiness of the software) in guaranteeing anonymity. On the other hand, if members of a small group know each other well, they may be able to guess the author of an anonymous exchange [Nunamaker et al., 1991b]. According to Nunamaker et al. [1996], however, such guesses are more often than not incorrect.

The effects of anonymity have been especially well studied for idea generation or brainstorming tasks, with interesting results obtained in a series of papers by Nunamaker, Dennis, Valacich, and Vogel (e.g., Nunamaker et al. [1991b]). Prior research found that anonymous groups generated more ideas during brainstorming than nonanonymous groups when using computer-supported communication, at least for tasks with low levels of conflict and under appropriate circumstances. Such groups also judged the interaction process to be both more effective and more satisfying, with similar results obtained in a variety of experimental settings. This occurred for groups with preexisting group histories and those without, groups of varying sizes, and groups from public and private organizations [Nunamaker et al., 1991b]. However, although so-called *negotiation support systems* increase idea productivity or generation of alternative solutions in low-conflict situations, these systems do not appear to have a significant impact on idea generation in high-conflict situations. Some have proposed using interaction processes that require a noncritical tone for group interactions to enhance idea generation, but in fact conflict and criticality of tone seem intrinsic to such processes (see, e.g., Connolly et al. [1993], which evaluated the effect of anonymity vs. evaluative tone).

The impact of anonymity on idea productivity is most pronounced in groups with high status differentials, with behavior changing as one migrates from a peer group to a status group. There is little impact from anonymity in laboratory-scale groups where there are no preexisting power structures, no preexisting vested interests in outcomes, and no fear of negative consequences for nonconformity, but there are significant anonymity effects in groups with existing organizational contexts [Nunamaker et al., 1991b].

Another important process loss is free-riding, the type of loss that occurs when some members of a group rely on others to do the group's work without making their own contribution or making minimum contributions [Dennis et al., 1990]. This loss is also called *social loafing* [Latane et al., 1979]. Free-riding can occur in any group environment. In a face-to-face environment, free-riding is exacerbated by physical group size, because size provides for a degree of anonymity in a physical environment. In a computer-supported environment, group size may promote free-riding, but anonymity is a more likely factor (see, e.g., Dennis and Valacich [1993] and Dennis et al. [1990]).

Computer-supported communications have both positive and negative impacts on free-riding. On the one hand, anonymous mediated communications can increase free-riding, because it may not be evident which members are contributing. That is, anonymity decreases accountability, thereby increasing free-riding. On the other hand, computer-supported communications lessen the barriers to participation in group exchanges.

50.3.4 Process and Task Structures

A process structure is an overall organization for group interaction. A variety of process structuring techniques has been developed, including dialectical inquiry, devil's advocacy, and the Delphi method (see Nunamaker et al. [1996] and Dennis et al. [1997]). *Dialectical inquiry* structures group interactions by splitting participants into subgroups, each of which argues for one alternative solution to a problem and against another. This tends to yield a more complete problem analysis. A related approach is *devil's advocacy*, in which one subgroup acts as a foil to dispute a solution proposed by another subgroup, thereby structuring the evaluation process. Similarly, the *Delphi method* is used "to develop the strongest pro and con arguments for alternative resolutions to a policy issue" [Turoff, 1991] using (but not restricted to) domain experts to represent alternatives and combining alternative generation and evaluation (see Hiltz and Turoff [1993] for an extensive review of this technique).

Process structures are *global* if they apply to the entire interaction process and *local* if they apply to only a single step or phase of the interaction. An example of a global process structure is an agenda or

set of rules according to which a meeting will be conducted. DeGross et al. [1990], in a broad-ranging review, concluded that participants in computer-supported groups rated the process support provided by anonymity and the process structure provided by agendas as the most crucial elements of such systems. Agendas help ensure focus and proper allocation of time, so that pertinent issues are not overlooked and premature decisions are not made [DeGross et al., 1990]. The human facilitator frequently provided in electronic meeting systems (EMS) to direct the process represents a global process structure.

Information technology has usually supplied task support for accessing and integrating information, such as allowing group members to access a database. In contrast, task structure uses analytical techniques to improve group decisions and can be either qualitative or quantitative. Qualitative techniques include stakeholder analysis, value chain analysis, and assumption surfacing. Task structure information could be constructed by a human facilitator for an environment. An example is cognitive maps that depict the relations between the comments in a discussion for the purpose of clarifying the influence of one discussion factor on another or for depicting causal relations between factors [Nunamaker et al., 1996; Dennis et al., 1997].

Process structures are not organizationally neutral. Because they determine the patterns and timing of interactions — namely, what, when, how, and by whom things are done — they must address the question of roles: who does what. Consequently, process structures provided by groupware presuppose some kind of group organization. Kernaghan and Cooke [1990] identify three organizational styles typically used by groups for planning. In interacting groups, discussion is unbridled except as directed by the basic charge of the group and the time allowed for discussion. In leader-directed groups, the group leader is the individual recognized as most capable or who is able to identify the most talented members of the group. In nominal groups (a different use of the term than Steiner's), there is no formal group leader; each member states the problem and records responses and suggestions, with group decisions made on the basis of rankings and votes.

50.3.5 Process Support Tools

Templates are built-in sequences of problem-solving activities and so represent a type of global process structure. The templates a groupware environment provides to manage interactions may be hardwired into the interface or merely offered as options. As Nunamaker et al. [1996] observe, “Having a set of standard templates for processes can make it easier for a group to decide what tools to use and what processes to follow.” Voting or group polling is useful for dynamically clarifying deliberations, because it helps a group to understand the nature of its disagreements, focusing the direction for the next round of group interactions. This method is also good for the standard purpose of recognizing when consensus has been reached.

Computer-supported environments transform the role of traditional consensus and approval methods like voting. In conventional interactions, voting typically occurs when discussions are nearing completion and is used to close, consummate, or approve conclusions. Computer-supported polling is much more dynamic and provides the group with the opportunity for real-time feedback on the collective state of mind of the group. “Teams find that [electronic] polling clarifies communication, focuses discussion, reveals patterns of consensus, and stimulates thinking” [Nunamaker et al., 1996]. Thus, voting becomes a problem-clarification tool, an alternative-selection tool, and a tool for facilitating consensus-based meeting management. Voting also supplements the information deficit caused by the reduced cues in a distributed meeting.

50.4 Information Sharing

The exchange of information is a defining difference between individual and group problem solving. Despite this, it is often done incompletely and exchanged information is often used ineffectively. This section looks at factors that affect how groups handle information, including the availability characteristics of information (such as whether it is initially common, unique, or partially shared among its members), and issues related to opinion formation, like the role of **information influence** and normative influence.

50.4.1 Information Availability

Information available to a group can be characterized as common, unique, or partially shared. **Common information** is known to every member before work begins. **Unique information** is initially known to only one member. Partially shared information is known to a subgroup prior to collaboration [Dennis, 1996].

The way groups react to shared information can be subtle. Results by Stasser et al. [1989] indicate that information unique to the presenting individual tends to be ignored by the group after its initial presentation more than common information. Group decisions tend to be based on preexisting, commonly held information rather than unique information exchanged in meetings [Gigone and Hastie, 1993]. There are also cognitive effects related to whether or not information supports an individual's preexisting preferences. For example, if information is exchanged, only some elements of which support aspects of an issue, participants tend to focus on those elements that support their preexisting preferences and discount those contrary to existing preferences, although this depends on the prevalence of a preference. Individuals also tend to assume the majority opinion is at least the correct frame of reference and interpret their own preferences in reference to it.

50.4.2 Opinion Formation in Computer-Supported Groups

Mere dissemination of information is not enough to establish or alter opinions. Doing so depends strongly on normative and information influence. *Normative influence* is based on the status of individuals proposing information or extraneous factors like the attractiveness of an advocate, the number of people supporting a position [Dennis, 1996], or sanctions imposed for nonconformity [Short et al., 1976; early work by Deutsch and Gerard, 1955]. This contrasts with *information influence*, which is based on the exchange of facts, ignoring social status clues. Information influence theory (also called persuasive arguments theory) proposes that individuals change their opinions primarily based on factual information [Dennis, 1996]. Normative influence theory (social comparison theory), on the other hand, claims that individuals adapt their opinions to conform to social norms, so that the preferences of the group are more critical than the information exchanged for decision making. To some extent, normative influence theory asserts that mere exposure to preference information is sufficient to alter preferences, although the evidence is inconclusive [Myers and Lamm, 1976; Dennis, 1996]. Normative influence theory also tends to imply that mere public assertion of a preference reinforces the acceptance of that preference.

Group support systems appear to increase the role of factual information or information influence relative to participant preferences or normative influence because of the process gains they provide. One reason is that the members of a computer-supported group can enter information more easily, because parallel input eliminates the input-driven production blocking characteristic of face-to-face environments. Furthermore, since parallelism removes the conceptual dependencies associated with sequential presentations, more themes or threads tend to emerge in such parallel environments than in face-to-face environments, whose sequential character makes them more subject to cognitive inertia [Dennis and Valacich, 1994]. The parallel communication also reduces the blocking in face-to-face environments related to the mutual exclusion between listening to information and processing that information. The group memory that group support systems provide also facilitates recalling common or shared information and unique information.

According to Dennis [1996], computer-supported environments increase information exchange relative to face-to-face groups, but the increased exchange does not appear to improve the group decisions or increase consensus. Computer-supported groups exhibit the typical predilection for common information over unique information exhibited by face-to-face groups and the same tendency for information that supports their preexisting preferences, rather than for neutral information or information that opposes *a priori* preferences. Such preferences, when expressed by a group leader, strongly affect both group discussions and outcomes [Janis, 1982]. Significantly, computer-supported groups are even less likely to use the information they exchange and take longer to make their decisions, even though those decisions are not, on average, better. The impact of group support systems on consensus change, defined as the difference between individuals' opinions before and after the group decision, reveals no significant differences between computer-supported and face-to-face groups. In most other respects, computer-supported groups

exhibit the same cognitive failings that face-to-face groups do. In fact, members of computer-supported groups were even more likely than face-to-face groups to contribute information that supported their *a priori* preferences; this was true regardless of the kind of information exchanged. Members of computer-supported groups also recall less originally unknown information than members of face-to-face groups. Overall, while the availability of parallel communication, anonymous communication, and group memory substantially increases information exchange, the members of computer-supported groups appeared to not use the exchanged information to improve their decisions.

The information activities of a group consist in information exchange, information use, and information recall. Each of these places its own cognitive demands on the members of the group, each of whom has limited cognitive resources available for these activities. Petty and Cacioppo [1986a] have observed that processing preference information is less cognitively demanding than processing factual information. One consequence of this is that if too much factual information is shared or shared too rapidly, the individuals in the group tend to deal with the more easily processed preference information first. Since the very availability of information in computer-supported environments tends to flood participants with information for which the processing time is limited or unavailable, factual information may be processed inadequately, poorly integrated with existing information, or replaced altogether by the more readily processed *a priori* preference information. The same effect can occur on purely perceptual grounds if individuals merely perceive that extraction of available information from the computer-supported source is awkward or tedious. Failure to use information available in a computer-supported environment may also be due to unfamiliarity with how to use the system because of lack of prior experience. Other factors affecting the impact of information on a decision-making deliberation are the perceived importance, novelty, and credibility of the information [Dennis, 1996].

We previously discussed process gains associated with anonymous communication in computer-supported groups. Because these gains also affect how information is evaluated, they are not without associated process losses. For example, there is a trade-off between anonymity and credibility because credibility is negatively affected by anonymity [Dennis, 1996]. The credibility of a source of information critically influences its acceptability, particularly if the information is ambiguous or difficult to process [Petty and Cacioppo, 1986b]. When the source is anonymous, this credibility is harder to evaluate. Source anonymity also makes it harder to challenge the contributor. Thus, a key question becomes whether anonymity reduces source credibility to such an extent that it also reduces information processing. However, anonymity also reduces the impact of the dominant group preference [Nunamaker et al., 1991a, 1991b] and thereby of *a priori* preferences. In nonanonymous environments, members maintain their positions and contribute information to the group on the basis of whether it undermines alternatives presented by other members or supports their own preferences. This is less of an issue in an anonymous environment, because there is little need to save face in defense of previously announced public preferences, because those preferences are anonymous [Dennis, 1996].

50.5 Groupware

The context of a collaborative technology has a decisive influence on the success of that technology, yet the organizational, motivational, political, and economic factors that are central to group activity are infrequently addressed explicitly in the design of collaborative systems [Deek and McHugh, 2003]. Grudin [1994] identified various impediments that hindered developing and using groupware systems. To begin with, there is often a perceived disparity between the effort required to work in collaborative environments and the benefits perceived to accrue from their use. Collaborative tools require a critical mass of users to succeed, and thus must pass an initial adoption barrier before which the tool may not appear to be to the advantage of any single individual in a prospective collaborative group. Collaborative environments also tend to level the playing field, violating in-place social hierarchies. Groupware may not be flexible enough to accommodate the exception handling and improvisation required by group activity. Infrequently used features often obscure functionality by being integrated with less frequently used features. Groupware is also more difficult to evaluate than single-user systems, which are not affected by the backgrounds or

personalities of group members. Groupware systems are often developed based on the needs of a subset of users or on experience from single-user applications. Developers often fail to recognize that groupware applications require participation from a range of users. With any computing system, organizational integration is critical, but especially careful efforts must be made to ensure that groupware is accepted on an organizationwide basis.

The success of e-mail provides an interesting reference point for understanding collaborative environments [Grudin, 1994]. In terms of effort vs. benefit (perceived disparity), e-mail provides a reasonable balance between sender and receiver, with the sender incurring somewhat more effort because the message must be composed and entered, while the receiver merely reads or scans a message. Critical mass is trivially attained, because even with only a single other user, e-mail can be useful; furthermore, its marginal utility increases monotonically with the number of other users. In terms of social practice, e-mail is natural and conversational. On the other hand, e-mail may upset or alter the typical communication patterns of organizational bureaucracies (disruption of social processes). Information flow between organizational units is usually vertical, in contrast to the lateral communication provided by e-mail. The asynchronous character of e-mail makes its use robust, and its basic features are easy to learn (unobtrusive availability). Evaluation of its costs and utility can be complex to determine, but its widespread use demonstrates its success. The vector of how e-mail use spread (adoption) is also notable, beginning in academic environments and spreading to business and popular uses, rather than through marketing.

Groupware applications tend to require additional work in order to enter the information the application requires for its tools or features to work. Because the benefits of the features may vary among group members, it may not be easy to get every individual to cooperate with this increased entry requirement, because of perceived and possibly real disparity in benefit. For example, scheduling tools primarily benefit one person, so the asymmetry or nonuniformity of the benefit vs. the cost in effort for the members may cause such tools to go unused, representing a so-called *misaligned benefit* [Grudin, 1994]. Testing or evaluating groupware is vastly more complicated than evaluating single-user systems (see Fjermestad and Hiltz [2000]). While laboratory-scale experiments can ferret out the perceptual, cognitive, and motor aspects of single-user applications in a relatively straightforward way, this is a labyrinthine task for group systems, which have inextricably embedded social, political, and motivational factors that influence their usability [Svanaes, 2001]. The acceptance of groupware is particularly sensitive to how it is introduced, because acceptance is required by all the individuals in the group expected to use the system (see Majchrzak et al. [2000]). Because groupware requires possibly substantial learning in order to extract its benefits, an incremental approach that simplifies learning and acceptance is to introduce groupware by adding or overlaying groupware functionality on existing systems.

These impediments challenge the design and acceptance of groupware. The perceived disparity and critical mass effects can be mitigated by educating potential users to the advantages of the systems, such as via training programs that enhance the sense of self-efficacy, defined in cognitive theory as the belief that one is able to use such technologies effectively [Compeau et al., 1999; Deek et al., 2003]. Nidamarthi et al. [2001] emphasize that collaborative environments should supplement, rather than replace, existing methods of communication. The systems should not destabilize traditional, effective means of communication, such as pencil-and-paper calculations. This criterion has implications for the specification of the technological implementation of collaborative systems and suggests the importance of a bottom-up view of groupware design, where systems are built on top of features that support the activities of individuals.

50.6 Research Issues and Summary

This chapter has selectively reviewed research concepts and principles in the area of computer-supported collaborative work, focusing especially on the following:

- Media issues that arise in synchronous and asynchronous distributed collaboration
- Basic characteristics of face-to-face and distributed interactions
- The structure of interaction dialogs

Evaluation of the performance characteristics of computer-supported interactions
Challenges that arise in establishing the shared ground necessary for collaborative work
Various social–psychological effects, like group polarization, which manifest themselves in group environments and which may be either exacerbated or attenuated in computer-supported environments
Management information impacts, like the equivocality of information
The diverse effects and consequences of asynchronous vs. synchronous communications

We also address the impact of CSCW on the productivity of group work and specific types of process losses and process gains, like production blocking and anonymity, which arise in or may be ameliorated by computer-supported environments. We consider the impact of the distributed and partial awareness of information on group decision making and of social psychology factors, like normative influence, on opinion formation. Finally, we examine some of the organizational phenomena that can impede the adoption of groupware systems that support CSCW.

We have only touched the surface of the conceptual, perceptual, psychological, social, cognitive, technical, organizational, and process issues in collaboration. These issues have become increasingly important because of the rapid advances in computer interfaces and networked computing and the impact of these advances on CSCW. All of these areas are the subject of extensive research and development interest. For example, in the area of human cognition in distributed environments, an extensive body of theoretical and experimental knowledge has been developed, including quite sophisticated mathematical models and simulations of distributed cognition and also elaborations of classical models of individual cognition. There have been extensive empirical and statistical studies on the impact of computer support on groups' productivity, as well as much research on the correlative issue of statistical design (see Deek and McHugh [2003] for further discussion and references).

Defining Terms

- Anonymity:** Anonymous computer-mediated communications intended to reduce evaluation apprehension, especially in the presence of status differences or pressure to conform.
- Collocated work:** Collaboration where participants are at a common site with workspaces separated by a short walk (less than 30 meters).
- Common ground factors:** Environmental characteristics that facilitate establishing a shared collaborative experience. These characteristics include factors that enhance cueing (copresence, visibility of participants to each other, audibility, contemporality [immediate receipt of messages], simultaneity [all participants can send/receive messages simultaneously]), and factors that enhance message quality (reviewability [messages can be reviewed later] and revisability [messages can be revised before sending]).
- Common information:** Information that is known to all the members of a collaborative group prior to group discussion.
- Deictic reference:** Pointing to objects or ideas, gesturing, and ability to use *this* or *that* as references, for example, supported in a distributed environment by a telepointer.
- Equivocality:** This refers to uncertainty about the meaning of information. Consensus interpretation can be obtained by using negotiation to converge on an accepted meaning.
- Free-riding:** A type of process loss in which members of a group rely on others to achieve the task without their own contribution. In a noncomputerized environment, this is exacerbated by physical group size; in a computerized environment, this may be exacerbated by anonymity.
- Group polarization:** This phenomenon, also called *risky shift*, refers to the alleged tendency of groups to adopt more extreme positions or decisions than individuals, possibly because of normative influence.
- Information influence:** Support for an opinion derived from primary factors, such as the correctness, quality, or persuasiveness of information, rather than from social factors, such as the status or number of advocates of a position.

- Interaction environment:** The mechanism through which interaction occurs. In face-to-face interactions, it is the physical world. In computer-mediated environments, it is the technological or interface support system.
- Normative influence:** Support for an opinion derived from secondary factors, such as the number or the status of participants who hold a position. Normative influence also refers to the tendency of individuals to defer to what they perceive as the group opinion without the need for group pressure, coercion, or persuasion.
- Process gains:** Factors that increase performance in a collaborative environment or efficiencies associated with the intrinsic characteristics of a process, such as possible synergies and learning that can occur in a group environment.
- Process losses:** Inefficiencies associated with the intrinsic characteristics of a process, or factors that decrease performance. For example, in verbal communication, speakers must take turns speaking because only one person can have access to the floor at a time.
- Process structure:** Rules for directing the pattern, sequencing, or content of communications among group members. Group process structures include techniques such as dialectical inquiry (subgroups argue for different alternatives) and devil's advocacy (one subgroup acts as the foil to dispute a solution proposed by another subgroup).
- Production blocking:** Blocking associated with mutually exclusive access to a resource. For example, in a verbal exchange, only one person can speak at a time, so other participants are blocked in the meantime. Mitigated by simultaneous communication, such as that provided by groupware.
- Tightly coupled work:** Work that is not partitionable into subtasks requiring limited and less frequent communication among individuals. Tight coupling requires rapid and frequent communications, particularly for ambiguity resolution or repair, and may require geographical colocation. Design is typically tightly coupled, whereas a task like coauthoring is only moderately coupled.
- Unique information:** Information that is known only to a single member of a collaborative group prior to group discussion.

Applying International Usability Standards

51.1 Introduction

51.2 Underlying Principles

User Interface Reference Models • The IFIP Reference Model
• Usability Test Criterion • Structure and Content of the
Usability Standards • Standards in Relation to the European
Council Directive

51.3 Best Practices

Standards as Guidelines • User Participation • Analyzing the
Context of Use • Coping with the Uncertainty Principle in a
Design–Use Cycle • Conformity in Terms of Usability Test
Criteria • Conformance Testing vs. Heuristic Evaluations

51.4 Research Issues and Summary

Wolfgang Dzida

Pro Context GmbH

51.1 Introduction

Two types of standards are distinguished in **user interface** technology: standard user interfaces and standards *for* user interfaces [Stewart 1990]. The first type establishes a *de facto* standard for user interface implementation, either provided as a corporate standard by a leading software producer (e.g., OPEN LOOK [Sun 1990] and Windows [Microsoft 1994]) or defined by consensus within the software industry (see OSF/Motif [OSF 1994; Berlage 1995]). The second type comprises a series of standards [ISO 9241 1999, Part 10 through Part 17] that are devoted to dialogue techniques of interactive systems, such as menu dialogues or **direct manipulation**. These standards provide design recommendations but do not include any guidance for implementation, nor do they involve toolboxes or programming interfaces. In addition to the product design standards, a process standard has been published [ISO 13407 1999] providing recommendations for user-centered design processes, such as context and requirements analyses. Meanwhile, usability engineering has been established as a discipline on its own right, like software engineering [Mayhew, 1999; Rosson and Carroll, 2002]. Both disciplines will set their own standards, as is typical with traditional engineering disciplines (e.g., civil engineering). Hence, the previously mentioned standards for designing products and processes can be called *usability standards* or *usability engineering standards*.

As is usual in the standardization of interface components for system-to-system interaction, the existing technologies of different companies are integrated by consensus — for example, so-called computer-aided design (CAD) frameworks to link CAD tools or protocols to ensure that different applications can interoperate at run-time. This kind of standardization is aimed at reducing development costs and time to market, an approach driven mainly by technology. One may therefore call this type of standard

a *technical* standard. The second type of standard, the standards for user interfaces, may appropriately be called *ergonomic* standards. Hence, the design object is far more than purely technical, because the interface component is not located between technical components but between user and system. Standards for user interfaces hold for a variety of user interface products in all kinds of interactive systems and applications.

The major difference between the two types of standards is that ergonomic standards do not merely rest on the technical state of the art. Rather, their development is predominantly determined by the state of evidence obtained from ergonomic research [Dzida 1989]. The impetus for developing ergonomic standards is to achieve an acceptable level of ergonomic quality according to the current state of knowledge in the community of ergonomists.

Standards may also be distinguished by their scope of validity, which range from locally defined proprietary guidelines to international standards or directives. Within a software company, the user interface designer may be required to stick firmly to the corporate style guide and the associated toolkit, thereby assuring that similar interfaces are implemented for different applications [Pangalos 1992]. Consistency in design can be the main benefit for the user; however, designing consistency with the aid of user interface toolkits addresses only the tip of the iceberg [Berry 2000], that is, about 25% of usability [Travis 1997].

The international standards pursue more ambitious objectives than proprietary guidelines. They define a minimum level of usability that should be respected within an international market. Accordingly, the European Council Directive [ECD 1990] requires by law that interface design adhere to such a minimum level of ergonomic quality, so as to establish a harmonized level of work conditions across all member states of the European Union.

Many people are concerned about whether too much standardization in the user interface area might stifle the designer's creativity and competition between companies, in the same way that copyright might stifle them [Samuelson 1995]. Some of this criticism may apply to early approaches to ergonomic standardization and may still be valid for standard interfaces; for a discussion of further objections to standard interfaces, see Potosnak [1988]. However, the international ergonomic standards developed by the International Standards Organization [ISO TC 159/SC 4/WG 5, 2003] cannot be viewed in that way. ISO standards rely on consensus about the minimum level of quality to be required; above that level, there is freedom of design.

Sometimes standards have also been suspected of freezing a certain state of technical development. The innovative progress in user interface technology, however, should not be impeded by the ergonomic type of standards, because they are neutral toward any specific implementation. Nevertheless, standard user interfaces may have a conservative effect in the long run, unless new standard interfaces can outlive the established ones. The freezing of a state of technology may in fact be favored, if a standard interface is widely accepted as a reference for high quality.

This chapter focuses on international software ergonomic standards, increasingly referred to as usability standards. A methodology of testing products for compliance with international standards is of central concern, because a standard can contribute to improved design solutions only if the methods of requirement specification and testing are well accepted. Although usability standards suggest a procedure for requirements specification as well as for conformance testing, the "level of specification of the procedure is a matter of negotiation between the involved parties" [ISO 9241-14 1997, par. 4.3]. Relying only on such negotiations, however, will make it impossible to compare the quality of different products. Moreover, the negotiating partners must not specify usability requirements below the minimum level that is the defined in the usability standards.

The approach presented in this chapter has not yet achieved international consensus. However, a standard usability test has been agreed on at a national level. DATech [2003], the German body for the accreditation of test laboratories, is authorized to publish such a test in order to avoid letting a statement of conformity with a standard be an arbitrary interpretation of the standard. The DATech test procedures for usability of products and the maturity of processes are offered as downloads on the German DATech home page [DATech 2003].

51.2 Underlying Principles

Testing of **usability** has achieved the level of a standard procedure during the last decade. This chapter describes some methodological foundations that generally apply to usability testing of interactive systems and which may be of particular concern when testing products for conformity with standards. Key methodological questions include the following:

What portion of the user interface is under study?

What are the leading design objectives (principles of quality)?

How is usability embedded into a general quality model of software?

How are usability requirements structured in the international standards, so as to find them easily and apply them to design decisions or **conformity tests**?

Finally, the liability of ergonomic standards in an international market is addressed, especially from the perspective of the European Union.

51.2.1 User Interface Reference Models

To structure the rather complex user interface, through which the user interacts with the application program, one may specify areas of an interactive system particularly apt for usability design and evaluation. A number of human–computer interaction reference models have been published; for a survey, see Spring et al. [1993]. Some of the reference models are devoted to a functional specification, some describe system architectures, and others provide conceptual models [Norman 1988] for users. Conceptual models include a specific interface model, layer models [Fährnich and Ziegler 1985], and linguistic models of interaction [Moran 1981; Myers 1989; Marcus and van Dam 1991]. An interface may be described by a set of rules (or attributes) that determine the interchange of data (information) between user and computer. The interface model was developed by the International Federation for Information Processing (IFIP) Working Group 6.5; for the original model see IFIP [1981], and for its formalized description see Dzida [1987, 1988].

Information designers of user interfaces confine their concept of an interface to only one component (i.e., the input/output interface), which is characterized by facilities of data input as well as attributes of data presentation (such as grouping and coding of data or echoing keystrokes and mouse clicks). The software designers' conceptual models (e.g., the MVC model [Goldberg 1990] or the PAC model [Coutaz 1987]) do not necessarily fit well with the users' conceptual model of an interface.

Incompatibility was uncovered, particularly for inheritance-based decompositions of interactive systems [Wegener 1995], which aimed at taking better account of the reusability of interface components. Abstract data types representing the input/output interface (e.g., push buttons, menus, icons) can be well separated as far as they are neutral toward the application. But data types for the **dialogue** have not found their way into the software designers' conceptual model as explicit abstractions; they are represented as part of input/output or application (sometimes both), but not separately. Separate data types for the dialogue thus appear to be irrelevant for software designers, although this concept remains significant from the user's perspective. As a consequence, the designer may develop an interaction between user and system with a concept of interface in mind that may be more restricted than the user's model. This may bring about a limited understanding of how the user wants to conduct a task.

51.2.2 The IFIP Reference Model

The IFIP user interface reference model (Figure 51.1) had some impact on the structure of international usability standards, insofar as ergonomic principles of design could be grouped according to the conceptual components of the user interface.

The user's interaction with the system is enabled by an interface, which can be structured into three interface components, each representing a separate aspect of interaction: input/output; the conduct of dialogue; and access to tools, services, or data. This structure can be amended by a fourth component for involving a specific type of interaction: information exchange in an organization or within a computer

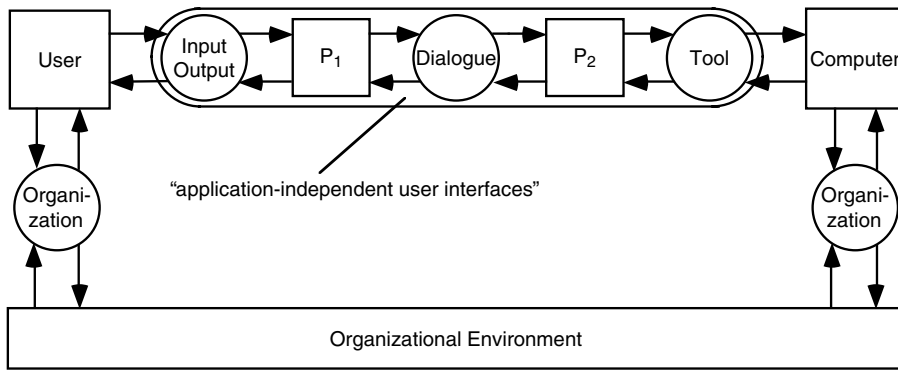

FIGURE 51.1 User interface reference model of IFIP WG 6.5. (From Dzida, W., *Psychological Issues of Human-Computer Interaction in the Work Place*, North-Holland, Amsterdam, 1987. With permission.)

network (see the organizational interface). Whereas the first three interface components are always available when using the computer as a tool, the fourth component is typically available when using the computer as a medium. An advantage of the model is its focus on four relatively independent concepts appropriate to structuring the interface and distinguishing between the computer as a tool and as a medium. The focus facilitates communication between users and designers on usability issues or on those issues that pertain to the design of a medium. Objectives for designing a medium may be incompatible with usability objectives. The Internet provides many examples demonstrating, for instance, the incompatibility between usability and marketing objectives.

In Figure 51.1, circles indicate interfaces, rectangles represent activities (processes), arrows point to the direction of dataflow.* From the user's point of view, the four interface components are of central concern, but the user may also be interested in the processes (e.g., P_1 and P_2) representing software components of the user interface provided by a user interface management system (UIMS) or application program. For instance, P_1 may realize a user input and then react by echoing the input; P_2 may prompt the user for further data input or signal an input error. P_1 and P_2 do not necessarily induce data processing by the application program, but they do change the display state. A separation of display-related interaction and task-related interaction can be introduced this way. This is a necessary conceptual separation, because the user is interested in the effects of an input (i.e., whether it solely changes the attributes of the screen or causes a transition from the current data state of a task at hand to a new data state).

A feature of the model that relies on the Petri net notation is the assimilation of three components into one interface, indicating that the user is virtually faced with one interface that presents three of the interface aspects simultaneously before or after running the application program. (See Figure 51.1) Note that the Petri net notation does not account for time relations among interface components; only causal relations are addressed.

Before design principles are discussed for the user interface components, their functions and attributes are described.

51.2.2.1 Input/Output Interface

This part is often referred to as the *surface* of the software. Rules for user input and system output govern the interface — for instance, movement and positioning of the cursor by a mouse or arrow keys, placement of a pop-up menu or an icon, size of a window, highlighting of a menu option, color coding, and information design. The design of this part of the user interface is predominantly captured by toolboxes or UIMSes. The notion of user interface is sometimes confined to this interface component, that is, to the tangible surface characteristics. This is, of course, too narrow a concept.

*The syntax of the model uses a type of Petri net called a *channel agency net* [Reisig 1985].

51.2.2.2 Dialogue Interface

Interaction with the system is dialogue-like: the user receives information and can control the system by means of an interface language. This language addresses the meaning of communication, including command names, letters of shortcut keys, symbols, direct manipulation, voice input, and gestures. Furthermore, the data exchange necessary for conducting a task characterizes the dialogue, which includes activities such as prompting, interrupting, switching to another window, and resuming an editing process. Also, data exchange is necessary after task accomplishment, such as recovering from errors in response to error messages, adhering to warnings, system messages, and help information. Characteristics of the dialogue (e.g., being sequential, asynchronous, or concurrent [Hartson 1989; Hartson and Hix 1989]) may also help to determine this interface.

51.2.2.3 Tool Interface or Application Interface

Rules or conventions govern the access to tools, data, and services. The user may want to undo the change of data, put into sequence a number of tools by a pipe (as in the UNIX system), concatenate tools in terms of a macro or a command procedure, or configure the set of tools actually necessary for use. Characteristics of tools determine this interface (e.g., generic or specific, elementary or compounded). There is no doubt about the impact of the tool interface characteristics on the usability of software. However, many of these characteristics are highly application-dependent compared with the attributes of dialogue or input/output. Consequently, the international standardization group restricted the scope of ergonomic requirements to application-independent characteristics. Nevertheless, the tool interface should not be ignored when evaluating the usability of software beyond the ergonomic standard requirements.

Notably, the IFIP user interface reference model has influenced the Seeheim model of interactive systems [Pfaff 1985], which is an approach to developing a system architecture that is effective in usability engineering for the development of UIMs [Olsen 1992].

51.2.2.4 Principles of Design

The interface components of the reference model can help apply the principles of ergonomic design. They represent objectives of usability, the achievement of which is verified when a number of conceptually coherent user requirements have been satisfied.

The following principles of information design pertain to the input/output component of the interface [ISO 9241-12 1998]:

- **Clarity** — The information can be quickly conveyed.
- **Discriminability** — The information items can be accurately distinguished.
- **Conciseness** — Only necessary information is given.
- **Consistency** — The expected information is given in the same way.
- **Detectability** — Attention is directed to the information required.
- **Legibility** — The information is easy to read.
- **Comprehensibility** — The meaning is clearly understandable.

The following principles of ergonomic dialogue design are published in ISO 9241-10 [1996]; for the empirical basis of these principles, see Dzida et al. [1978]:

- **Suitability for the task** — Only relevant and task-related steps are required.
- **Self-descriptiveness** — The information is immediately clear or clarified on demand.
- **Controllability** — The user is in control of the dialogue steps required by the task.
- **Conformity with user expectations** — The dialogue fits well with conventions and user attributes.
- **Error tolerance** — Mismatches are prevented or can be managed with minimal effort.
- **Suitability for individualization** — The dialogue can be adapted to individual, special needs.
- **Suitability for learning** — Explorative system use is beneficial for becoming an advanced user.

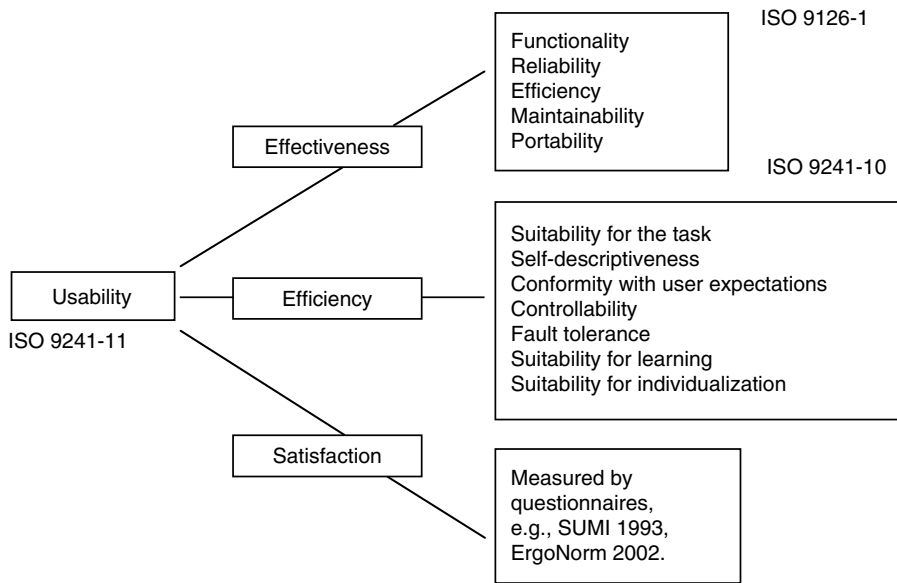

FIGURE 51.2 Usability quality model.

Although the international usability standards rarely involve ergonomic requirements for the design of the tool interface, a list of such principles is presented below as a suggestion; see also ISO/IEC 9126-1 [2001] and McCall et al. [1977]. In software development, it is indispensable to adhere to these principles, so that the user can use the software effectively (see effectiveness as a factor in the quality model, Figure 51.2; see also the definition of **usability**):

- **Functionality** — Functions suit user needs and provide accurate results.
- **Reliability** — System performance avoids faults or is fault tolerant.
- **Efficiency** — System performance provides appropriate processing time.
- **Maintainability** — Modifications include corrections, adaptations, and improvements.
- **Portability** — The software can be transferred to other environments.

Characteristics of the organizational interface are highly application-dependent and are therefore not an issue of ergonomic standardization; this interface will not be further discussed here. However, to be complete, as far as the design of tasks determines this interface (see the left part of the organizational interface in Figure 51.1), principles of task design [ISO 9241-2 1992] can help specify and improve the ergonomic quality of user performance. Regarding the organizational interface as a medium among computers of an organization (see the right part of the organizational interface in Figure 51.1), conventional rules of conduct may be described in terms of ergonomic principles of groupware design, which include suitability for cooperation, responsiveness, negotiability, and security [Herrmann et al. 1996]. As a medium, the organizational interface may also adhere to principles of marketing, especially in the Internet.

These principles help the designer to structure the short tradition of thought in usability engineering in abstract concepts, thereby developing a general understanding of user requirements. A specific requirement can be interpreted in terms of a principle, thereby guiding the designer and the user in achieving a common understanding. Principles may also help to clarify trade-offs and priorities among design proposals. Principles can also guide the reader of a standard to specify a requirement according to the needs implied in the product's context of use.

51.2.2.5 Usability Quality Model

Last but not least, principles of design contribute to the development of a quality model. A number of software engineering quality models have been discussed; see, for instance, Boehm et al. [1976] and McCall et al. [1977]. Results of this discussion have been crystallized in the international standards ISO/IEC 12119 [1994] and ISO/IEC 9126-1 [2001]. A usability quality model may analogously establish a framework of terminology for a growing international usability engineering community. After having structured the scope of usability design by means of principles, an attempt has been made to develop a usability quality model. But before presenting the suggested model (see Figure 51.2), the quality concept of usability must be defined.

Usability has been introduced as a general term for software quality; it replaces colloquial terms such as user friendliness or ease of use. In ISO 9241-11 [1998] usability is defined as the extent of **effectiveness**, **efficiency**, and **satisfaction** to which a product can be used to achieve specified goals in a particular **context of use**. Effectiveness, efficiency, and satisfaction can be viewed as the three quality factors of usability. Notably, high efficiency can only be achieved if effectiveness is given. Effectiveness is usually defined in terms of **task** results, and a degree of 100% effectiveness (complete and accurate result) is usually required. Given 100% effectiveness, the genuine ergonomic evaluation can take place, and the focus is then on the effort users must invest to achieve effectiveness. Effectiveness and efficiency are evaluated mostly by experts. But an expert may err, so the user's judgment about satisfaction is indispensable for usability evaluation. An observed dissatisfaction may help uncover a hidden shortcoming of the product. See Kirakowski and Corbett [1993] and also the ErgoNorm questionnaire [DATech 2002] for measuring subjective usability.

The usability quality model (Figure 51.2) introduces the concept of usability as one concept among many, but one that determines the overall quality of an interactive system. The rationale for setting usability as the ultimate quality objective is seen in the relation between validation and verification of quality. Adhering to software-technical principles just contributes to correctness, but a system being verified as correct is worthless to the user if it is invalid. The software-technical principles (e.g., reliability and functionality) determine the effectiveness with which a user can achieve a required task result. The usability-engineering principles (e.g., suitability for the task and controllability) determine the efficiency of user performance, with effectiveness included. (Note that efficiency of user performance and efficiency of system performance are distinguished.) The role of usability engineering in quality assurance is primarily appreciated due to its contribution to the validation of a product early in the manufacturing process [Dzida and Freitag 1998].

51.2.3 Usability Test Criterion

Testing an interactive system for usability requires that test criteria be specified. A usability **test criterion** is defined as a required level of measure, the achievement of which can be verified. To verify this level, the concept of usability is broken down into its constituent factors: effectiveness, efficiency, and satisfaction. As mentioned previously, effectiveness is assumed to be satisfied by the presence of all of the other technical quality concepts: reliability, portability, etc. Hence, a criterion of 100% effectiveness is postulated as a basis for an ergonomic specification of efficiency test criteria. Usually, these criteria are derived from subfactors (also referred to as *principles*) of efficiency. Two types of criteria should be specified during the construction of usability requirements:

- A **task performance** and its resulting effect, observable at the user interface or the outcome of a human cognitive process (user performance) accompanying a task performance
- A product attribute, which represents an appropriate design solution to enable the task performance or cognitive process

ISO 8402 [1994] defined a *requirement* as an expression of needs and/or their translation into stated requirements for the characteristics of an entity (par. 2.3). Although this definition is watered down in the newer standard ISO 9000 [2000], the good thinking in the original definition is that any requirement is twofold: a need and a corresponding product attribute. Hence, a usability requirement or test criterion is almost always expressed in terms of a task or user performance and a corresponding product attribute.

As an example of a required effect of task performance, consider the echoing of the selection of a menu option to the user. Note that, although echoing is an effect of task performance, it is not the intended (complete and accurate) final task result.

As an example of a required human cognitive outcome, consider the ability of a user to discriminate between active and nonactive menu options. Note here that discrimination is the required outcome.

As an example of a required product attribute, consider the use of brightness coding (highlighting) in menus to facilitate discrimination between active and nonactive menu options. Note that the highlighted menu option as an attribute is an appropriate design solution to enable a required user performance.

One may argue that echoing a user input is just as much a product attribute as highlighting a menu option. Indeed, an effect of task performance can be a user interface attribute. The difference, however, can be seen in the relation of an attribute to a user's activity (performance). When an attribute appears on the display as a consequence of such an activity, it is taken as an effect in the interaction. Effects are, for instance, echo, prompt, error or help message, alert, and cursor positioning. If an attribute is used to design for such an effect, it is taken as a product attribute. Highlighting, for instance, can be used as an attribute to design the system's echo (an effect) to the selection of a menu option (a user performance). Although the distinction between effects and attributes may appear artificial, it will become more useful when we deal with the evaluation of attributes that are task-related and those that are neutral (see [Section 51.3.5](#)). Effects are always task-related.

These examples illustrate how different kinds of usability criteria may complement each other in a design solution. Hence, when defining the user's list of requirements, it may be unsatisfactory to exclusively specify criteria in terms of product attributes because the designer may regard a required attribute as out of date or inconsistent with other design decisions. If the user simply requests a specific attribute, the designer may not know why. The level of measure to be specified for a test criterion, therefore, should consider the required effect of task performance at the user interface or the level of outcome of human performance. It should be up to the designer to select an adequate product attribute that fits well with the required levels of performance.

A user interface may provide numerous high-tech features, but the work performed at this interface may nevertheless be of low ergonomic quality. This may be caused by the fact that the tasks are designed without regard for basic ergonomic task requirements. The poor design of a task, of course, does not bring the usability of a product into discredit. However, a really human-centered approach considers not only the design of user interface attributes, but also the human conditions of work and organization. It is worth mentioning that the introduction of information technology can have effects on the content of jobs and individual interdependencies in an organization. These changes should be taken as an opportunity to redesign tasks and develop organizations according to ergonomic task requirements. ISO 9241-2 [1992] not only requires task design to facilitate tasks but also recommends that task design provide an appropriate degree of autonomy to the user in deciding on priority, pace, and procedure. The features of such a task can be mirrored by user interface attributes of controllability (see [Section 51.2.2.4](#)).

51.2.4 Structure and Content of the Usability Standards

The usability quality model (Figure 51.2) may clarify the structure of usability standards shown in [Figure 51.3](#). Similar to the model, the standards are hierarchical, beginning with usability as the most general quality concept (Part 11), continuing with principles (Part 10 and Part 12), and ending with a series of standards (Part 13 through Part 17) devoted to specific forms of dialogue. With the quality model in mind, the reader can rapidly find an appropriate standard requirement at the intended level of abstraction. If a specific standard does not provide the guiding information to make a design proposal, the reader should ask for information in one of the two principal standards (dialogue or information presentation). The principles encourage freedom of design but remind the designer to meet design principles as closely as possible. In [Figure 51.3](#), the principal standards, along with the specific standards on dialogue techniques, form the core of standard requirements. Their interpretation is primarily based on task requirements (Part 2) and the requirements derived from a context-of-use analysis (Part 11).

FIGURE 51.3 A structure of the usability parts of ISO 9241. (From Dzida, W. 1995. Standards for user-interfaces. *Comput. Stand. & Interfaces* 17: 89–97. With permission.)

TABLE 51.1 Parts of ISO 9241 (January 2003); Parts 10–17 are Software Usability Standards

Part	Title
1	General introduction
2	Guidance on task requirements
3	Visual display requirements
4	Keyboard requirements
5	Workstation layout and postural requirements
6	Environmental requirements
7	Display requirements with reflections
8	Requirements for displayed colors
9	Requirements for non-keyboard input devices
10	Dialogue principles
11	Guidance on usability
12	Presentation of information
13	User guidance
14	Menu dialogues
15	Command dialogues
16	Direct manipulation dialogues
17	Form filling dialogues

Source: From Dzida, W. 1995. Standards for user-interfaces. *Comput. Stand. & Interfaces* 17: 89–97. With permission.

Table 51.1 provides a list of all standards under the title ISO 9241 [1999]: Ergonomic requirements for office work with visual display terminals (VDTs). The specific usability parts of this standard are Part 10 through Part 17.

The differentiation between types of usability criteria helps to identify what type of information is provided by a specific standard requirement. Having the types of criteria in mind, the reader will immediately

know how a requirement can be interpreted and which information must be acquired for checking its applicability. A standard contains the following:

- A required effect of a user's task performance
- A required human outcome
- A product attribute

Here are some examples from different standards:

- **Effect of task performance** — “The user actions required to move the cursor from one entry field to the next should be minimized” [ISO 9241-17 1998, par. 6.1.1].
- **Human outcome** — “In order to enable direct manipulation of objects, objects that can be directly manipulated should have areas which can be easily recognized and discriminated by the user . . .” [ISO 9241-16 1999, par. 6.2.6].
- **Product attribute** — “If command input is typed, command words should generally not exceed 7 characters” [ISO 9241-15 1997, par. 5.1.5].

Some standard requirements involve a mixture of these three types of information. Nearly all requirements are accompanied by examples, which illustrate the requirement in terms of an implemented product attribute. [Section 51.3](#) of this chapter explains how to deal with types of standard requirements in conformance testing.

51.2.5 Standards in Relation to the European Council Directive

To finish this section on principles of usability, we consider an issue of internationalization. The European Council Directive [ECD 1990] requires that “the principles of software ergonomics must be applied, in particular to human data processing” [ECD 1990, p. 18]. For an interpretation of this regulation, the notion of principles must be clarified. Further requirements in the list of minimum requirements (Section 3 of the Directive) point to the background information the authors probably had in mind when referring to principles. The minimum requirements are as follows:

“(a) software must be suitable for the task; (b) software must be easy to use and, where appropriate, adaptable to the operator's level of knowledge or experience; no quantitative or qualitative checking facility may be used without the knowledge of the workers; (c) systems must provide feedback to workers on their performance; (d) systems must display information in a format and at a pace which are adapted to operators . . .” [ECD 1990, p.18].

The following is an interpretation of the requirements in terms of principles:

Point (a) corresponds to the dialogue principle suitability for the task, although the system's functionality is also addressed.

Point (b) is a twofold requirement: the required adaptability corresponds to the dialogue principle conformity with user expectations, and it also addresses maintainability.

Point (c) corresponds to the dialogue principle self-descriptiveness.

Point (d) corresponds to the dialogue principle controllability, although principles of information design are also addressed.

To sum up, when adhering to the principles of software ergonomics, the practitioner is well advised to adopt the ISO principles of dialogue [ISO 9241-10 1996] and the principles of information design [ISO 9241-12 1998].

An additional issue is the legal obligation of the European Council Directive previously listed. All member states of the European Union must transpose the Council Directive into national law. Certainly, national legislation will refer, at least indirectly, to these international standards, because the European minimum requirements correspond to the ISO minimum requirements. Although an ISO standard originally has the status of recommendation, all standards will be conceived as obligatory requirements within the European software market [Stewart 1992].

Concerning the software-producing companies outside of Europe, there is a question of how they will cope with the specific European standards if they want to deliver products to this market. Software producers will establish European service companies to intensify contact with customers as regards requirements specification, system adaptations, and conformance testing at the users' workplaces [Keil and Carmel 1995]. The next section, on best practices, is an attempt to address these issues in detail.

51.3 Best Practices

The series of software-ergonomic standards will be of no value if software designers and product assessors do not know how to apply them. Members of the standardization committee repeatedly asked software designers and usability assessors to judge the applicability of standards. Complaints about the difficulty of interpreting the standards were made. The main difficulties were in testing products for compliance with the standards. Another concern was raised about when which standard must be applied. This section provides help in reading and interpreting the usability standards in order to convert the recommendations given in the standards into valid test criteria.

51.3.1 Standards as Guidelines

Usability standards are mostly formulated as guidelines, rather than precise specifications. The problem with guidelines is that they may become too detailed and voluminous or too brief (and thus overly generic). The authors of the most comprehensive collection of guidelines predicted that designers may be disappointed if they look to guidelines for specific rules but find only general advice instead [Mosier and Smith 1986]. The standard guidelines represent the present state of an ergonomically accepted technology, but the product attributes involved in the standard lack exact quantitative values. This lack of exactness may make it difficult for the designer to obtain a compliant proposal for a specific design decision; it may also make it difficult for the assessor to check a product feature for compliance with a guideline.

Nevertheless, this characteristic of the guidelines need not be regarded as a drawback. The opposite may be true, in fact, because the guidelines are not at all unclearly stated for a reader who acquires usability requirements from the context of use before interpreting the guidelines. This is similar to interpreting another type of standards, national or international laws, which also require the reader to apply them to a specific state of affairs and its context. To judge conformity, the reader of a usability standard should not expect that a paragraph of a standard can easily be compared to a product attribute. Before introducing best practices for applying the usability standards, we outline why usability standards are like guidelines, what the advantages of guidelines are, and how test criteria can be determined so as to enable the designer or the assessor to apply a standard.

Usability standards are formulated as guidelines for several reasons:

- Freedom of design is warranted, that is, the standard does not specify any particular product attribute.
- The requirements do not imply any specific implementation.
- The requirements do not imply any specific user or user target group.
- The requirements do not presuppose any specific task or organizational setting.

Certainly, the standardization committee should not specify requirements for specific target groups, tasks, or contexts of use. This would produce a tremendous proliferation of standards that would be practically unmanageable. Software-producing companies would protest against standardized attributes, because it is the style of such attributes that should establish the appearance of a product as being unique to a specific company.

Using the standards as a source for specifying usability test criteria requires the usability specialist to acquire valid user data with the help of the user target group(s).

51.3.2 User Participation

The development of usability requirements evolves from a mature relationship between customer and manufacturer. Valid user data can only be gathered in the customer organization at the users' workplaces. It may be a risk to the validity of a product when users are ignored in the cooperation of customer and manufacturer. What a customer wants is not always what the users really need. Users are experts at describing what is going on at their workplaces and which problems occur when using a product within its context. Nevertheless, what a user wants is not always what a user really needs. It happens that the latest advances in features and functions impress users. It is tempting to require them, and we should not prohibit users from doing so. The requirements engineer, however, should try to redirect the users' attention to the required task performance rather than technical attributes. For example, we know that almost every user seems to be an expert at designing color combinations. As far as the color attribute is a matter of taste, the user is always right. However, if the color attribute is a matter of usability (e.g., discriminability of items), then the user is respected as an expert on discriminability, but not on color design. Users are not good designers of product attributes, just as designers are not experts on user performance.

User participation is indispensable in usability engineering [ISO 13407 1999], in particular during context analysis and explorative prototyping. In the past, the usability specialists' common phrase was "Know the user." However, this turned out to be too narrow a focus, because only a few findings of mainstream psychology really helped to understand the computer user. While establishing usability research in the 1980s, the focus expanded toward "Know the user's task." However, even this focus was too narrow, because the initial understanding of task was that of a computerized task performance. Existing system features biased this understanding. User participation was confined to testing the user's acceptance of these features. In response to this immunization trap, the notion of *context of use* has been introduced [ISO 9241-11 1998], with the user, the actual key tasks, and organizational and social constraints being the source for creating a valid understanding of usability requirements.

51.3.3 Analyzing the Context of Use

The advantages of the guideline-like character of standards are achieved at the expense of readers who immediately want to apply them to design or testing. These readers first must define usability requirements to provide the basis for an interpretation of a guideline. ISO 9241-11 [1998] serves as a standard which guides the reader in analyzing the context of use of the product in order to specify the usability requirements. Additional guidance for context analysis can be retrieved from Bowden and Thomas [1995] and Bevan and Macleod [1994]. Essentially, this analysis provides a specification of user characteristics, their goals and tasks, the equipment (hardware, software, and materials), and the physical and social environments in which the product is or will be used. The specification of users' goals can be converted into a list of usability requirements. The DATech usability group [DATech 2003] has published a scenario-based analysis of the context of use and its application to specifying usability requirements. See Beyer and Holtzblatt [1998] and Rosson and Carroll [2002] for further approaches to context analysis. Information about the context of use provides the rationale for those usability requirements that are context-related. Usability requirements, which are independent of the context, must be further specified. Use of scenarios or prototypes can provide the rationale for these requirements [Carroll 1995; Rosson and Carroll 2002; DATech 2003]. The scenario-based techniques have been established as best practices of user participation.

The previously described practices of user participation in the analysis of a product's context of use contribute to the validation of usability requirements. Validation of requirements is thus introduced as a milestone in a mature usability engineering process [DATech 2003]. A narrow view of validation simply requires that the systems requirements be matched with the user's intention [Loukopoulos and Karakostas 1995]. In usability engineering, validation has been conceptualized as a consensus-formation process [Dzida and Freitag 1998], a process in the course of which proposed system attributes are evaluated against usability requirements to achieve a consensus among partners about usability requirements and corresponding design solutions. Validation is thus defined as a consensual process, rather than a simple analytic comparison. Validation becomes a constructive activity, which invites the user to intervene in the

design process and invites the designer to refine an understanding of requirements. This process enables a shared understanding, that is, a valid understanding.

51.3.4 Coping with the Uncertainty Principle in a Design–Use Cycle

Partners in a project (i.e., manufacturer and customer) have shared responsibilities for specifying usability requirements before signing the contract. The ISO 9000 [2000] requires the manufacturer to focus on the customer's needs. The first quality management principle postulates that manufacturers depend on their customers and therefore should understand customer needs (par. 0.2.a). The customer's responsibility is laid down in the ISO 9001 [2000] standard: the customer shall select manufacturers based on their ability to supply products in accordance with the customer's requirements (par. 7.4.1). Hence, the partners should share responsibility for developing requirements throughout the project, even after installation of the product in its context of use.

From experiences in usability engineering, it became evident that the development of an interactive system can only be finished in the context of use. This experience fits well with Humphrey's uncertainty principle [1995], which states that the requirements will not be completely known until after the users have used the system. Therefore, in usability engineering, the so-called *software life cycle* is called **design–use cycle**. To meet the needs of users and customers, the model of the design–use cycle takes account of quality improvements to be evolutionarily achieved. For the software-engineering origin of the model, see Floyd et al. [1989].

The customer's responsibility (in the role of employer) is addressed in the European Council Directive [ECD 1990]. Article 3 requires an analysis of users' workstations to evaluate conditions that may result in complaints about physical problems, health problems, or mental stress. The test of a product for compliance with international standards could be used as a preventive measure, as the directive requires. The customer will require such a test to be performed in advance by the developer. However, subsequent use of a product can also uncover **defects and faults**, which would soon initiate an adaptation or a redesign of the product.

To manage these quality problems, "effective communications should be maintained to encourage users to discuss their concerns and to ensure timely and effective organization responses" [ISO 9241-2 1992, par. 5]. An organization may respond either by adapting the product or by adapting the product's context of use, so as to embed the system more properly. After the product has been adapted to user needs, the adaptation should be tested for conformity with the standards, taking into account that the customer will be responsible for making that test. From the evolutionary character of the design–use cycle, it is clear that a product's conformity with standards is not achieved once and forever but requires periodic retests during redesign and application.

51.3.5 Conformity in Terms of Usability Test Criteria

When testing a product for conformity with an international usability standard, one should not expect to conduct the test in the same way as style-guide compliance for specific product attributes, according to ISO/IEC 12119 [1994]. This kind of testing is the exception in usability conformance testing. The rule is that usability requirements derived from the context of use must be translated in terms of test criteria to prepare for the conformance test. The translation essentially involves an interpretation of a standard requirement in the light of the usability requirements. As previously outlined, this interpretation is necessary due to the fact that standard guidelines are formulated neutrally toward users, tasks, and environmental conditions. In principle, there are three possibilities to determine the test criteria:

The standard requirement genuinely represents the test criterion (which is the exception). This holds for a required product attribute. For example, help explanations should vary in type and length [ISO 9241-10 1996]. Type and length are attributes, which can be inspected regardless of task and users, that is, a context of use analysis can be skipped.

The standard requirement must be interpreted with regard to the task at hand. Let us assume that the user wants to avoid the recurrent input of the same data, which instead should be easily available on the display after the first input. The standard [ISO 9241-10 1996] contains a corresponding requirement concerning default values, but this must be interpreted in the light of the real task. This task may be, for instance, the task of a CAD engineer who works on modeling the geometry of a steel girder and is repeatedly concerned with the values of its flange. The CAD system conforms to the standard if it presents the flange values as defaults.

The standard requirement must be interpreted with regard to task *and* user needs. This holds true for a required human outcome resulting from task performance. For example, “Explanations should assist the user in gaining a general understanding of the dialogue system. . .” [ISO 9241-10 1996, par. 3.3]; understanding can be assessed only in view of the user and the task. For a user who interacts with an integrated office system, the general level of understanding should be much higher than for a user who simply applies a form-filling dialogue. After having determined the required level of understanding, the test criterion is specified and the test for conformity with the standard is well prepared.

The usability standards, especially Part 13 through Part 17, introduce the concept of the conditional requirement, which is a special form of the criterion-oriented approach. A conditional requirement is a sentence formulated in terms of an *if-then* rule, thereby structuring the sentence into two components: a conditional part and a subsequent guideline part. For example, ISO 9241-14 [1997] contains the following conditional requirement for menu options: “If options can be arranged into conventional or natural groups known to users, options should be organized into levels and menus consistent with that order” (par. 5.1.1). The *if*-clause refers to the condition of applying the guideline. Actually, the context of use must be analyzed and the users must be interviewed in order to determine the test criterion, which is a specific interpretation of the guideline.

The criterion-oriented approach to conformance testing is organized as a process mainly determined by three activities (see Figure 51.4).

1. Derive the usability requirement from the context of use.
2. Specify the requirement in terms of a test criterion in view of the standards.
3. Test for conformity.

The second step determines the minimum level of usability. Finally, the test criterion is compared with relevant product attributes of the design solution. This step provides the test of the product for conformity with usability standard. In most cases, it suffices to consult ISO 9241-10 when a requirement is converted into a test criterion. The conformity test (step 3) acknowledges whether the design solution meets the

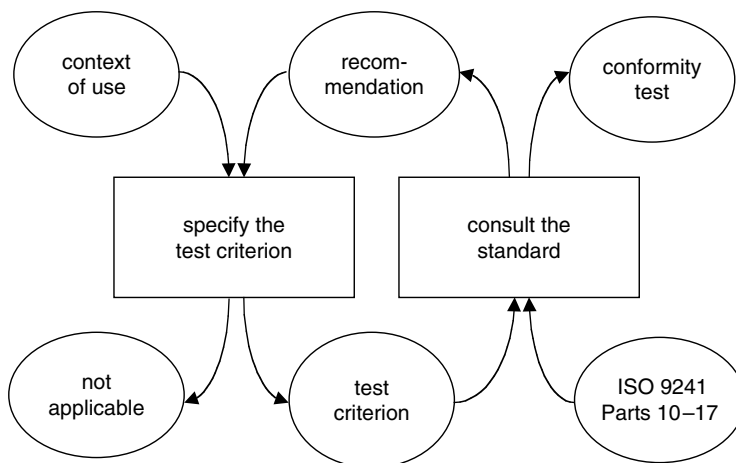

FIGURE 51.4 Conversion of a usability requirement in terms of a test criterion.

usability requirement, in principle. If a deviation from a principle is detected, then an appropriate standard within the series of ISO 9241 Part 12 through Part 17 should be consulted to specify a rationale for the minimum quality a design solution should satisfy.

It may occur that the design solution provides a higher level of quality than the standard requires. Conformity with the standard is achieved if the user or task performance enabled by the design solution equals or exceeds the minimum level of quality specified by the test criterion.

To avoid redundancy, some parts of ISO 9241 [1999] do not explicitly phrase requirements or recommendations in terms of an *if-then* clause. For example, the principle of suitability for the task recommends that “Help information should be task dependent” [ISO 9241-10 1996, par. 3.2]. Although no conditional clause is explicitly included, it is evident that this guideline can be applied only under the condition that the task has been investigated, so as to specify the test criterion prior to the conformance test. When adopting the criterion-oriented approach, conformance testing is possible for all guideline-like standards [Dzida 1995], regardless of what turn of phrase is used in the standard (conditional requirement or application of a principle).

Figure 51.4 summarizes the steps in interpreting a recommendation provided by a usability standard. It may be necessary to consult the usability standards repeatedly during the process of interpreting the appropriateness of recommendations before a test criterion is specified. As a final result, a checklist of usability test criteria can be achieved, which represents the scope of the conformance tests to be done. The major advantage of this checklist is that it can be made part of the test report, thereby explicitly confining the scope of conformity tested. The reproducibility of the test results is thus warranted. Documenting the conformity of a product in undifferentiated terms can be avoided. If a usability requirement changes during the application phase of a product, the assessor can easily pick up the corresponding test criteria that determine whether a subsequent conformance test is necessary.

The checklist containing usability test criteria differs from the typical type of checklist frequently applied in usability evaluation. Typically, checklists contain a mixture of required product attributes and arbitrarily stated user performance requirements. It seems to be quite convenient to adopt such a checklist in a variety of investigations, regardless of the product under study or the product's context of use. Opposite to this type of checklist, the criterion-oriented checklist is validated for a specific context of use and is legitimized as each item in the list has a defined linkage to a valid usability requirement. The major drawback of a conventional checklist, containing solely product attributes, can be seen in the unspecified linkage of these attributes to usability requirements.

51.3.6 Conformance Testing vs. Heuristic Evaluations

The criterion-oriented approach to usability testing should also be compared with other frequently applied methods; for a survey of methods, see Nielsen and Mack [1994]. In particular, the heuristic evaluation approach [Nielsen 1992] should be selected for a comparison, to contrast this method with the striking features of conformance testing. Nielsen classifies usability problems and allocates them to nine “principles” of good interface design, such as consistency, feedback, and shortcuts. All principles correspond to principles of the international standards; for instance, consistency issues are subsumed within the dialogue principle of conformity with user expectations [ISO 9241-10 1996].

Nevertheless, heuristic evaluation serves another purpose that is beyond the test for conformity with international standards. Heuristic evaluation is a cost-effective and rapid inspection method, like usability walkthroughs, with the main difference being that it is less formal than conformance testing. Inspection of the product can be taken as a *debugging* of usability defects, that is, an identification and diagnosis of the most striking and serious usability problems. Therefore, heuristic evaluation is particularly suited to the inspection of prototypes during the design cycle.

Just as conformance testing mostly includes an inspection of the product, so does heuristic evaluation. The major difference lies in the question of what is inspected. A conformance test is an inspection of a required product attribute, that is, a relevant attribute that fits well with a valid usability requirement. A heuristic evaluation inspects a usability problem. This approach requires the assessor to have the nine

principles in mind as a vague quality definition to be matched with a number of arbitrarily selected product attributes. The product is not necessarily inspected for a selected set of relevant tasks (i.e., a specific context of use is not addressed and suitability for the task is not included in the list of heuristics). Hence, the output of heuristic evaluation is not a list of defects that violate specific test criteria but of those that indicate more or less serious usability problems. A shortcoming of heuristic evaluation is that the identified usability problems cannot be fixed for a constructive solution, because it will then be necessary to know a valid usability requirement. The advantage of heuristic evaluation, however, is its effectiveness in uncovering the major problems in a user interface. Thus, heuristic evaluation contributes to achieving the minimum level of quality, just as conformance tests do.

51.4 Research Issues and Summary

Many standard requirements need further development through empirical investigations. Research issues can easily be found in some of the usability standards (Part 13 through Part 17) by looking at the annex that provides references to source documents for almost every requirement. Three types of sources are distinguished there: research studies, guidelines, and experts' consensus. For example, the following requirement was selected from guidelines (see Galitz [1985]) to be put into the menu standard [ISO 9241-14 1997, par. 5.3.6]: "If the frequency of option use is known . . . and option groups are small (eight or less), the most frequently used options should be placed first." This requirement may be reasonable for a pull-down menu, but it should not be generalized for pop-up menus without further empirical evidence. It may turn out that in a pop-up menu, the most frequently used option is more adequately placed at the end of the menu panel, in order to meet Fitts' law (i.e., to minimize the time necessary for moving the mouse to a frequently selected target option). Readers of the usability standards should be made aware of the rich potential for research issues that is raised by the need for empirical evidence to support standard requirements.

Usually, experts in usability design and evaluation will apply standards. A significant aspect is that expert judgment is based largely on accumulated practical experience rather than solid empirical data. Although for each requirement the empirical evidence is checked during the development of the standards, the practitioner will usually neglect the underlying source document. For many empirical studies, the related experimental results could not always be generalized as far as suggested by the standard requirement. Even if a requirement is based on solid data, a specific application may lead to a divergent interpretation because of the specific circumstances given in the context of use [Landauer and Galotti 1984]. The practitioner will not be concerned with such issues. For a professional researcher, however, the notion that design decisions may be based on judgment rather than on experimental data is repugnant [Smith 1986].

At the designer's workbench, design decisions cannot be postponed until supportive data have been obtained from empirical research. Therefore, many design decisions could be investigated *ex post facto* in experiments, the results of which then may influence the revision of design and standards. Unfortunately, professional researchers are not yet sufficiently integrated into this process. Also, they may be reluctant to take part in design decisions, thereby accompanying the designer when obtaining from this experience the impetus for further experimental studies. Even if a laboratory researcher is willing to take part in this process, there may be good reasons not to be too committed, because of the limitations of laboratory research to study usability [Eason 1984].

Thus, we may question whether solid empirical foundations for standard requirements can ever be achieved. This is why a design decision, as well as the underlying guideline, will rarely be absolutely true or false, but will be more or less appropriate relative to the usability requirements derived from a product's context of use.

With the publication of a standard concerning the usability design process [ISO 13407 1999], a new research issue has been identified. Every defect of a product can be traced back to a shortcoming in the manufacturing process. The process, as well as the product, can be assessed for its shortcomings and defects, thereby investigating the causal relationship of process and product quality. A challenging research issue is seen in a combination of assessment and subsequent improvement of both process and product, thus establishing a test and improvement cycle.

The series of usability standards [ISO 9241 1999, Part 10 through Part 17] provides a set of requirements for the minimum level of usability of interactive systems. Although the evidence for some of the requirements may be questioned and may need to be revised in a later review, the worth of the standards should not be underestimated. The set of requirements is based on a balance of different interests among partners in an international market and on a state-of-the-art knowledge in usability research, as well. Although the standards are as yet merely conceived as recommendations (except within the European Union), they should be respected throughout the world as a baseline of usability, beyond which software companies will have sufficient space for developing competitive, high-quality products. There may be regions of the world where ergonomic aspects of products and quality of work do not yet play an important role. With the advent of international standards, a worldwide harmonization of work conditions at computerized workplaces may become the most significant effect of this work in the long run.

Defining Terms

- Conformity test:** An operation that compares relevant attributes of a product with applicable standard requirements for determining the achievement of the level of quality required.
- Context of use:** The users, goals, tasks, equipment (hardware, software, and materials), and the physical and social environments in which a product is used [ISO 9241-11 1998].
- Defect:** An unintended attribute that impairs the efficient use of a product.
- Design–use cycle:** The evolutionary course of developmental improvements through which a product passes from its conception, through its use, to its redesign or the termination of its use.
- Dialogue:** A process in the course of which the user, to perform a given task, inputs data in one or more dialogue steps and receives for each step feedback with regard to the processing of the data concerned.
- Direct manipulation:** A dialogue technique by which the user acts directly on objects on the screen, for example, by pointing at them, moving them, or changing their physical characteristics (or values) via the use of an input device [ISO 9241-16 1999].
- Effectiveness:** The accuracy and completeness with which users achieve specified goals [ISO 9241-11 1998].
- Efficiency:** The accuracy and completeness, in relation to the resources expended, with which users achieve goals [ISO 9241-11 1998].
- Fault:** A missing attribute that impairs the effective use of a product.
- Satisfaction:** The comfort and acceptability of use [ISO 9241-11 1998].
- Task:** A specification including the intended result of an activity to be performed on an object (material) by a specified means (method).
- Task performance:** An activity carried out at a user interface and aimed at completing a task.
- Test criterion:** A measure of required level of quality against which attributes of an object (e.g., a product) or of a process (e.g., the design cycle) are judged, to assess the level of quality achieved.
- Usability:** The extent to which a product can be used by specified users to achieve specified goals of effectiveness, efficiency, and satisfaction in a specified context of use [ISO 9241-11 1998].
- User interface:** An interface that enables information to be passed between a human user and hardware or software components of a computer system [ISO/IEC 12119 1994].
- User participation:** The involvement of target users for developing and validating usability requirements and evaluating design proposals (or solutions) throughout the design–use cycle.

Further Information

Requests for information concerning international standards should be addressed to one of the ISO members listed here. The complete list can be obtained from the following address:

ISO Central Secretariat, 1, rue de Varembe, Case postale 56, 1211 Genève 20, Switzerland

Information about the current state of development of ISO standards can be retrieved from the Internet: <http://www.iso.ch>.

ISO members currently active in ISO TC 159/SC 4/WG 5 (“Ergonomics of human–system interaction”) are as follows:

Canada (SCC) — Standards Council of Canada, 270 Albert Street, Suite 200, Ottawa, Ontario K1P 6N7

Denmark (DS) — Dansk Standard, Kollegievej 6, 2920 Charlottenlund

France (AFNOR) — Association Française de Normalisation, 11, avenue Francis de Pressensé, 93571 Saint-Denis La Plaine Cedex

Germany (DIN) — DIN Deutsches Institut für Normung, Burggrafenstraße 6, 10787 Berlin

Italy (UNI) — Ente Nazionale Italiano di Unificazione, Via Battistotti Sassi 11/b, 20133 Milano

Japan (JISC) — Japanese Industrial Standards Committee, Ministry of International Trade and Industry, 1-3-1, Kasumigaseki, Chiyoda-ku, Tokyo 100

Netherlands (NEN) — Nederlands Normalisatie-instituut, Vlinderweg 6, 2623 AX Delft

Sweden (SIS) — Swedish Standards Institute, Sankt Paulsgatan 6, 11880 Stockholm

United Kingdom (BSI) — BSI British Standards Headquarters, 389 Chiswick High Road, London W4 4AL

United States (ANSI) — American National Standards Institute, 11 West 42nd Street, 13th floor, New York, NY 10036

More information on standards in computer science and engineering also can be found in the appendices of this Handbook.

Active national member bodies of ISO organize meetings of working groups, which mirror the previously mentioned ISO working group. The meetings are open to anyone who wants to contribute to the current ISO projects, either by proposals or by comments to committee drafts, or draft international standards.

Most standards need a period of 5 to 10 years from the first working document to the final version of the international standard. During this time, standards are commented on in national and international journals. A recognized source is the journal *Computer Standards & Interfaces*, published by Elsevier, Amsterdam.

VI

Information Management

Information Management is concerned with the collection, design, storage, organization, retrieval, and security of information in large databases. From a technology viewpoint, the emphasis is on the algorithms and structures underlying the databases. From an organizational viewpoint, the emphasis is on the relationship of information to business performance. Considerable research is also devoted to information management techniques that support the emerging global technological infrastructure. Particularly interesting here is the study of transaction processing in distributed computing environments, multimedia databases, and issues surrounding database security and privacy.

52.1 Introduction

Underlying the structure of a database is the concept of a *data model*. A data model is a collection of conceptual tools for describing the real-world entities to be modeled in the database and the relationships among these entities. Data models differ in the primitives available for describing data and in the amount of semantic detail that can be expressed.

The various data models that have been proposed fall into three different groups: physical data models, record-based logical models, and object-based logical models. Physical data models are used to describe data at the lowest level. Physical data models capture aspects of database system implementation that are not covered in this article. Database system interfaces used by application programs are based on the logical data model; databases hide the underlying implementation details from applications.

This chapter focuses on logical data models, covering the relational data model, the E-R model, the object-oriented and object-relational data models, and XML.

52.2 The Relational Model

The **relational model** is currently the primary data model for commercial data-processing applications. It has attained its primary position because of its simplicity, which eases the job of the programmer, as compared to earlier data models.

A relational database consists of a collection of **tables**, each of which is assigned a unique name. An *instance* of a table storing customer information is shown in [Table 52.1](#). The table has several rows, one for each customer, and several columns, each storing some information about the customer. The values in the *customer-id* column of the *customer* table serve to uniquely identify customers, while other columns store information such as the name, street address, and city of the customer.

The information stored in a database is broken up into multiple tables, each storing a particular kind of information. For example, information about accounts and loans at a bank would be stored in separate tables. [Table 52.2](#) shows an instance of the *loan* table, which stores information about loans taken from the bank.

TABLE 52.1 The *Customer* Table

<i>Customer-id</i>	<i>Customer-Name</i>	<i>Customer-Street</i>	<i>Customer-City</i>
019-28-3746	Smith	North	Rye
182-73-6091	Turner	Putnam	Stamford
192-83-7465	Johnson	Alma	Palo Alto
244-66-8800	Curry	North	Rye
321-12-3123	Jones	Main	Harrison
335-57-7991	Adams	Spring	Pittsfield
336-66-9999	Lindsay	Park	Pittsfield
677-89-9011	Hayes	Main	Harrison
963-96-3963	Williams	Nassau	Princeton

TABLE 52.2 The *Loan* Table

<i>Loan-Number</i>	<i>Amount</i>
L-11	900
L-14	1500
L-15	1500
L-16	1300
L-17	1000
L-23	2000
L-93	500

TABLE 52.3 The *Borrower* Table

<i>Customer-id</i>	<i>Loan-Number</i>
019-28-3746	L-11
019-28-3746	L-23
244-66-8800	L-93
321-12-3123	L-17
335-57-7991	L-16
555-55-5555	L-14
677-89-9011	L-15
963-96-3963	L-17

In addition to information about “entities” such as customers or loans, there is also a need to store information about “relationships” between such entities. For example, the bank needs to track the relationship between customers and loans. Table 52.3 shows the *borrower* table, which stores information indicating which customers have taken which loans. If several people have jointly taken a loan, the same loan number would appear several times in the table with different customer-ids (e.g., loan number L-17). Similarly, if a particular customer has taken multiple loans, there would be several rows in the table with the customer-id of that customer (e.g., 019-28-3746), with different loan numbers.

52.2.1 Formal Basis

The power of the relational data model lies in its rigorous mathematical foundations and a simple user-level paradigm for representing data. Mathematically speaking, a **relation** is a subset of the Cartesian product of an ordered list of domains. For example, let E be the set of all employee identification numbers, D the set of all department names, and S the set of all salaries. An employment relation is a set of 3-tuples (e, d, s) where $e \in E$, $d \in D$, and $s \in S$. A tuple (e, d, s) represents the fact that employee e works in department d and earns salary s .

At the user level, a relation is represented as a table. The table has one column for each domain and one row for each tuple. Each column has a name, which serves as a column header, and is called an **attribute** of the relation. The list of attributes for a relation is called the **relation schema**. The terms “table” and “relation” are used synonymously, as are row and tuple, as also column and attribute.

Data models also permit the definition of *constraints* on the data stored in the database. For instance, *key constraints* are defined as follows. If a set of attributes L is specified to be a *super-key* for relation r , in any consistent (“legal”) database, the set of attributes L would uniquely identify a tuple in r ; that is, no two tuples in r can have the same values for all attributes in L . For instance, *customer-id* would form a super-key for relation *customer*. A relation can have more than one super-key, and usually one of the super-keys is chosen as a *primary key*; this key must be a minimal set, that is, dropping any attribute from the set would make it cease to be a super-key.

Another form of constraint is the *foreign key* constraint, which specifies that for each tuple in one relation, there must exist a matching tuple in another relation. For example, a foreign key constraint *from borrower referencing customer* specifies that for each tuple in *borrower*, there must be a tuple in *customer* with a matching *customer-id* value.

Users of a database system can query the data, insert new data, delete old data, or update the data in the database. Of these tasks, the task of querying the data is usually the most complicated. In the case of the relational data model, because data is stored as tables, a user can query these tables, insert new tuples, delete tuples, and update (modify) tuples. There are several languages for expressing these operations.

The tuple relational calculus and the domain relational calculus are nonprocedural languages that represent the basic power required in a relational query language. Both of these languages are based on statements written in mathematical logic. We omit details of these languages.

The relational algebra is a procedural query language that defines several operations, each of which takes one or more relations as input and returns a relation as output. For example:

- The **selection** operation is used to get a subset of tuples from a relation, by specifying a predicate. The selection operation $\sigma_P(r)$ returns the set of tuples of r that satisfy the predicate P .
- The **projection** operation $\Pi_L(r)$ is used to return a relation containing a specified set of attributes L of a relation r , removing the other attributes of r .
- The **union** operation $r \cup s$ returns the union of the tuples in r and s . The **intersection** and **difference** operations are similarly defined.
- The **natural join** operation \bowtie is used to combine information from two relations. For example, the natural join of the relations *loan* and *borrower*, denoted $loan \bowtie borrower$ would be the relation defined as follows. First match each tuple in *loan* with each tuple in *borrower* that has the same values for the shared attribute *loan-number*; for each pair of matching tuples, the join operation creates a tuple containing all attributes from both tuples; the join result relation is the set of all such tuples.

For instance, the natural join of the *loan* and *borrower* tables in Tables 52.2 and 52.3 contains tuples (L-17, 1000, 321-12-3123) and (L-17, 1000, 963-96-3963), since the tuple with loan number L-17 in the *loan* table matches two different tuples with loan number L-17 in the *borrower* table.

The relational algebra has other operations as well; for example, operations that can aggregate values from multiple tuples, for example by summing them up, or finding their average.

Because the result of a relational algebra operation is itself a relation, it can be used in further operations. As a result, complex expressions with multiple operations can be defined in the relational algebra.

Among the reasons for the success of the relational model are its basic simplicity, representing all data using just a single notion of tables, as well as its formal foundations in mathematical logic and algebra.

The relational algebra and the relational calculi are terse, formal languages that are inappropriate for casual users of a database system. Commercial database systems have, therefore, used languages with more “syntactic sugar.” Queries in these languages can be translated into queries in relational algebra.

52.2.2 SQL

The SQL language has clearly established itself as *the* standard relational database language. The SQL language has a data definition component for specifying schemas, and a data manipulation component for querying data as well as for inserting, deleting, and updating data.

We illustrate some examples of queries and updates in SQL. The following query finds the name of the customer whose *customer-id* is 192-83-7465:

```
select  customer.customer-name
from    customer
where   customer.customer-id = '192-83-7465'
```

Queries may involve information from more than one table. For example, the following query finds the amount of all loans owned by the customer with customer-id 019-28-3746:

```
select  loan.loan-number, loan.amount
from    borrower, loan
where   borrower.customer-id = '019-28-3746' and
         borrower.loan-number = loan.loan-number
```

If the above query were run on the tables shown earlier, the system would find that the loans L-11 and L-23 are owned by customer 019-28-3746, and would print out the amounts of the two loans, namely 900 and 2000.

The following SQL statement adds an interest of 5% to the loan amount of all loans with amounts greater than 1000.

```
update  loan
set     amount = amount * 1.05
where   amount > 10000
```

Over the years, there have been several revisions of the SQL standard. The most recent is SQL:1999. QBE and Quel are two other significant query languages. Of these, Quel is no longer in widespread use, while QBE is used only in a few database systems such as Microsoft Access.

52.2.3 Relational Database Design

The process of designing a conceptual level schema for a relational database involves the selection of a set of relational schemas. There are several approaches to relational database design. One approach, which we describe in [Section 52.3.1](#), is to create a model of the enterprise using a higher-level data model, such as the entity-relationship model, and then translate the higher-level model into a relational database design.

Another approach is to directly create a design, consisting of a set of tables and a set of attributes for each table. There are often many possible choices that the database designer might make. A proper balance must be struck among three criteria for a good design:

1. Minimization of redundant data
2. Ability to represent all relevant relationships among data items
3. Ability to test efficiently the data dependencies that require certain attributes to be unique identifiers

To illustrate these criteria for a good design, consider a database of employees, departments, and managers. Let us assume that a department has only one manager, but a manager may manage one or more departments. If we use a single relation *emp-info1(employee, department, manager)*, then we must repeat the manager of a department once for each employee. Thus we have **redundant** data.

We can avoid redundancy by *decomposing* (breaking up) the above relation into two relations *emp_mgr(employee, manager)* and *emp_dept(manager, department)*. However, consider a manager, Martin, who manages both the sales and the service departments. If Clark works for Martin, we cannot represent the fact that Clark works in the service department but not the sales department. Thus we cannot represent all

relevant relationships among data items using the decomposed relations; such a decomposition is called a *lossy-join decomposition*. If instead, we chose the two relations *emp-dept*(*employee*, *department*) and *dept-mgr*(*department*, *manager*), we would avoid this difficulty, and at the same time avoid redundancy. With this decomposition, joining the information in the two relations would give back the information in *emp-info1*; such a decomposition is called a *lossless-join decomposition*.

There are several types of data dependencies. The most important of these are **functional dependencies**. A functional dependency is a constraint that the value of a tuple on one attribute or set of attributes determines its value on another. For example, the constraint that a department has only one manager could be stated as “department functionally determines manager.” Because functional dependencies represent facts about the enterprise being modeled, it is important that the system check newly inserted data to ensure no functional dependency is violated (as in the case of a second manager being inserted for some department). Such checks ensure that the update does not make the information in the database inconsistent. The cost of this check depends on the design of the database.

There is a formal theory of relational database design that allows us to construct designs that have minimal redundancy, consistent with meeting the requirements of representing all relevant relationships, and allowing efficient testing of functional dependencies. This theory specifies certain properties that a schema must satisfy, based on functional dependencies. For example, a database design is said to be in a *Boyce-Codd normal form* if it satisfies a certain specified set of properties; there are alternative specifications, for instance the *third normal form*. The process of ensuring that a schema design is in a desired normal form is called **normalization**.

More details can be found in standard textbooks on databases; Ullman [Ull88], provides a detailed coverage of database design theory.

52.2.4 History

The relational model was developed in the late 1960s and early 1970s by E.F. Codd. The 1970s saw the development of several experimental database systems based on the relational model and the emergence of a formal theory to support the design of relational databases. The commercial application of relational databases began in the late 1970s but was limited by the poor performance of early relational systems. During the 1980s numerous commercial relational systems with good performance became available. Simultaneously, simple database systems based loosely on the relational approach were introduced for single-user personal computers. In the latter part of the 1980s, efforts were made to integrate collections of personal computer databases with large mainframe databases.

The relational model has since established itself as the primary data model for commercial data processing applications. Earlier generation database systems were based on the *network data model* or the *hierarchical data model*. Those two older models are tied closely to the data structures underlying the implementation of the database. We omit details of these models because they are now of historical interest only.

52.3 Object-Based Models

The relational model is the most widely used data model at the implementation level; most databases in use around the world are relational databases. However, the relational view of data is often too detailed for conceptual modeling. Data modelers need to work at a higher level of abstraction.

Object-based logical models are used in describing data at the conceptual level. The object-based models use the concepts of **entities** or **objects** and relationships among them rather than the implementation-based concepts of the record-based models. They provide flexible structuring capabilities and allow data constraints to be specified explicitly. Several object-based models are in use; some of the more widely known ones are:

- The entity-relationship model
- The object-oriented model
- The object-relational model

The entity-relationship model has gained acceptance in database design and is widely used in practice. The object-oriented model includes many of the concepts of the entity-relationship model, but represents executable code as well as data. The object-relational data model combines features of the object-oriented data model with the relational data model.

The semantic data model and the the functional data model are two other object-based data models; currently, they are not widely used.

52.3.1 The Entity-Relationship Model

The E-R data model derives from the perception of the world or, more specifically, of a particular enterprise in the world, as consisting of a set of basic objects called *entities*, and *relationships* among these objects. It facilitates database design by allowing the specification of an *enterprise schema*, which represents the overall logical structure of a database. The E-R data model is one of several semantic data models; that is, it attempts to represent the meaning of the data.

52.3.1.1 Basics

There are three basic notions that the E-R data model employs: entity sets, relationship sets, and attributes. An **entity** is a “thing” or “object” in the real world that is distinguishable from all other objects. For example, each person in the universe is an entity.

Each entity is described by a collection of features, called **attributes**. For example, the attributes *account-number* and *balance* may describe one particular account in a bank, and they form attributes of the *account* entity set. Similarly, attributes *customer-name*, *customer-street* address and *customer-city* may describe a *customer* entity.

The values for some attributes may uniquely identify an entity. For example, the attribute *customer-id* may be used to uniquely identify customers (because it may be possible to have two customers with the same name, street address, and city). A unique customer identifier must be assigned to each customer. In the United States, many enterprises use the social-security number of a person (a unique number the U.S. Government assigns to every person in the United States) as a customer identifier.

An entity may be concrete, such as a person or a book, or it may be abstract, such as a bank account, a holiday, or a concept.

An **entity set** is a set of entities of the same type that share the same properties (attributes). The set of all persons working at a bank, for example, can be defined as the entity set *employee*, and the entity John Smith may be a member of the *employee* entity set. Similarly, the entity set *account* might represent the set of all accounts in a particular bank. A database thus includes a collection of entity sets, each of which contains any number of entities of the same type.

Attributes are descriptive properties possessed by all members of an entity set. The designation of attributes expresses that the database stores similar information concerning each entity in an entity set; however, each entity has its own value for each attribute. Possible attributes of the *employee* entity set are *employee-name*, *employee-id*, and *employee-address*. Possible attributes of the *account* entity set are *account-number* and *account-balance*. For each attribute there is a set of permitted values, called the *domain* (or *value set*) of that attribute. The domain of the attribute *employee-name* might be the set of all text strings of a certain length. Similarly, the domain of attribute *account-number* might be the set of all positive integers.

Entities in an entity set are distinguished based on their attribute values. A set of attributes that suffices to distinguish all entities in an entity set is chosen, and called a **primary key** of the entity set. For the *employee* entity set, *employee-id* could serve as a primary key; the enterprise must ensure that no two people in the enterprise can have the same employee identifier.

A **relationship** is an association among several entities. Thus, an *employee* entity might be related by an *emp-dept* relationship to a *department* entity where that employee entity works. For example, there would be an *emp-dept* relationship between John Smith and the bank’s credit department if John Smith worked in that department. Just as all *employee* entities are grouped into an *employee* entity set, all *emp-dept* relationship instances are grouped into a *emp-dept relationship set*. A relationship set may also have descriptive attributes. For example, consider a relationship set *depositor* between the *customer* and

FIGURE 52.1 E-R diagram.

account entity sets. We could associate an attribute *last-access* to specify the date of the most recent access to the account. The relationship sets *emp-dept* and *depositor* are examples of a binary relationship set, that is, one that involves two entity sets. Most of the relationship sets in a database system are binary.

The overall logical structure of a database can be expressed graphically by an E-R **diagram**. Such a diagram consists of the following major components:

- **Rectangles**, which represent entity sets
- **Ellipses**, which represent attributes
- **Diamonds**, which represent relationship sets
- **Lines**, which link entity sets to relationship sets, and link attributes to both entity sets and relationship sets

An entity-relationship diagram for a portion of our simple banking example is shown in Figure 52.1. The primary key attributes (if any) of an entity set are shown underlined.

Composite attributes are attributes that can be divided into subparts (that is, other attributes). For example, an attribute *name* could be structured as a composite attribute consisting of *first-name*, *middle-initial*, and *last-name*. Using composite attributes in a design schema is a good choice if a user wishes to refer to an entire attribute on some occasions, and to only a component of the attribute on other occasions.

The attributes in our examples so far all have a single value for a particular entity. For instance, the *loan-number* attribute for a specific loan entity refers to only one loan number. Such attributes are said to be **single valued**. There may be instances where an attribute has a set of values for a specific entity. Consider an *employee* entity set with the attribute *phone-number*. An employee may have zero, one, or several phone numbers, and hence this type of attribute is said to be **multivalued**.

Suppose that the *customer* entity set has an attribute *age* that indicates the customer's age. If the *customer* entity set also has an attribute *date-of-birth*, we can calculate *age* from *date-of-birth* and the current date. Thus, *age* is a **derived attribute**. The value of a derived attribute is not stored, but is computed when required.

Figure 52.2 shows how composite, multivalued, and derived attributes can be represented in the E-R notation. Ellipses are used to represent composite attributes as well as their subparts, with lines connecting the ellipse representing the attribute to the ellipse representing its subparts. Multivalued attributes are represented using a double ellipse, while derived attributes are represented using a dashed ellipse.

Most of the relationship sets in a database system are *binary*, that is, they involve only two entity sets. Occasionally, however, relationship sets involve more than two entity sets. As an example, consider the entity sets *employee*, *branch*, and *job*. Examples of *job* entities could include manager, teller, auditor, and so on. Job entities may have the attributes *title* and *level*. The relationship set *works-on* among *employee*, *branch*, and *job* is an example of a **ternary relationship**. A ternary relationship among Jones, Perryridge, and manager indicates that Jones acts as a manager at the Perryridge branch. Jones could also act as auditor at the Downtown branch, which would be represented by another relationship. Yet another relationship could be among Smith, Downtown, and teller, indicating Smith acts as a teller at the Downtown branch.

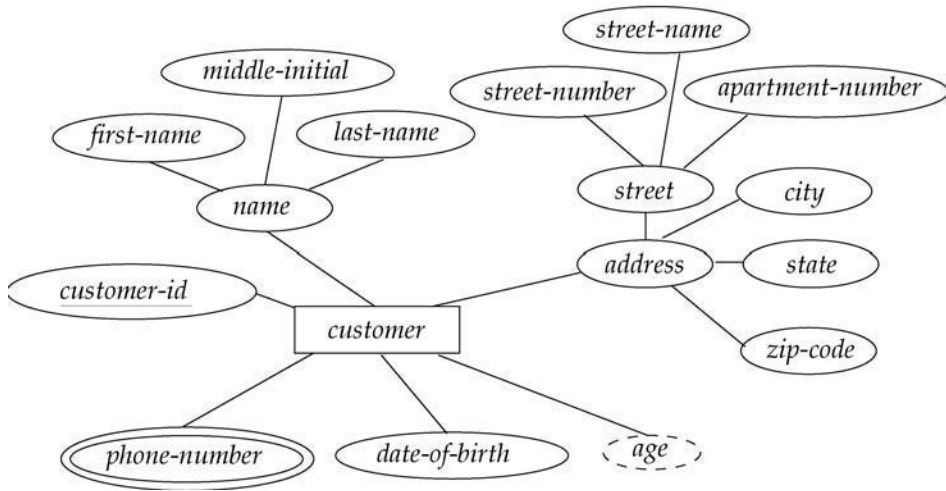

FIGURE 52.2 E-R diagram with composite, multivalued, and derived attributes.

FIGURE 52.3 E-R diagram with role indicators.

Consider, for example, a relationship set *works-for* relating the entity set *employee* with itself. Each employee entity is related to the entity representing the manager of the employee. One employee takes on the role of *worker*, whereas the second takes on the role of *manager*. Roles can be depicted in E-R diagrams as shown in Figure 52.3.

Although the basic E-R concepts can model most database features, some aspects of a database may be more aptly expressed by certain extensions to the basic E-R model. Commonly used extended E-R features include specialization, generalization, higher- and lower-level entity sets, attribute inheritance, and aggregation. The notion of specialization and generalization are covered in the context of object-oriented data models in Section 52.3.2. A full explanation of the other features is beyond the scope of this chapter; we refer readers to the references listed at the end of this chapter for additional information.

52.3.1.2 Representing Data Constraints

In addition to entities and relationships, the E-R model represents certain constraints to which the contents of a database must conform. One important constraint is **mapping cardinalities**, which express the number of entities to which another entity can be associated via a relationship set. Therefore, relationships can be classified as many-to-many, many-to-one, or one-to-one. A many-to-many *works-for* relationship between *employee* and *department* exists if a department may have one or more employees and an employee may work for one or more departments. A many-to-one *works-for* relationship between *employee* and *department* exists if a department may have one or more employees but an employee must work for only department. A one-to-one *works-for* relationship exists if a department were required to have exactly one employee,

FIGURE 52.4 Relationship cardinalities.

FIGURE 52.5 Cardinality limits on relationship sets.

and an employee was required to work for exactly one department. In an E-R diagram, an arrow is used to indicate the type of relationship, as shown in Figure 52.4.

E-R diagrams also provide a way to indicate more complex constraints on the number of times each entity participates in relationships in a relationship set. An edge between an entity set and a binary relationship set can have an associated minimum and maximum cardinality, shown in the form $l..h$, where l is the minimum and h the maximum cardinality. A maximum value of 1 indicates that the entity participates in at most one relationship, while a maximum value $*$ indicates no limit.

For example, consider Figure 52.5. The edge between *loan* and *borrower* has a cardinality constraint of 1..1, meaning the minimum and the maximum cardinality are both 1. That is, each loan must have exactly one associated customer. The limit 0..* on the edge from *customer* to *borrower* indicates that a customer can have zero or more loans. Thus, the relationship *borrower* is one to many from *customer* to *loan*.

It is easy to misinterpret the 0..* on the edge between *customer* and *borrower*, and think that the relationship *borrower* is many-to-one from *customer* to *loan* — this is exactly the reverse of the correct interpretation.

If both edges from a binary relationship have a maximum value of 1, the relationship is one-to-one. If we had specified a cardinality limit of 1..* on the edge between *customer* and *borrower*, we would be saying that each customer must have at least one loan.

52.3.1.3 Use of E-R Model in Database Design

A high-level data model, such as the E-R model, serves the database designer by providing a conceptual framework in which to specify, in a systematic fashion, the data requirements of the database users and how the database will be structured to fulfill these requirements. The initial phase of database design, then, is to fully characterize the data needs of the prospective database users. The outcome of this phase will be a *specification of user requirements*. The initial specification of user requirements may be based on interviews with the database users, and the designer's own analysis of the enterprise. The description that arises from this design phase serves as the basis for specifying the logical structure of the database.

By applying the concepts of the E-R model, the user requirements are translated into a conceptual schema of the database. The schema developed at this **conceptual design** phase provides a detailed overview of the

enterprise. Stated in terms of the E-R model, the conceptual schema specifies all entity sets, relationship sets, attributes, and mapping constraints. The schema can be reviewed to confirm that all data requirements are indeed satisfied and are not in conflict with each other. The design can also be examined to remove any redundant features. The focus at this point is on describing the data and its relationships, rather than on physical storage details.

A fully developed conceptual schema also indicates the functional requirements of the enterprise. In a *specification of functional requirements*, users describe the kinds of operations (or transactions) that will be performed on the data. Example operations include modifying or updating data, searching for and retrieving specific data, and deleting data. A review of the schema for meeting functional requirements can be made at the conceptual design stage.

The process of moving from a conceptual schema to the actual implementation of the database involves two final design phases. Although these final phases extend beyond the role of data models, we present a brief description of the final mapping from model to physical implementation. In the **logical design** phase, the high-level conceptual schema is mapped onto the implementation data model of the database management system (DBMS). The resulting DBMS-specific database schema is then used in the subsequent **physical design** phase, in which the physical features of the database are specified. These features include the form of file organization and the internal storage structures.

Because the E-R model is extremely useful in mapping the meanings and interactions of real-world enterprises onto a conceptual schema, a number of database design tools draw on E-R concepts. Further, the relative simplicity and pictorial clarity of the E-R diagramming technique may well account, in large part, for the widespread use of the E-R model.

52.3.1.4 Deriving a Relational Database Design from the E-R Model

A database that conforms to an E-R diagram can be represented by a collection of tables. For each entity set and each relationship set in the database, there is a unique table that is assigned the name of the corresponding entity set or relationship set. Each table has a number of columns that, again, have unique names. The conversion of database representation from an E-R diagram to a table format is the basis for deriving a relational database design.

The column headers of a table representing an entity set correspond to the attributes of the entity, and the primary key of the entity becomes the primary key of the relation. The column headers of a table representing a relationship set correspond to the primary key attributes of the participating entity sets, and the attributes of the relationship set. Rows in the table can be uniquely identified by the combined primary keys of the participating entity sets. For such a table, the primary keys of the participating entity sets are *foreign keys* of the table. The rows of the tables correspond to individual members of the entity or relationship set.

Table 52.1 through Table 52.3 show instances of tables that correspond, respectively, to the *customer* and *loan* entity sets, the *borrower* relationship set, of Figure 52.5.

52.3.2 Object-Oriented Model

The object-oriented data model is an adaptation of the object-oriented programming paradigm to database systems. The object-oriented approach to programming was first introduced by the language Simula 67, which was designed for programming simulations. More recently, the languages Smalltalk, C++, and Java have become the most widely known object-oriented programming languages. Database applications in such areas as computer-aided design and bio-informatics do not fit the set of assumptions made for older, data-processing-style applications. The object-oriented data model has been proposed to deal with some of these applications. The model is based on the concept of encapsulating data, and code that operates on that data, in an object.

52.3.2.1 Basics

Like the E-R model, the object-oriented model is based on a collection of objects. Entities, in the sense of the E-R model, are represented as **objects** with attribute values represented by *instance variables* within

the object. The value stored in an instance variable may itself be an object. Objects can contain objects to an arbitrarily deep level of nesting. At the bottom of this hierarchy are objects such as integers, character strings, and other data types that are built into the object-oriented system and serve as the foundation of the object-oriented model. The set of built-in object types varies from system to system.

In addition to representing data, objects have the ability to initiate operations. An object may send a *message* to another object, causing that object to execute a *method* in response. Methods are procedures, written in a general-purpose programming language, that manipulate the object's local instance variables and send messages to other objects. Messages provide the only means by which an object can be accessed. Therefore, the internal representation of an object's data need not influence the implementation of any other object. Different objects may respond differently to the same message. This encapsulation of code and data has proven useful in developing higher modular systems. It corresponds to the programming language concept of abstract data types.

The only way in which one object can access the data of another object is by invoking a method of that other object. This is called *sending a message* to the object. Thus, the call interface of the methods of an object defines its externally visible part. The internal part of the object — the instance variables and method code — are not visible externally. The result is two levels of data abstraction.

To illustrate the concept, consider an object representing a bank account. Such an object contains instance variables *account-number* and *account-balance*, representing the account number and account balance. It contains a method *pay-interest*, which adds interest to the balance. Assume that the bank had been paying 4% interest on all accounts but now is changing its policy to pay 3% if the balance is less than \$1000 or 4% if the balance is \$1000 or greater. Under most data models, this would involve changing code in one or more application programs. Under the object-oriented model, the only change is made within the *pay-interest* method. The external interface to the object remains unchanged.

52.3.2.2 Classes

Objects that contain the same types of values and the same methods are grouped together into *classes*. A class may be viewed as a type definition for objects. This combination of data and code into a type definition is similar to the programming language concept of abstract data types. Thus, all *employee* objects may be grouped into an *employee* class. Classes themselves can be grouped into a hierarchy of classes; for example, the *employee* class and the *customer* classes may be grouped into a *person* class. The class *person* is a **superclass** of the *employee* and *customer* classes because all objects of the *employee* and *customer* classes also belong to the *person* class. Superclasses are also called **generalizations**. Correspondingly, the *employee* and *customer* classes are **subclasses** of *person*; subclasses are also called **specializations**.

The hierarchy of classes allows sharing of common methods. It also allows several distinct views of objects: an employee, for an example, may be viewed either in the role of person or employee, whichever is more appropriate.

52.3.2.3 The Unified Modeling Language UML

The **Unified Modeling Language** (UML) is a standard for creating specifications of various components of a software system. Some of the parts of UML are:

- **Class diagram.** Class diagrams play the same role as E-R diagrams, and are used to model data. Later in this section we illustrate a few features of class diagrams and how they relate to E-R diagrams.
- **Use case diagram.** Use case diagrams show the interaction between users and the system, in particular the steps of tasks that users perform (such as withdrawing money or registering for a course).
- **Activity diagram.** Activity diagrams depict the flow of tasks between various components of a system.
- **Implementation diagram.** Implementation diagrams show the system components and their interconnections, both at the software component level and the hardware component level.

We do not attempt to provide detailed coverage of the different parts of UML here; we only provide some examples illustrating key features of UML class diagrams. See the bibliographic notes for references on UML for more information.

UML class diagrams model objects, whereas E-R models entities. Objects are similar to entities, and have attributes, but additionally provide a set of functions (called methods) that can be invoked to compute values on the basis of attributes of the objects, or to update the object itself. Class diagrams can depict methods in addition to attributes.

We represent binary relationship sets in UML by drawing a line connecting the entity sets. We write the relationship set name adjacent to the line. We may also specify the role played by an entity set in a relationship set by writing the role name on the line adjacent to the entity set. Alternatively, we may write the relationship set name in a box, along with attributes of the relationship set, and connect the box by a dotted line to the line depicting the relationship set. This box can then be treated as an entity set, in the same way as an aggregation in E-R diagrams and can participate in relationships with other entity sets. UML 1.3 supports non-binary relationships, using the same diamond notation used in E-R diagrams.

Cardinality constraints are specified in UML in the same way as in E-R diagrams, in the form $l..h$, where l denotes the minimum and h the maximum number of relationships an entity can participate in. However, the interpretation here is that the constraint indicates the minimum/maximum number of relationships an object can participate in, *given that the other object in the relationship is fixed*. You should be aware that, as a result, the positioning of the constraints is exactly the reverse of the positioning of constraints in E-R diagrams, as shown in [Figure 52.6](#). The constraint $0..*$ on the $E2$ side and $0..1$ on the $E1$ side means that each $E2$ entity can participate in, at most, one relationship, whereas each $E1$ entity can participate in many relationships; in other words, the relationship is many-to-one from $E2$ to $E1$.

Single values such as 1 or $*$ may be written on edges; the single value 1 on an edge is treated as equivalent to $1..1$, while $*$ is equivalent to $0..*$.

We represent generalization and specialization in UML by connecting entity sets by a line with a triangle at the end corresponding to the more general entity set. For instance, the entity set *person* is a generalization of *customer* and *employee*. UML diagrams can also represent explicitly the constraints of disjoint/overlapping on generalizations. For instance, if the *customer/employee-to-person* generalization is disjoint, it means that no one can be both a *customer* and an *employee*. An overlapping generalization allows a person to be both a *customer* and an *employee*. [Figure 52.6](#) shows how to represent disjoint and overlapping generalizations of *customer* and *employee* to *person*.

52.3.2.4 Object-Oriented Database Programming Languages

There are two approaches to creating an object-oriented database language: the concepts of object orientation can be added to existing database languages, or existing object-oriented languages can be extended to deal with databases by adding concepts such as persistence and collections. Object-relational database systems take the former approach. Persistent programming languages follow the latter approach.

Persistent extensions to C++ and Java have made significant technical progress in the past decade. Several object-oriented database systems succeeded in integrating persistence fairly seamlessly and orthogonally with existing language constructs. The Object Data Management Group (ODMG) developed standards for integrating persistence support into several programming languages such as Smalltalk, C++, and Java. However, object-oriented databases based on persistent programming languages have faced significant hurdles in commercial adoption, in part because of their lack of support for legacy applications, and in part because the features provided by object-oriented databases did not make a significant difference to typical data processing applications.

Object-relational database systems, which integrate object-oriented features with traditional relational support, have fared better commercially because they offer an easy upgrade path for existing applications.

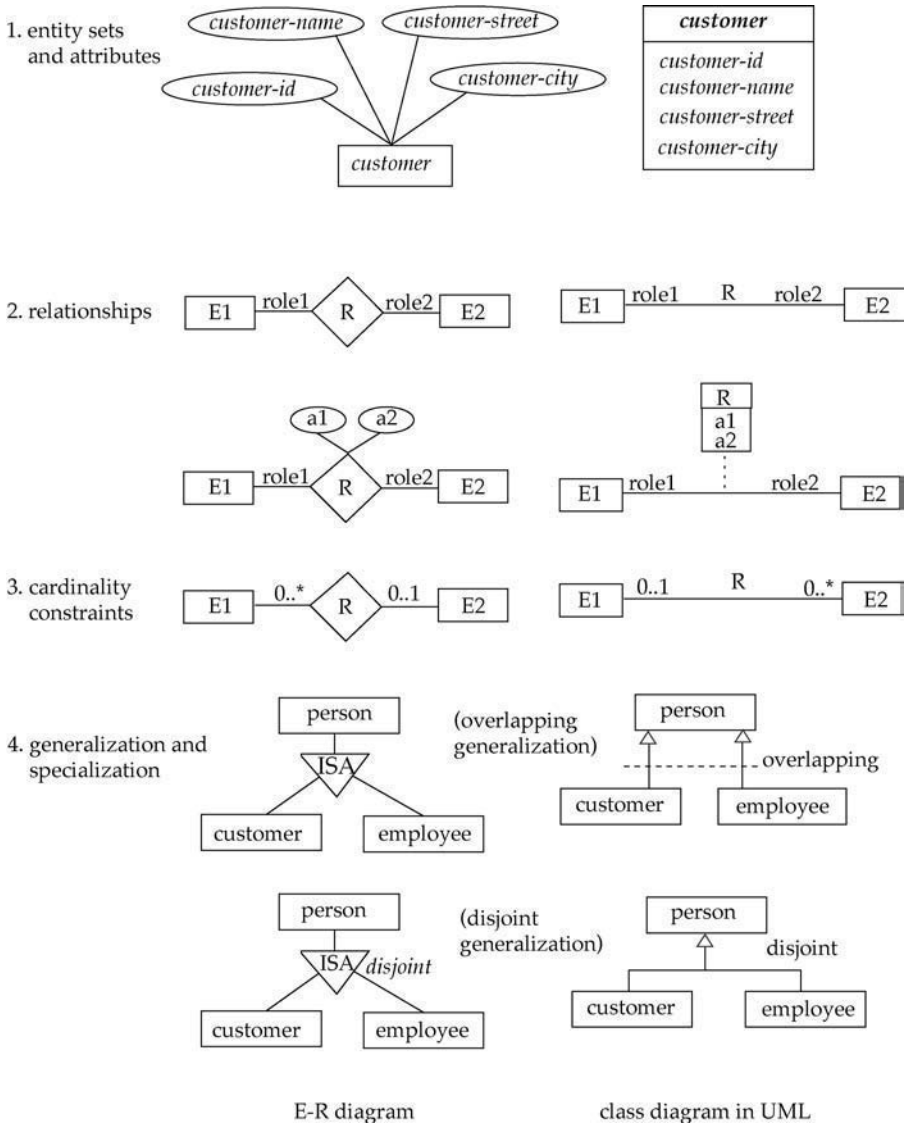

FIGURE 52.6 Correspondence of symbols used in the E-R diagram and UML class diagram notation.

52.3.3 Object-Relational Data Models

Object-relational data models extend the relational data model by providing a richer type system including object orientation. Constructs are added to relational query languages such as SQL to deal with the added data types. The extended type systems allow attributes of tuples to have complex types, including non-atomic values such as nested relations. Such extensions attempt to preserve the relational foundations, in particular the declarative access to data, while extending the modeling power.

Object-relational database systems (that is, database systems based on the object-relational model) provide a convenient migration path for users of relational databases who wish to use object-oriented features. Complex types such as nested relations are useful to model complex data in many applications. Object-relational systems combine complex data based on an extended relational model with object-oriented concepts such as object identity and inheritance. Relations are allowed to form an inheritance hierarchy;

each tuple in a lower-level relation must correspond to a unique tuple in a higher-level relation that represents information about the same object. Inheritance of relations provides a convenient way of modeling roles, where an object can acquire and relinquish roles over a period of time.

Several object-oriented extensions to SQL have been proposed in the recent past. The SQL:1999 standard supports a variety of object-oriented features, including complex data types such as records and arrays, and type hierarchies with classes and subclasses. Values of attributes can be of complex types. Objects, however, do not have an independent existence; they correspond to tuples in a relation. SQL:1999 also supports references to objects; references must be to objects of a particular type, which are stored as tuples of a particular relation.

SQL:1999 supports table inheritance; if r is a subtable of s , the type of tuples of r must be a subtype of the type of tuples of s . Every tuple present in r is implicitly (automatically) present in s as well. A query on s would find all tuples inserted directly to s as well as tuples inserted into r ; however, only the attributes of table s would be accessible, even for the r tuples. Thus, subtables can be used to represent specialization/generalization hierarchies. However, while subtables in the SQL:1999 standard can be used to represent disjoint specializations, where an object cannot belong to two different subclasses of a particular class, they cannot be used to represent the general case of overlapping specialization.

In addition to object-oriented data-modeling features, SQL:1999 supports an imperative extension of the SQL query language, providing features such as *for* and *while* loops, *if-then-else* statements, procedures, and functions.

52.4 XML

Unlike most of the data models, the **Extensible Markup Language (XML)** was not originally conceived as a database technology. In fact, like the *Hyper-Text Markup Language (HTML)* on which the World Wide Web is based, XML has its roots in document management. However, unlike HTML, XML can represent database data, as well as many other kinds of structured data used in business applications. It is particularly useful as a data format when an application must communicate with another application, or integrate information from several other applications.

The term **markup** in the context of documents refers to anything in a document that is not intended to be part of the printed output. For the family of markup languages that includes HTML and XML, the markup takes the form of **tags** enclosed in angle-brackets, $\langle \rangle$. Tags are used in pairs, with $\langle \text{tag} \rangle$ and $\langle / \text{tag} \rangle$ delimiting the beginning and the end of the portion of the document to which the tag refers. For example, the title of a document might be marked up as follows:

$\langle \text{title} \rangle$ Database System Concepts $\langle / \text{title} \rangle$

Unlike HTML, XML does not prescribe the set of tags allowed, and the set may be specialized as needed. This feature is the key to XML's major role in data representation and exchange, whereas HTML is used primarily for document formatting.

For example, in our running banking application, account and customer information can be represented as part of an XML document as in [Table 52.4](#). Observe the use of tags such as `account` and `account-number`. These tags provide context for each value and allow the semantics of the value to be identified. The contents between a start tag and its corresponding end tag is called an **element**.

Compared to storage of data in a database, the XML representation may be inefficient because tag names are repeated throughout the document. However, despite this disadvantage, an XML representation has significant advantages when it is used to exchange data, for example, as part of a message:

- The presence of the tags makes the message **self-documenting**; that is, a schema need not be consulted to understand the meaning of the text. We can readily read the fragment above, for example.
- The format of the document is not rigid. For example, if some sender adds additional information, such as a tag `last-accessed` noting the last date on which an account was accessed, the recipient of the XML data may simply ignore the tag. The ability to recognize and ignore unexpected tags allows the format of the data to evolve over time, without invalidating existing applications.

TABLE 52.4 XML Representation of Bank Information

```
<bank>
  <account>
    <account-number> A-101 </account-number>
    <branch-name> Downtown </branch-name>
    <balance> 500 </balance>
  </account>
  <account>
    <account-number> A-102 </account-number>
    <branch-name> Perryridge </branch-name>
    <balance> 400 </balance>
  </account>
  <account>
    <account-number> A-201 </account-number>
    <branch-name> Brighton </branch-name>
    <balance> 900 </balance>
  </account>
  <customer>
    <customer-name> Johnson </customer-name>
    <customer-street> Alma </customer-street>
    <customer-city> Palo Alto </customer-city>
  </customer>
  <customer>
    <customer-name> Hayes </customer-name>
    <customer-street> Main </customer-street>
    <customer-city> Harrison </customer-city>
  </customer>
  <depositor>
    <account-number> A-101 </account-number>
    <customer-name> Johnson </customer-name>
  </depositor>
  <depositor>
    <account-number> A-201 </account-number>
    <customer-name> Johnson </customer-name>
  </depositor>
  <depositor>
    <account-number> A-102 </account-number>
    <customer-name> Hayes </customer-name>
  </depositor>
</bank>
```

- Elements can be nested inside other elements, to any level of nesting. [Table 52.5](#) shows a representation of the bank information from [Table 52.4](#), but with account elements nested within customer elements.

The nested representation permits representation of complex information within a single document. For instance, a purchase order element may have within it elements representing the supplier, customer, and each of the parts ordered. Each of these elements, in turn, may have subelements; for instance, a part element may have subelements for its part number, name, and price.

Although the nested representation makes it easier to represent some information, it can result in redundancy; for example, the nested representation of the bank database would store an account element redundantly (multiple times) if it is owned by multiple customers.

Nested representations are widely used in XML data interchange applications to avoid joins. For instance, a shipping application would store the full address of sender and receiver redundantly on a shipping document associated with each shipment, whereas a normalized representation may require a join of shipping records with a *company-address* relation to get address information.

- Because the XML format is widely accepted, a wide variety of tools are available to assist in its processing, including browser software and database tools.

TABLE 52.5 Nested XML Representation of Bank Information

```
<bank-1>
  <customer>
    <customer-name> Johnson </customer-name>
    <customer-street> Alma </customer-street>
    <customer-city> Palo Alto </customer-city>
    <account>
      <account-number> A-101 </account-number>
      <branch-name> Downtown </branch-name>
      <balance> 500 </balance>
    </account>
    <account>
      <account-number> A-201 </account-number>
      <branch-name> Brighton </branch-name>
      <balance> 900 </balance>
    </account>
  </customer>
  <customer>
    <customer-name> Hayes </customer-name>
    <customer-street> Main </customer-street>
    <customer-city> Harrison </customer-city>
    <account>
      <account-number> A-102 </account-number>
      <branch-name> Perryridge </branch-name>
      <balance> 400 </balance>
    </account>
  </customer>
</bank-1>
```

Just as SQL is the dominant *language* for querying relational data, XML is becoming the dominant *format* for data exchange.

In addition to elements, XML specifies the notion of an *attribute*. For example, the type of an account is represented below as an attribute named *acct-type*.

```
...
  <account acct-type= "checking">
    <account-number> A-102 </account-number>
    <branch-name> Perryridge </branch-name>
    <balance> 400 </balance>
  </account>
...
```

The attributes of an element appear as *name=value* pairs before the closing “>” of a tag. Attributes are strings and do not contain markup. Furthermore, an attribute name can appear only once in a given tag, unlike subelements, which may be repeated.

Note that in a document construction context, the distinction between subelement and attribute is important — an attribute is implicitly text that does not appear in the printed or displayed document. However, in database and data exchange applications of XML, this distinction is less relevant, and the choice of representing data as an attribute or a subelement is often arbitrary.

The **document type definition (DTD)** is an optional part of an XML document. The main purpose of a DTD is much like that of a schema: to constrain and type the information present in the document. However, the DTD does not, in fact, constrain types in the sense of basic types like integer or string. Instead, it only constrains the appearance of subelements and attributes within an element. The DTD is primarily a list of rules for what pattern of subelements appear within an element.

For instance, the DTD for the XML data in [Table 52.5](#) is shown below:

```
<!DOCTYPE bank [  
  <!ELEMENT bank (customer*)>  
  <!ELEMENT customer ( customer-name customer-street customer-city account+)>  
  <!ELEMENT customer-name( #PCDATA )>  
  <!ELEMENT customer-street( #PCDATA )>  
  <!ELEMENT customer-city( #PCDATA )>  
  <!ELEMENT account ( account-number branch-name balance )>  
  <!ELEMENT account-number ( #PCDATA )>  
  <!ELEMENT branch-name ( #PCDATA )>  
  <!ELEMENT balance( #PCDATA )>  
>
```

The above DTD indicates that a bank may have zero or more customer subelements. Each customer element has a single occurrence of each of the subelements customer-name, customer-street, and customer-city, and one or more subelements of type account. These subelements customer-name, customer-street, and customer-city are declared to be of type #PCDATA, indicating that they are character strings with no further structure (PCDATA stands for “parsed character data”). Each account element, in turn, has a single occurrence of each of the subelements account-number, branch-name, and balance.

The following DTD illustrates a case where the nesting can be arbitrarily deep; such a situation can arise with complex parts that subparts that themselves have complex subparts, and so on.

```
<!DOCTYPE parts [  
  <!ELEMENT part (name, subpartinfo*)>  
  <!ELEMENT subpartinfo (part, quantity)>  
  <!ELEMENT name ( #PCDATA )>  
  <!ELEMENT quantity ( #PCDATA )>  
>
```

The above DTD specifies that a part element may contain within it zero or more subpart elements, each of which in turn contains a part element. DTDs such as the above, where an element type is recursively contained within an element of the same type, are called **recursive DTDs**. The **XMLSchema** language plays the same role as DTDs, but is more powerful in terms of the types and constraints it can specify.

The **XPath** and **XQuery** languages are used to query XML data. The XQuery language can be thought of as an extension of SQL to handle data with nested structure, although its syntax is different from that of SQL.

Many database systems store XML data by mapping them to relations. Unlike in the case of E-R diagram to relation mappings, the XML to relation mappings are more complex and done transparently. Users can write queries directly in terms of the XML structure, using XML query languages.

In summary, the XML language provides a flexible and self-documenting mechanism for modeling data, supporting a variety of features such as nested structures and multivalued attributes, and allowing multiple types of data to be represented in a single document. Although the basic XML model allows data to be arbitrarily structured, the schema of a document can be specified using DTDs or the XMLSchema language. Both these mechanisms allow the schema to be flexibly and partially specified, unlike the rigid schema of relational data, thus supporting **semi-structured data**.

52.5 Further Reading

- **The Relational Model.** The relational model was proposed by E.F. Codd of the IBM San Jose Research Laboratory in the late 1960s [Cod70]. Following Codd’s original paper, several research projects were formed with the goal of constructing practical relational database systems, including System R at the IBM San Jose Research Laboratory (Chamberlin et al. [CAB⁺81]), Ingres at the

University of California at Berkeley (Stonebraker [Sto86b]), and Query-by-Example at the IBM T.J. Watson Research Center (Zloof [Zlo77]).

General discussion of the relational data model appears in most database texts, including Date [Dat00], Ullman [Ull88], Elmasri and Navathe [EN00], Ramakrishnan and Gehrke [RG02], and Silberschatz et al. [SKS02]. Textbook descriptions of the SQL-92 language include Date and Darwen [DD97] and Melton and Simon [MS93].

Textbook descriptions of the network and hierarchical models, which predated the relational model, can be found on the Web site <http://www.db-book.com> (this is the Web site of the text by Silberschatz et al. [SKS02])

- **The Object-Based Models.**

- **The Entity-Relationship Model.** The entity-relationship data model was introduced by Chen [Che76]. Basic textbook discussions are offered by Elmasri and Navathe [EN00], Ramakrishnan and Gehrke [RG02], and Silberschatz et al. [SKS02]. Various data manipulation languages for the E-R model have been proposed, although none is in widespread commercial use. The concepts of generalization, specialization, and aggregation were introduced by Smith and Smith [SS77].

- **Object-Oriented Models.** Numerous object-oriented database systems were implemented as either products or research prototypes. Some of the commercial products include ObjectStore, Ontos, Orion, and Versant. More information on these may be found in overviews of object-oriented database research, such as Kim and Lochovsky [KL89], Zdonik and Maier [ZM90], and Dogac et al. [DOBS94]. The ODMG standard is described by Cattell [Cat00].

Descriptions of UML may be found in Booch et al. [BJR98] and Fowler and Scott [FS99].

- **Object-Relational Models.** The nested relational model was introduced in [Mak77] and [JS82]. Design and normalization issues are discussed in [OY87, [RK87], and [MNE96]. POSTGRES ([SR86] and [Sto86a]) was an early implementation of an object-relational system. Commercial databases such as IBM DB2, Informix, and Oracle support various object-relational features of SQL:1999. Refer to the user manuals of these systems for more details.

Melton et al. [MSG01] and Melton [Mel02] provide descriptions of SQL:1999; [Mel02] emphasizes advanced features, such as the object-relational features, of SQL:1999. Date and Darwen [DD00] describes future directions for data models and database systems.

- **XML.** The XML Cover Pages site (www.oasis-open.org/cover/) contains a wealth of XML information, including tutorial introductions to XML, standards, publications, and software. The World Wide Web Consortium (W3C) acts as the standards body for Web-related standards, including basic XML and all the XML-related languages such as XPath, XSLT, and XQuery. A large number of technical reports defining the XML related standards are available at www.w3c.org.

A large number of books on XML are available in the market. These include [CSK01], [CRZ03], and [W⁺00].

Defining Terms

Attribute: 1. A descriptive feature of an entity or relationship in the entity-relationship model. 2. The name of a column header in a table, or, in relational-model terminology, the name of a domain used to define a relation.

Class: A set of objects in the object-oriented model that contains the same types of values and the same methods; also, a type definition for objects.

Data model: A collection of conceptual tools for describing the real-world entities to be modeled in the database and the relationships among these entities.

Element: The contents between a start tag and its corresponding end tag in an XML document.

Entity: A distinguishable item in the real-world enterprise being modeled by a database schema.

Foreign key: A set of attributes in a relation schema whose value identifies a unique tuple in another relational schema.

Functional dependency: A rule stating that given values for some set of attributes, the value for some other set of attributes is uniquely determined. X functionally determines Y if whenever two tuples in a relation have the same value on X, they must also have the same value on Y.

Generalization: A superclass; an entity set that contains all the members of one or more specialized entity sets.

Instance variable: attribute values within objects.

Key: 1. A set of attributes in the entity relationship model that serves as a unique identifier for entities. Also known as *superkey*. 2. A set of attributes in a relation schema that functionally determines the entire schema. 3. *Candidate key*: a minimal key. 4. *Primary key*: a candidate key chosen as the primary means of identifying/accessing an entity set, relationship set, or relation.

Message: The means by which an object invokes a method in another object.

Method: Procedures within an object that operate on the instance variables of the object and/or send messages to other objects.

Normal form: A set of desirable properties of a schema. Examples include the Boyce-Codd normal form and the third normal form.

Object: Data and behavior (methods) representing an entity.

Persistence: The ability of information to survive (persist) despite failures of all kinds, including crashes of programs, operating systems, networks, and hardware.

Relation: 1. A subset of a Cartesian product of domains. 2. Informally, a table.

Relation schema: A type definition for relations, consisting of attribute names and a specification of the corresponding domains.

Relational algebra: An algebra on relations; consists of a set of operations, each of which takes as input one or more relations and returns a relation, and a set of rules for combining operations to create expressions.

Relationship: An association among several entities.

Subclass: A class that lies below some other class (a superclass) in a class inheritance hierarchy; a class that contains a subset of the objects in a superclass.

Subtable: A table such that (a) its tuples are of a type that is a subtype of the type of tuples of another table (the supertable), and (b) each tuple in the subtable has a corresponding tuple in the supertable.

Specialization: A subclass; an entity set that contains a subset of entities of another entity set.

53.1 Introduction

In fields ranging from arbitrage to tactical missile defense, speed of access to data can determine success or failure. Database tuning is the activity of making a database system run faster. Like optimization activities in other areas of computer science and engineering, database tuning must work within the constraints of its underlying technology. Just as compiler optimizers, for example, cannot directly change the underlying hardware, database tuners cannot change the underlying database management system.

The tuner can, however, modify the design of tables, select new indexes, rearrange transactions, tamper with the operating system, or buy hardware. The goals are to eliminate bottlenecks, decrease the number of accesses to disks, and guarantee response time, at least in a statistical sense.

Understanding how to do this well requires deep knowledge of the interaction among the different components of a database management system (Figure 53.1).

Further, interactions between database components and the nature of the bottlenecks change with technology. For example, inserting data in a table with a clustered index was a potential source of bottleneck using page locking; currently, all systems support row locking, thus removing the risk of such bottlenecks. Tuning, then, is for well-informed generalists. This chapter introduces a principled foundation for tuning, focusing on principles that are likely to hold true for years to come.

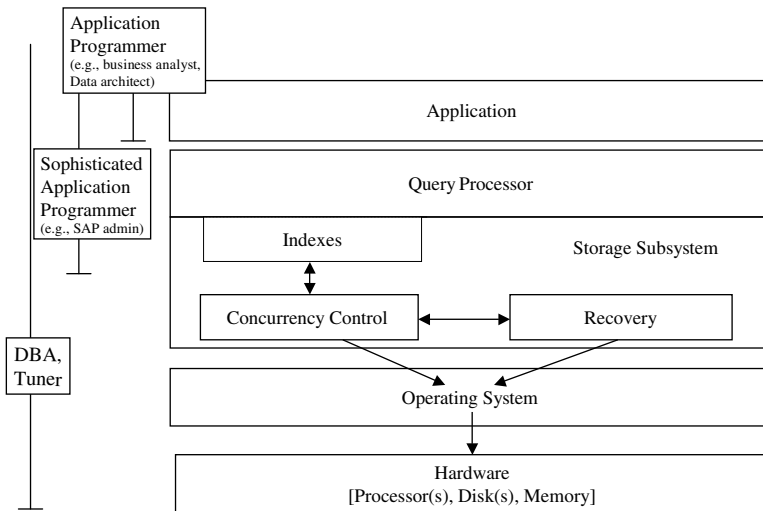

FIGURE 53.1 Database system architecture. Database tuning requires deep knowledge of the interaction among the different components and levels of a database system.

53.2 Underlying Principles

To understand the principles of tuning, you must understand the two main kinds of database applications and what affects performance.

53.2.1 What Databases Do

At a high level of abstraction, databases are used for two purposes: online transaction processing and decision support. **Online transaction processing** typically involves access to a small number of records, generally to modify them. A typical such transaction records a sale or updates a bank account. These transactions use indexes to access their few records without scanning through an entire table. **E-commerce** applications share many of these characteristics, especially the need for speed — it seems that potential e-customers will abandon a site if they have to wait more than 7 seconds for a response.

Decision support queries, by contrast, read many records often from a **data warehouse**, compute an aggregate result, and sometimes apply that aggregate back to an individual level. Typical decision support queries are “find the total sales of widgets in the last quarter in the northeast” or “calculate the available inventory per unit item.” Sometimes, the results are actionable, as in “find frequent flyer passengers who have encountered substantial delays in their last few flights and send them free tickets and an apology.”

53.2.2 Performance Spoilers

Having divided the database applications into two broad areas, we can now discuss what slows them down:

1. *Imprecise data searches.* These occur typically when a selection retrieves a small number of records from a large table, yet must search the entire table to find those data. Establishing an index may help in this case, although other actions, including reorganizing the table, may also have an effect (see [Figure 53.2](#)).
2. *Random vs. sequential disk accesses.* Sequential disk bandwidth is between one and two orders of magnitude larger than random-access disk bandwidth. In 2002, for mid-range disks, sequential

FIGURE 53.2 Benefits of clustering index. In this graph, each query returns 100 records out of the 1,000,000 that the table contains. For such a query, a clustering index is twice as fast as a non-clustering index and orders of magnitude faster than a full table scan when no index is used; clustering and non-clustering indexes are defined below. These experiments were performed on DB2 UDB V7.1, Oracle8i, and SQL Server 7 on Windows 2000.

FIGURE 53.3 Index may hurt performances. We submit range queries selecting a variable portion of the underlying table and measure the performance using an index or a scan. We observe that the non-clustering index is better when the percentage of selected records is below a certain threshold. Above this threshold, a scan performs better because it is faster to sequentially access all records than to randomly access a relatively large portion of them (15% in this experiment). This experiment was performed using DB2 UDB V7.1 on Windows 2000.

bandwidth was about 20 Mb/sec while random bandwidth was about 200 KB/sec. (The variation depends on technology and on tunable parameters, such as the degree of prefetching and size of pages.) Non-clustered index accesses tend to be random, whereas scans are sequential. Thus, removing an index may sometimes improve performance, because either the index is never used for reading (and therefore constitutes only a burden for updates) or the index is used for reading and behaves poorly (see Figure 53.3).

3. *Many short data interactions, either over a network or to the database.* This may occur, for example, if an object-oriented application views records as objects and assembles a collection of objects by accessing a database repeatedly from within a “for” loop rather than as a bulk retrieval (see Figure 53.4).

FIGURE 53.4 Loop constructs. This graph compares two programs that obtain 2000 records from a large table (line item from TPC-H). The *loop* program submits 200 queries to obtain this data, while the *no loop* program submits only one query and thus enjoys much better performance.

4. *Delays due to lock conflicts.* These occur either when update transactions execute too long or when several transactions want to access the same datum, but are delayed because of locks. A typical example might be a single variable that must be updated whenever a record is inserted. In the following example, the `COUNTER` table contains the next value which is used as a key when inserting values in the `ACCOUNT` table.

```
begin transaction
  NextKey := select nextkey from COUNTER;
  insert into ACCOUNT values (nextkey, 100, 200);
  update COUNTER set nextkey = NextKey + 1;
end transaction
```

When the number of such transactions issued concurrently increases, `COUNTER` becomes a bottleneck because all transactions read and write the value of `nextkey`.

As mentioned in the introduction, avoiding such performance problems requires changes at all levels of a database system. We will discuss tactics used at several of these levels and their interactions — hardware, concurrency control subsystem, indexes, and conceptual level. There are other levels, such as recovery and query rewriting, that we mostly defer to reference [4].

53.3 Best Practices

Understanding how to tune each level of a database system (see [Figure 53.1](#)) requires understanding the factors leading to good performance at that level. Each of the following subsections discusses these factors before discussing tuning tactics.

53.3.1 Tuning Hardware

Each processing unit consists of one or more processors, one or more disks, and some memory. Assuming a 1-GIPS (billion instructions per second) processor, disks will be the bottleneck for online transaction processing applications until the processor is attached to around 10 disks (counting 500,000 instructions per random I/O issued by the database system and 200 random I/O per second). Each transaction spends far more time waiting for head movement on disk than in the processor.

Decision support queries, by contrast, often entail massive scans of a table. In theory, a 1-GIPS processor is saturated when connected to three disks (counting 500,000 instructions per sequential I/O and 5000 I/O per second, considering 20 MB/sec and 64 KB per I/O). In practice, around three disks overflow the PCI

FIGURE 53.5 Buffer organization. The database buffer is located in virtual memory (i.e., RAM and paging file). Its greater part should be in RAM. It is best to have the paging file on its own disk.

bus of the server they are connected to. Thus, decision support sites may need fewer disks per processor than transaction processing sites for the purposes of matching aggregate disk bandwidth to processor speed.*

Solid-state random access memory (RAM) obviates the need to go to disk. Database systems reserve a portion of RAM as a *buffer*, whose logical role is illustrated in Figure 53.5. In all applications, the buffer usually holds frequently accessed pages (*hot* pages, in database parlance), including the first few levels of indexes. Increasing the amount of RAM buffer tends to be particularly helpful in online transaction applications where disks are the bottleneck.

The read **hit ratio** in a database is the portion of database reads that are satisfied by the buffer. Hit ratios of 90% or higher are common in online transaction applications but less common in decision support applications. Even in transaction processing applications, hit ratios tend to level off as you increase the buffer size if there are one or more tables that are accessed unpredictably and are much larger than available RAM (e.g., sales records for a large department store).

53.3.2 Tuning the Operating System

The operating system, in combination with the lower levels of the database system, determines such features as the layout of files on disk as well as the assignment and safe use of transaction priorities.

53.3.2.1 File Layout

File layout is important because of the moving parts on mechanical (as opposed to solid state) disks (Figure 53.6). Such a disk consists of a set of platters, each of which resembles a CD-ROM. A platter holds a set of tracks, each of which is a concentric circle. The platters are held together on a spindle, so that track *i* of one platter is in the same *cylinder* as track *i* of all other platters.

Accessing (reading or writing) a page on disk requires (1) moving the disk head over the proper track, say track *t*, an operation called **seeking** (the heads for all tracks move together, so all heads will be at cylinder *t* when the seek is done); (2) waiting for the appropriate page to appear under the head, a time

*This point requires a bit more explanation. There are two reasons you might need more disks: (1) for disk bandwidth (the number of bytes coming from the disk per second), or (2) for space. Disk bandwidth is usually the issue in online transaction processing. Airline reservations systems, for example, often run their disks at less than 50% utilization. Decision support applications tend to run into the space issue more frequently, because scanning allows disks to deliver their optimal bandwidth.

FIGURE 53.6 Disk organization. A disk is a collection of circular platters placed one on top of the other and rotating around a common axis (called a spindle). The concentric dashed circles are called tracks.

period called rotational delay; and (3) accessing the data. Mechanical disk technology implies that seek time > rotational delay > access time.

As noted above, if you could eliminate the overhead caused by seeks and rotational delay, the aggregate bandwidth could increase by a factor of 10 to 100. Making this possible requires laying out the data to be read sequentially along tracks.*

Recognizing the advantage of sequential reads on properly laid-out data, most database systems encourage administrators to lay out tables in relatively large *extents* (consecutive portions of disk). Having a few large extents is a good idea for tables that are scanned frequently or (like database recovery logs or history files) are written sequentially. Large extents, then, are a necessary condition for good performance, but not sufficient, particularly for history files. Consider, for example, the scenario in which a database log is laid out on a disk in a few large extents, but another hot table is also on that disk. The accesses to the hot table may entail a seek from the last page of the log; the next access to the log will entail another seek. So, much of the gain of large extents will be lost. For this reason, each log or history file should be the only hot file on its disk, unless the disk makes use of a large RAM cache to buffer the updates to each history file (Figure 53.7).

When accesses to a file are entirely random (as is the case in online transaction processing), seeks cannot be avoided. But placement can still minimize their cost, because seek time is roughly proportional to a constant plus the square root of the seek distance.

53.3.3 Tuning Concurrency Control

As the chapter on Concurrency Control and Recovery in this handbook explains, database systems attempt to give users the illusion that each transaction executes in isolation from all others. The ANSI SQL standard, for example, makes this explicit with its concept of degrees of isolation [3, 5]. Full isolation or **serializability** is the guarantee that each transaction that completes will appear to execute one at a time *except that its*

*Informed readers will realize that the physical layout of sequential data on tracks is not always contiguous — whether it is or not depends on the relative speed ratios of the controller and the disk. The net effect is that there is a layout that eliminates rotational and seek time delay for table scans.

FIGURE 53.7 Impact of the controller cache. For this experiment, we use the line item table from the TPC-H benchmark and we issue 300,000 insert or update statements. This experiment was performed with Oracle8i on a Windows server with a RAID controller. This graph shows that the controller cache hides the performance penalty due to disk seeks.

performance may be affected by other transactions. This ensures, for example, that in an accounting database in which every update (e.g., sale, purchase, etc.) is recorded as a double-entry transaction, any transaction that sums assets, liabilities, and owners' equity will find that assets equal the sum of the other two. There are less stringent notions of isolation that are appropriate when users do not require such a high degree of consistency.

The concurrency-control algorithm in predominant use is two-phase locking, sometimes with optimizations for data structures. Two-phase locking has **read** (or *shared*) and **write** (or *exclusive*) locks. Two transactions may both hold a shared lock on a datum. If one transaction holds an exclusive lock on a datum, however, then no other transaction can hold any lock on that datum; in this case, the two transactions are said to **conflict**. The notion of datum (the basic unit of locking) is deliberately left unspecified in the theory of concurrency control because the same algorithmic principles apply regardless of the size of the datum, whether a page, a record, or a table. The performance may differ, however. For example, record-level locking works much better than page-level locking for online transaction processing applications.

53.3.3.1 Rearranging Transactions

Tuning concurrency control entails trying to reduce the number and duration of conflicts. This often entails understanding application semantics. Consider, for example, the following code for a purchase application of item i for price p for a company in bankruptcy (for which the cash cannot go below 0):

PURCHASE TRANSACTION (p, i)

```

1  BEGIN TRANSACTION
2    if cash < p then roll back transaction
3    inventory( $i$ ) := inventory( $i$ ) + p
4    cash := cash - p
5  END TRANSACTION
```

From a concurrency-control-theoretical point of view, this code does the right thing. For example, if the cash remaining is 100, and purchase P1 is for item i with price 50, and purchase P2 is for item j with price 75, then one of these will roll back.

From the point of view of performance, however, this transaction design is very poor, because every transaction must acquire an exclusive lock on cash from the beginning to avoid deadlock. (Otherwise, many transactions will obtain shared locks on cash and none will be able to obtain an exclusive lock on cash.) That will make cash a bottleneck and have the effect of serializing the purchases. Because inventory is apt to be large, accessing $\text{inventory}(i)$ will take at least one disk access, requiring about 10 ms. Because

the transactions will serialize on cash, only one transaction will access inventory at a time. This will limit the number of purchase transactions to about 100 per second. Even a company in bankruptcy may find this rate unacceptable.

A surprisingly simple rearrangement helps matters greatly:

REDESIGNED PURCHASE TRANSACTION (p, i)

```
1 BEGIN TRANSACTION
2   inventory( $i$ ) := inventory( $i$ ) +  $p$ 
3   if cash <  $p$  then roll back transaction
4   else cash := cash -  $p$ 
5 END TRANSACTION
```

Cash is still a hot spot, but now each transaction will avoid holding cash while accessing inventory. Because cash is so hot, it will be in the RAM buffer. The lock on cash can be released as soon as the commit occurs.

Other techniques are available that “chop” transactions into independent pieces to shorten lock times further, but they are quite technical. We refer interested readers to [4].

53.3.3.2 Living Dangerously

Many applications live with less than full isolation due to the high cost of holding locks during user interactions. Consider the following full-isolation transaction from an airline reservation application:

AIRLINE RESERVATION TRANSACTION (p, i)

```
1 BEGIN TRANSACTION
2   Retrieve list of seats available.
3   Reservation agent talks with customer regarding availability.
4   Secure seat.
5 END TRANSACTION
```

The performance of a system built from such transactions would be intolerably slow because each customer would hold a lock on all available seats for a flight while chatting with the reservations agent. This solution does, however, guarantee two conditions: (1) no two customers will be given the same seat, and (2) any seat that the reservation agent identifies as available in view of the retrieval of seats will still be available when the customer asks to secure it.

Because of the poor performance, however, the following is done instead:

LOOSELY CONSISTENT AIRLINE RESERVATION TRANSACTION (p, i)

```
1 Retrieve list of seats available.
2 Reservation agent talks with customer regarding availability.
3 BEGIN TRANSACTION
4 Secure seat.
5 END TRANSACTION
```

This design relegates lock conflicts to the secure step, thus guaranteeing that no two customers will be given the same seat. It does allow the possibility, however, that a customer will be told that a seat is available, will ask to secure it, and will then find out that it is gone. This has actually happened to a particularly garrulous colleague of ours.

53.3.4 Indexes

Access methods, also known as indexes, are discussed in another chapter. Here we review the basics, then discuss tuning considerations. An **index** is a data structure plus a method of arranging the data tuples in the table (or other kind of collection object) being indexed. Let’s discuss the data structure first.

53.3.4.1 Data Structures

Two data structures are most often used in practice: B-trees and Hash structures. Of the two, B-trees are used most often (one vendor's tuning book puts it this way: "When in doubt, use a B-tree"). Here, we review those concepts about B-trees most relevant to tuning.

A **B-tree** (strictly speaking, a B+ tree) is a balanced tree whose nodes contain a sequence of key–pointer pairs [2]. The keys are sorted by value. The pointers at the leaves point to the tuples in the indexed table.

B-trees are self-reorganizing through operations known as splits and merges (although occasional reorganizations for the purpose of reducing the number of seeks do take place). Further, they support many different query types well: equality queries (find the employee record of the person having a specific social security number), min–max queries (find the highest-paid employee in the company), and range queries (find all salaries between \$70,000 and \$80,000).

Because an access to disk secondary memory costs about 5 ms if it requires a seek (as index accesses will), the performance of a B-tree depends critically on the number of nodes in the average path from root to leaf. (The root will tend to be in RAM, but the other levels may or not be, and the farther down the tree the search goes, the less likely they are to be in RAM.) The number of nodes in the path is known as the number of levels. One technique that database management systems use to minimize the number of levels is to make each interior node have as many children as possible (1000 or more for many B-tree implementations). The maximum number of children a node can have is called its *fan-out*. Because a B-tree node consists of key–pointer pairs, the bigger the key is, the smaller the fan-out.

For example, a B-tree with a million records and a fan-out of 1000 requires three levels (including the level where the records are kept). A B-tree with a million records and a fan-out of 10 requires seven levels. If we increase the number of records to a billion, the numbers of levels increase to four and ten, respectively. This is why accessing data through indexes on large keys is slower than accessing data through small keys on most systems (the exceptions are those few systems that have good compression).

Hash structures, by contrast, are a method of storing key–value pairs based on a pseudorandomizing function called a *hash function*. The hash function can be thought of as the root of the structure. Given a key, the hash function returns a location that contains either a page address (usually on disk) or a directory location that holds a set of page addresses. That page either contains the key and associated record or is the first page of a linked list of pages, known as an *overflow chain* leading to the record(s) containing the key. (You can keep overflow chaining to a minimum by using only half the available space in a hash setting.)

In the absence of overflow chains, hash structures can answer equality queries (e.g., find the employee with Social Security number 156-87-9864) in one disk access, making them the best data structures for that purpose. The hash function will return arbitrarily different locations on key values that are close but unequal (e.g., Smith and Smythe). As a result, records containing such close keys will likely be on different pages. This explains why hash structures are completely unhelpful for range and min–max queries.

53.3.4.2 Clustering and Sparse Indexes

The data structure portion of an index has pointers at its leaves to either data pages or data records, as shown in [Figure 53.8](#).

- If there is at most one pointer from the data structure to each data page, then the index is said to be **sparse**.
- If there is one pointer to each record in the table, then the index is said to be **dense**.

If records are small compared to pages, then there will be many records per data page and the data structure supporting a sparse index will usually have one less level than the data structure supporting a dense index. This means one less disk access if the table is large. By contrast, if records are almost as large as pages, then a sparse index will rarely have better disk access properties than a dense index.

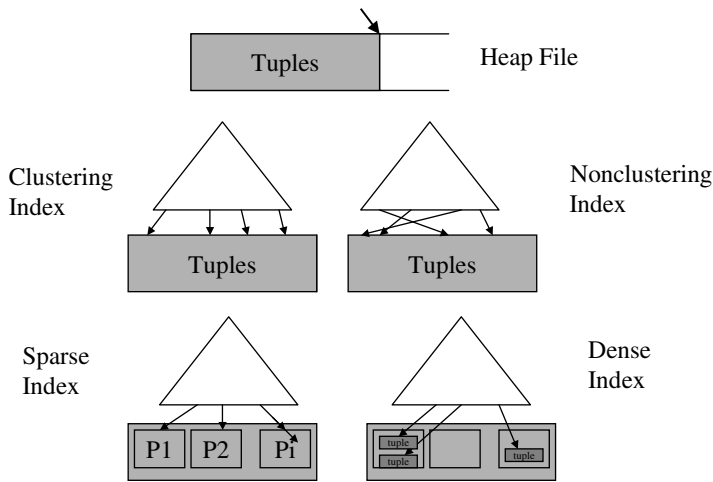

FIGURE 53.8 Data organization. This diagram represent various data organization: a heap file (records are always inserted at the end of the data structure), a clustering index (records are placed on disk according to the leaf node that points to them), a nonclustering index (records are placed on disk independently of the index structure), a sparse index (leaf-nodes point to pages), and a dense index (leaf nodes point to records). Note that a nonclustering index must be dense, while a clustering index might be sparse or dense.

The main virtue of dense indexes is that they can support certain read queries within the data structure itself, in which case they are said to **cover** the query. For example, if there is a dense index on the keywords of a document retrieval system, a query can count the records containing some term (e.g., “derivatives scandals,”) without accessing the records themselves. (Count information is useful for that application because queriers frequently reformulate a query when they discover that it would retrieve too many documents.) A secondary virtue is that a query that makes use of several dense indexes can identify all relevant tuples before accessing the data records; instead, one can just form intersections and unions of pointers to data records.

A **clustering index** on an attribute (or set of attributes) X is an index that puts records close to one another if their X -values are *near* one another. What “near” means depends on the data structure. On B-trees, two X -values are near if they are close in their sort order. For example, 50 and 51 are near, as are Smith and Sneed. In hash structures, two X -values are near only if they are identical.

Sparse indexes must be clustering, but clustering indexes need not be sparse. In fact, clustering indexes are sparse in some systems (e.g., SQL Server, ORACLE hash structures) and dense in others (e.g., ORACLE B-trees, DB2). Because a clustering index implies a certain table organization and the table can be organized in only one way at a time, there can be at most one clustering index per table.

A **nonclustering index** (sometimes called a *secondary* index) is an index on an attribute (or set of attributes) Y that puts no constraint on the table organization. The table can be clustered according to some other attribute X or can be organized as a heap, as we discuss below. A nonclustering index must be dense, so there is one leaf pointer per record. There can be many nonclustering indexes per table. Throughput trade-offs among these various indexing strategies are illustrated in [Figure 53.9](#).

A **heap** is the simplest table organization of all. Records are ordered according to their time of entry (Figure 53.8). That is, new insertions are added to the last page of the data structure. For this reason, inserting a record requires a single page access.

Nonclustering indexes are useful if each query retrieves significantly fewer records than there are pages in the file. We use the word “significant” for the following reason: a table scan can often save time by reading many pages at a time, provided the table is stored on contiguous tracks. Therefore, even if the scan and the index both read all the pages of the table, the scan may complete more than 10 times faster than if it reads one page at a time (see [Figure 53.3](#)).

FIGURE 53.9 Covering index. This experiment illustrates that a covering index can be as good as or even better than a clustering index as long as (1) the query submitted is a prefix match query (a *prefix match query* on an attribute or sequence of attributes X is one that specifies only a prefix of X); and (2) the order of the attributes in the prefix match query matches the order in which the attributes have been declared in the index. If this is not the case, then the composite index does not avoid a full table scan on the underlying relation. A covering index is also significantly faster than a nonclustering index that is not covering because it avoids access to the table records. This experiment was performed with SQL Server 7 on Windows 2000 (i.e., the clustering index is sparse).

In summary, nonclustering indexes work best if they cover the query. Otherwise, they work well if the average query using the index will access far fewer records than there are data pages. Large records and high selectivity both contribute to the usefulness of nonclustering indexes.

53.3.4.3 Data Structures for Decision Support

Decision support applications often entail querying on several, perhaps individually unselective, attributes. For example, “Find people in a certain income range who are female, live in California, buy boating equipment, and work in the computer industry.” Each of these constraints is unselective in itself, but together form a small result. The best all-around data structure for such a situation is the bitmap. A bitmap is a collection of vectors of bits. The length of each vector equals the length of the table being indexed and has a 1 in position i if the i th record of the table has some property. For example, a bitmap on state would consist of 50 vectors, one for each state. The vector for California would have a 1 for record i if record i pertains to a person from California. In our experiments, bitmaps outperform multidimensional indexes by a substantial margin.

Some decision support queries compute an aggregate, but never apply the result of the aggregate back to individuals. For example, you might want to find the approximate number of California women having the above properties. In that case, you can use approximate summary tables as a kind of indexing technique. The Aqua system [1], for example, proposes an approximation based on constructing a database from a random sample of the most detailed table T (sometimes known as the *fact table* in data warehouse parlance) and then joining that result with the reference tables R_1, R_2, \dots, R_n based on foreign key joins. In the TPC-H setting, for example, the fact table is lineitem. With even a 10% sample, a seven-fold improvement in performance is obtained at a decent accuracy. (See [Figure 53.10](#) through [Figure 53.12](#)).

53.3.4.4 Final Remarks Concerning Indexes

The main point to remember is that the use of indexes is a two-edged sword: we have seen an index reduce the time to execute a query from hours to a few seconds in one application, yet increase batch load time by a factor of 80 in another application. Add them with care.

FIGURE 53.10 Approximation on one relation. We sample 1% and 10% of the line item table by selecting the top N records on an attribute which is not related to the attributes involved in the subsequent queries (here *l.linenum*). That is, we are taking an approximation of a random sample. We compare the results of a query (Q1 in TPC-H) that accesses only records in the line item relation. The graph shows the difference between the aggregated values obtained using the base relations and our two samples. There are 8 aggregate values projected out in the select clause of this query. Using the 1% sample, the difference between the aggregated value obtained using base relations and sample relations is never greater than 9%; using a 10% sample, this difference falls to around 2% in all cases but one.

FIGURE 53.11 Approximation on a 6-way join. As indicated in this section, we take a sample of the line item table and join from there on foreign keys to obtain samples for all tables in the TPC-H schema. We run query Q5, which is a 6-way join. The graph shows the error for the five groups obtained with this query (only one aggregated value is projected out). For one group, using a 1% sample (of line item and using the foreign key dependencies to obtain samples on the other tables), we obtain an aggregated value which is 40% off the aggregated value we obtained using the base relations; and using a 10% sample, we obtain a 25% difference. As a consequence of this error, the groups are not ordered the same way using base relations and approximate relations.

53.3.5 Tuning Table Design

Table design is the activity of deciding which attributes should appear in which tables in a relational system. The *Conceptual Database Design* chapter discusses this issue, emphasizing the desirability of arriving at a **normalized** schema. Performance considerations sometimes suggest choosing a nonnormalized schema, however (see [Figure 53.13](#)). More commonly, performance considerations may suggest choosing one normalized schema over another or they may even suggest the use of redundant tables.

53.3.5.1 To Normalize or Not to Normalize

Consider the normalized schema consisting of two tables: *Sale*(*sale_id*, *customer_id*, *product*, *quantity*) and *Customer*(*customer_id*, *customer_location*).

FIGURE 53.12 Response time benefits of approximate results. The benefit of using approximated relations that are much smaller than the base relations is, naturally, significant.

FIGURE 53.13 Denormalization. We use the TPC-H schema to illustrate the potential benefits of denormalization. This graph shows the performance of a query that finds all line items whose supplier is in Europe. With the normalized schema, this query requires a 4-way join between line item, supplier, nation, and region. If we denormalize line item and introduce the name of the region each item comes from, then the query is a simple selection on line item. In this case, denormalization provides a 30% improvement in throughput. This graph was obtained with Oracle 8i Enterprise Edition running on Windows 2000.

If we frequently want sales per customer location or sales per product per customer location, then this table design requires a join on customer_id for each of these queries. A denormalized alternative is to add customer_location to *Sale*, yielding *Sale*(sale_id, customer_id, product, quantity, customer_location) and *Customer*(customer_id, customer_location). In this alternative, we still would need the *Customer* table to avoid anomalies such as the inability to store the location of a customer who has not yet bought anything.

Comparing these two schemas, we see that the denormalized schema requires more space and more work on insertion of a sale. Typically, the data-entry operator would type in the customer_id, product, and quantity; the system would generate a sale_id and do a join on customer_id to get customer_location. On the other hand, the denormalized schema is much better for finding the products sold at a particular customer location.

The trade-off of space plus insertion cost vs. improved speeds for certain queries is the characteristic one in deciding when to use a denormalized schema. Good practice suggests starting with a normalized schema and then denormalizing sparingly.

FIGURE 53.14 Aggregate maintenance with materialized views (queries). We implement redundant tables using materialized views in Oracle9i on Linux. Materialized views are transparently maintained by the system to reflect modifications on the base relations. The use of these materialized views is transparent when processing queries; the optimizer rewrites the aggregate queries to use materialized views if appropriate. The speed-up for queries is two orders of magnitude.

FIGURE 53.15 Aggregate maintenance with materialized views (insertions). There are two main parameters for the maintenance of materialized views as insertions/updates/deletions are performed on the base relations: (1) the materialized view can be updated in the transaction that performs the insertions (ON COMMIT) or it can be updated offline after all transactions are performed (ON DEMAND); (2) the materialized view is recomputed completely (COMPLETE) or only incrementally, depending on the modifications of the base tables (FAST). The graph shows the throughput when inserting 100,000 records in the orders relation for FAST ON COMMIT and COMPLETE ON DEMAND. On commit refreshing has a very significant impact on performance. On demand refreshing should be preferred if the application can tolerate that materialized views are not completely up-to-date or if insertions and queries are partitioned in time (as is the case in a data warehouse).

53.3.5.2 Redundant Tables

The previous example illustrates a special situation that we can sometimes exploit by implementing wholly redundant tables. Such tables store the aggregates we want. For example:

```
Sale(sale_id, customer_id, product, quantity)
Customer(customer_id, customer_location)
Customer_Agg (customer_id, totalquantity)
Loc_Agg (customer_location, totalquantity)
```

This reduces the query time but imposes an update time as well as a small space overhead (see Figure 53.14 and Figure 53.15). The trade-off is worthwhile in situations where many aggregate queries are issued (perhaps in a data warehouse situation) and an exact answer is required.

53.3.5.3 Tuning Normalized Schemas

Even restricting our attention to normalized schemas without redundant tables, we find tuning opportunities because many normalized schemas are possible. Consider a bank whose *Account* relation has the normalized schema (account_id is the key):

Account(account_id, balance, name, street, postal_code)

Consider the possibility of replacing this by the following pair of normalized tables:

AccountBal(account_id, balance)

AccountLoc(account_id, name, street, postal_code)

The second schema results from **vertical partitioning** of the first (all nonkey attributes are partitioned). The second schema has the following benefits for simple account update transactions that access only the id and the balance:

- A sparse clustering index on account_id of *AccountBal* may be a level shorter than it would be for the *Account* relation, because the name, street, and postal_code fields are long relative to account_id and balance. The reason is that the leaves of the data structure in a sparse index point to data pages. If *AccountBal* has far fewer pages than the original table, then there will be far fewer leaves in the data structure.
- More account_id–balance pairs will fit in memory, thus increasing the hit ratio. Again, the gain is large if *AccountBal* tuples are much smaller than *Account* tuples.

On the other hand, consider the further decomposition:

- *AccountBal*(account_id, balance)
- *AccountStreet*(account_id, name, street)
- *AccountPost*(account_id, postal_code)

Although still normalized, this schema probably would not work well for this application, because queries (e.g., monthly statements, account update) require both street and postal_code or neither. Vertical partitioning, then, is a technique to be used by users who have intimate knowledge of the application.

53.4 Tuning the Application Interface

A central tuning principle asserts *start-up costs are high; running costs are low*. When applied to the application interface, this suggests that you want to transfer as much necessary data as possible between an application language and the database per connection. Here are a few illustrations of this point.

53.4.1 Assemble Object Collections in Bulk

Object-oriented encapsulation allows the implementation of one class to be modified without affecting the rest of the application, thus contributing greatly to code maintenance. Encapsulation sometimes is interpreted as “the specification is all that counts.” That interpretation can lead to horrible performance.

The problem begins with the fact that the most natural object-oriented design on top of a relational database is to make records (or sometimes fields) into objects. Fetching one of these objects then translates to a fetch of a record or a field. So far, so good.

But then the temptation is to build bulk fetches from fetches on little objects (the “encapsulation imperative”). The net result is a proliferation of small queries instead of one large query.

Consider, for example, a system that delivers and stores documents. Each document type (e.g., a report on a customer account) is produced according to a certain schedule that may differ from one document

type to another. Authorization information relates document types to users. This gives a pair of tables of the form:

```
authorized(user, documenttype)
documentinstance(id, documenttype, documentdate)
```

When a user logs in, the system should say which document instances he or she can see. This can easily be done with the join:

```
select documentinstance.id, documentinstance.documentdate
from documentinstance, authorized
where documentinstance.documenttype = authorized.documenttype
and authorized.user = <input user name>
```

However, if each document type is an object and each document instance is another object, then one might be tempted to write the following code:

```
Authorized authdocs = new Authorized();
authdocs.init(<input user name>);
for (Enumeration e = authdocs.elements(); e.hasMoreElements();)
{
    DocInstance doc = new DocInstance();
    doc.init(e.nextElement());
    doc.print();
}
```

This application program will first issue one query to find all the document types for the user (within the init method of Authorized class):

```
select documentinstance.documenttype
from authorized
where authorized.user = <input user name>
```

and then for each such type *t* to issue the query (within the init method of DocInstance class):

```
select documentinstance.id, documentinstance.documentdate
from documentinstance
where documentinstance.documenttype = t
```

This is much slower than the previous SQL formulation. The join is performed in the application and not in the database server.

The point is not that object-orientation is bad. Encapsulation contributes to maintainability. The point is that programmers should keep their minds open to the possibility that accessing a bulk object (e.g., a collection of documents) should be done directly rather than by forming the member objects individually and then grouping them into a bulk object on the application side.

Figure 53.4 illustrates the performance penalty of looping over small queries rather than getting all necessary data at once.

53.4.2 Cursors Cause Friction

Programmers who have grown up with programming language loops find a familiar idiom in cursors. Unfortunately, the performance of cursors is horrible in almost all systems. Shasha once had the experience of rewriting an 8-hour query having nested cursors into a cursor-free query that took 15 seconds. We illustrate a less dramatic cursor penalty with a simple experiment, as shown in Figure 53.16.

FIGURE 53.16 Cursors drag. This experiment consists of retrieving 200,000 rows from the table Employee (each record is 56 bytes), using both a set-oriented formulation (SQL) and using a cursor to iterate over the table contents (cursor). Using the cursor, records are transmitted from the database server to the application one at a time. The query takes a few seconds with the SQL formulation and more than an hour using a cursor. This experiment was run on SQL Server 2000 on Windows 2000.

FIGURE 53.17 Batch size. We used the BULK INSERT command to load 600,500 tuples into the line item relation on SQL Server 2000 on Windows 2000. We varied the number of tuples loaded in each batch. The graph shows that throughput increases steadily until batch size reaches 100,000 tuples, after which there seems to be no further gain. This suggests that a satisfactory trade-off can be found between performance (the larger the batch, the better up to a certain point) and the amount of data that has to be reloaded in case of a problem when loading a batch (the smaller the batch, the better).

53.4.3 The Art of Insertion

We have spoken so far about retrieving data. Inserting data rapidly requires understanding the sources of overhead of putting a record into the database:

1. As in the retrieval case, the first source of overhead is an excessive number of round-trips across the database interface. This occurs if the batch size of your inserts is too small. In fact, up to 100,000 rows, increases in the batch size improve performance on some systems, as Figure 53.17 illustrates.
2. The second reason has to do with the ancillary overhead that an insert causes: updating all the indexes on the table. Even a single index can hurt performance as Figure 53.18 illustrates.
3. Finally, the layers of software within a database system can get in the way. Database systems provide bulk loading tools that achieve high performance by bypassing some of the database layers (mostly having to do with transactional recovery) that would be traversed if single row INSERT statements

FIGURE 53.18 High index overhead for insertion. We insert 100,000 records in the table Order(ordernum, itemnum, quantity, purchaser, vendor). We measure throughput with or without a nonclustered index defined on the ordernum attribute. The presence of the index significantly impacts performance.

were used, as we show in Figure 53.18. For example, *SQL * Loader* is a tool that bulk loads data into Oracle databases. It can be configured to bypass the query engine of the database server (using the direct path option).

The SQL Server BULK INSERT command and *SQL * Loader* allow the user to define the number of rows per batch or the number of kilobytes per batch. The smaller of the two is used to determine how many rows are loaded in each batch. There is a trade-off between the performance gained by minimizing the transaction overhead in the omitted layers and the work that has to be redone in case a failure occurs.

53.5 Monitoring Tools

When your system is slow, you must figure out where the problem lies. Is it a single query? Is some specific resource misconfigured? Is there insufficient hardware? Most systems offer the following basic monitoring tools:

1. Event monitors (sometimes known as Trace Data Viewer or Server Profiler) capture usage measurements (processor usage ratio, disk usage, locks obtained, etc.) at the end of each query. You might then look for expensive queries.
2. If you have found an expensive query, you might look to see how it is being executed by looking at the query plan. These Plan Explainer tools tell you which indexes are used, when sorts are done, and which join ordering is chosen.
3. If you suspect that some specific resource is overloaded, you can check the consumption of these resources directly using operating system commands. This includes the time evolution of processor usage, disk queueing, and memory consumption.

53.6 Tuning Rules of Thumb

Often, tuning consists of applying the techniques cited above, such as the selection and placement of indexes or the splitting up of transactions to reduce locking conflicts. At other times, tuning consists of recognizing fundamental inefficiencies and attacking them.

1. Simple problems are often the worst. We have seen a situation where the database was very slow because the computer supporting the database was also the mail router. Offloading nondatabase applications is the simplest method of speeding up database applications.

2. Another simple problem having a simple solution concerns locating and rethinking specific queries. The authors have had the experience of reducing query times by a factor of ten by the judicious use of outer joins to avoid superlinear query performance [4].
3. The use of triggers can often result in surprisingly poor performance. Because procedural languages for triggers resemble standard programming languages, bad habits sometimes emerge. Consider, for example, a trigger that loops over all records inserted by an update statement. If the loop has an expensive multitable join operation, it is important to pull that join out of the loop if possible. We have seen a ten-fold speedup for a critical update operation following such a change.
4. There are many ways to partition load to avoid performance bottlenecks in a large enterprise. One approach is to distribute the data across many sites connected by wide area networks. This can result, however, in performance and administrative overheads unless networks are extremely reliable. Another approach is to distribute queries over time. For example, banks typically send out $\frac{1}{20}$ of their monthly statements every working day rather than send out all of them at the end of the month.

53.7 Summary and Research Results

Database tuning is based on a few principles and a body of knowledge. Some of that knowledge depends on the specifics of systems (e.g., which index types each system offers), but most of it is independent of version number, vendor, and even data model (e.g., hierarchical, relational, or object oriented). This chapter has attempted to provide a taste of the principles that govern effective database tuning.

Various research and commercial efforts have attempted to automate the database tuning process. Among the most successful is the tuning wizard offered by Microsoft's SQL server. Given information about table sizes and access patterns, the tuning wizard can give advice about index selection, among other features. Tuners would do well to exploit such tools as much as possible. Human expertise then comes into play only when deep application knowledge is necessary (e.g., in rewriting queries and in overall design) or when these tools do not work as advertised (the problems are all NP-complete).

Diagnosing performance problems and finding solutions may not require a good bedside manner, but good tuning can transform a slothful database into one full of pep.

Acknowledgment

The anonymous reviewer of this chapter improved the presentation greatly.

Defining Terms

B-tree: The most used data structure in database systems. A B-tree is a balanced tree structure that permits fast access for a wide variety of queries. In virtually all database systems, the actual structure is a B+-tree in which all key-pointer pairs are at the leaves.

Clustering index: A data structure plus an implied table organization. For example, if there is a clustering index based on a B-tree on last name, then all records with the last names that are alphabetically close will be packed onto as few pages as possible.

Conflict (between locks): An incompatibility relationship between two lock types. Read locks are compatible (nonconflicting) with read locks, meaning different transactions may have read locks on the same data items. A write lock, however, conflicts with all kinds of locks.

Covering index: An index whose fields are sufficient to answer a query.

Decision support: Queries that help planners decide what to do next (e.g., which products to push, which factories require overtime, etc.).

Denormalization: The activity of changing a schema to make certain relations denormalized for the purpose of improving performance (usually by reducing the number of joins). Should not be used for relations that change often or in cases where disk space is scarce.

Dense index: An index in which the underlying data structure has a pointer to each record among the data pages. Clustering indexes can be dense in some systems (e.g., ORACLE). Nonclustering indexes are always dense.

E-commerce applications: Applications entailing access to a Web site and a back-end database system.

Hash structure: A tree structure whose root is a function, called the hash function. Given a key, the hash function returns a page that contains pointers to records holding that key or is the root of an overflow chain. Should be used when selective equality queries and updates are the dominant access patterns.

Heap: In the absence of a clustering index, the tuples of a table will be laid out in their order of insertion. Such a layout is called a heap. (Some systems, such as RDB, reuse the space in the interior of heaps, but most do not.)

Hit ratio: The number of logical accesses satisfied by the database buffer divided by the total number of logical accesses.

Index: A data organization to speed the execution of queries on tables or object-oriented collections. It consists of a data structure (e.g., a B-tree or hash structure) and a table organization.

Locking: The activity of obtaining and releasing read locks and write locks (see corresponding entries) for the purposes of concurrent synchronization (concurrency control) among transactions.

Nonclustering index: A dense index that puts no constraints on the table organization; also known as a secondary index. For contrast, see **clustering index**.

Normalized: A relation R is normalized if every functional dependency “ X functionally determines A ,” where A and the attributes in X are contained in R (but A does not belong to X), has the property that X is the key or a superset of the key of R . X functionally determines A if any two tuples with the same X values have the same A value. X is a key if no two records have the same values on all attributes of X .

Online transaction processing: The class of applications where the transactions are short, typically ten disk I/Os or fewer per transaction; the queries are simple, typically point and multipoint queries; and the frequency of updates is high.

Read lock: If a transaction T holds a read lock on a data item x , then no other transaction can obtain a write lock on x .

Seek: Moving the read/write head of a disk to the proper track.

Serializability: The assurance that each transaction in a database system will appear to execute in isolation of all others. Equivalently, the assurance that a concurrent execution of committed transactions will appear to execute in serial order as far as their input/output behaviors are concerned.

Sparse index: An index in which the underlying data structure contains exactly one pointer to each data page. Only clustering indexes can be sparse.

Track: A narrow ring on a single platter of a disk. If the disk head over a platter does not move, then a track will pass under that head in one rotation. The implication is that reading or writing a track does not take much more time than reading or writing a portion of a track.

Transaction: A program fragment delimited by Commit statements having database accesses that are supposed to appear as if they execute alone on the database. A typical transaction can process a purchase by increasing inventory and decreasing cash.

Two-phase locking: An algorithm for concurrency control whereby a transaction acquires a write lock on x before writing x and holds that lock until after its last write of x ; acquires a read or write lock on x before reading x and holds that lock until after its last read of x ; and never releases a lock on any item x before obtaining a lock on any (perhaps different) item y . Two-phase locking can encounter deadlock. The database system resolves this by rolling back one of the transactions involved in the deadlock.

Vertical partitioning: A method of dividing each record (or object) of a table (or collection of objects) so that some attributes, including a key, of the record (or object) are in one location and others are in another location, possibly another disk. For example, the account id and the current balance may be in one location, and the account id and the address information of each tuple may be in another location.

Write lock: If a transaction T holds a write lock on a datum x , then no other transaction can obtain any lock on x .

Transaction: Unit of work within a database application that should appear to execute atomically (i.e., either all its updates should be reflected in the database or none should; it should appear to execute in isolation).

Further Information

Whereas the remarks of this chapter apply to most database systems, each vendor will give you valuable specific information in the form of tuning guides or administrator's manuals. The guides vary in quality, but they are particularly useful for telling you how to monitor such aspects of your system as the relationship between buffer space and hit ratio, the number of deadlocks, the disk load, etc.

A performance-oriented general textbook on databases is Pat O'Neil's book, *Database*, published by Morgan-Kaufmann.

Jim Gray has produced some beautiful viewgraphs of the technology trends and applications leading to parallel database architectures (<http://research.microsoft.com/gray/>).

Our book, *Database Tuning: Principles, Experiments, and Troubleshooting Techniques*, published by Morgan Kaufmann goes into greater depth regarding all the topics in this chapter.

- 54.4 Research Issues and Summary

54.1 Introduction

Although main memories are becoming larger, there are still many large databases that cannot fit entirely in main memory. In addition, because main memory is larger and processing is faster, new applications are storing and displaying image data as well as text, sound, and video. This means that the data stored can be measured in terabytes. Few main memories hold a terabyte of data. So data still have to be transferred from a magnetic disk to main memory. Such a transferral is called a **disk access**.

Disk access speeds have improved. However, they have not and cannot improve as rapidly as central processing unit (CPU) speed. Disk access requires mechanical movement. To move a **disk page** from a magnetic disk to main memory, first one must move the **arm** of the disk drive to the correct **cylinder**. A cylinder is the collection of **tracks** at a fixed distance from the center of the disk drive. The disk arm moves toward or away from the center to place the read/write **head** over the correct track on one of the disks. As the disks rotate, the correct part of the track moves under the head. Only then can the page be transferred to the main memory of the computer. A disk drive is illustrated in [Figure 54.1](#).

The fastest disks today have an average access time of 5 ms. This is at a time when CPU operations are measured in nanoseconds. Therefore, the access of one disk page is at least one million times slower than adding two integers in the CPU. In addition, to request a disk page, the CPU has to perform several thousand instructions, and often the operating system must make a process switch. Thus, although the development of efficient access methods is not a new topic, it is becoming increasingly important.

In addition, new application areas are requiring more complex disk access methods. Some of the data being stored in large databases are multidimensional, requiring that the records stored in one disk page refer to points in two- or three-dimensional space, which are close to each other in that space. Data mining, or discovery of patterns over time, requires access methods that are sensitive to the time dimension. The use of video requires indexing that will allow retrieval by pictorial subject matter. The increasingly large amount of textual data being gathered electronically requires new thinking about information retrieval. Other chapters in this book look at video and text databases, but here we will treat spatial and temporal data as well as the usual linear business data.

FIGURE 54.1 A disk drive.

54.2 Underlying Principles

Because disk access is so expensive in elapsed time and in CPU operations, and because the minimum number of bytes that can be transferred at one time is now 8 kilobytes (8192 bytes) or so, the main goal of access methods is to group or cluster on one disk page data which will be requested by an application in a short timeframe. Then after a page is placed in main memory, in order to read a requested item, there will be a good chance that when a subsequent item is requested, a separate disk access will not be necessary.

Because application logic cannot be predicted in general, the clustering will follow some kind of logical relationship or some kind of specific knowledge about the applications that are run. For example, if it is known that address labels are printed out in order of the zip code, one can attempt to store records with the same zip code in the same page.

In addition to disk page clustering, there are several other important principles of access methods. One is that disk space should be used wisely. Suppose an application accesses customer records individually and randomly by social security number. A very simple solution that would require only one disk access per customer would be to reserve one disk page for each possible social security number. With 1000 customers, 1×10^9 disk pages would be reserved. Because each disk page are 8 kilobytes, this are about 8 terabytes of disk space. Although this seems like a ridiculous example, papers have been written that propose access methods and do not take into account the amount of disk space used. Total disk space used should always be considered in proposing a disk access method.

Another principle regards the number of pages needed to be accessed to find one particular record. In general, one aims to minimize the number of pages accessed that contain *none* of the data wanted. This is one of the reasons why binary search trees are not used for large databases. Binary search trees can be very unbalanced, and the mapping from parts of the tree to disk pages is not defined. One could, for example, read in the page that had the root of binary search tree in it and then follow the tree in memory until it led to another disk page, and so forth. If one of the records that is accessed relatively often thus required reading 20 disk pages every time it is requested, this is a poor access method for this application. In general, if pagination of the access method cannot be specified, it will perform poorly.

Finally, insertion and deletion of records should modify as few disk pages as possible. Most good access methods modify only one page when a new record is inserted most of the time. That is, the record is inserted into a page that has empty space. This page is the only one modified. Occasionally, one or two other pages must be modified. For a good access method, it is *never* necessary to modify a large number of pages when one record is inserted or deleted.

FIGURE 54.2 A typical disk page layout. New records are placed in the free space after old records (growing down) and new slot numbers and pointers are placed before the old ones (growing up). Variable-length records are accommodated.

We summarize the principles we have discussed in a list. We will often refer to these in the rest of the chapter. The **properties of good access methods** are as follows:

1. *Clustering*: Data should be clustered in disk pages according to anticipated queries.
2. *Space usage*: Total disk space usage should be minimized.
3. *Few answer-free pages in search*: Search should not touch many pages having no relevant data.
4. *Local insertion and deletion*: Insertion and deletion should modify only one page most of the time and occasionally two or three. Insertion and deletion should never modify a large number of pages.

Most access methods have **data pages** and also have pages that contain no data, which are called **index pages**. The index pages contain **references** to other index pages and/or references to data pages or references to records within data pages. A reference to a data page or an index page is a disk page address. A reference to a record may be only the disk page address of the page where the record is kept (and some other means must be used to locate the record in the page, usually the value of one of the attributes of the record), it may be the combination of a disk page address and a record slot number within that disk page (see Figure 54.2), or it may be some attribute value that can be used in another index to find the given record. (We freely exchange the words *index* and *access method*.)

If the index pages reference data pages but never individual records within those data pages, the access method is called a **sparse index** or sometimes a **primary index**. In this case, the location for insertion of a new record is determined by the access method and usually (but not always) depends on the value of a primary key for the record. (It could instead depend on some other attribute that is not primary, for example, the zip code in an address.) Thus, *primary indices* are not always associated with *primary keys*.

If there are references in the index to individual records, so that a data page with 20 data records in it has at least 20 separate references in the index, the index is called a **dense index** or a **secondary index**. Insertion of new records can then occur anywhere. Often, secondary indices are associated with data pages where the data is placed in order of insertion.

We will use the terms “primary index” and “secondary index.” A data collection often has one primary index and several secondary indices. The primary index determines the placement of the records and the secondary indices allow lookup by attributes other than the ones used for placement. Most primary indices can be converted to secondary indices by replacing the data records with references to the same data records and actually storing the data records elsewhere. Thus, the question, “Is this access method a primary index or a secondary index?” does not always make sense.

Indices are sometimes called **clustering indices**. In commercial products, this usually means that the data is loaded into data pages initially in the order specified by a secondary index. When new data is inserted in the database, such an index loses the clustering property. Such an index clusters data *statically*

and not *dynamically*. We will not again use the term “clustering index” in this chapter as we believe it has been abused and frequently misunderstood in both industry and academia.

Next in this chapter, we present one exceptionally good access method, the B⁺-tree [Bayer and McCreight 1972], and use it as an example against which other access methods are compared. The B⁺-tree has all of the good properties previously listed. We then present the hash table (and some proposed variants) and briefly review some of the proposed access methods for spatial and temporal data.

54.3 Best Practices

54.3.1 The B⁺-Tree

The B⁺-tree [Bayer and McCreight 1972] is the most widely used access method in databases today. A picture of a B⁺-tree is shown in Figure 54.3. Each node of the tree is a disk page and, hence, contains 4096 bytes. The leaves of the tree when it is used as a primary index contain the data records or, in the case of a secondary B⁺-tree, references to the data records that lie elsewhere. The leaves of the tree are all at the same level of the tree.

The index entries contain values and pointers. Search begins at the root. The search key is compared with the values in the index entries. In Figure 54.3, the pointer associated with the largest index entry value smaller than or equal to the search key is followed. To search for coconut, for example, first the pointer at the root associated with caramel is followed. Then at the next level, the pointer associated with chocolate is followed. Search for a single record visits only one node at each level of the tree.

In the remainder of this section, we assume the B⁺-tree is being used as a primary index. This is certainly not always the case. Many commercial database management systems have no primary B⁺-tree indices. Even those that do offer the B⁺-tree as a primary index must offer the B⁺-tree as a secondary index as well, as it will be necessary in most cases to have more than one index on each relation, and only one of them can be primary.

The main reasons that the B⁺-tree is the most widely used index is (1) that it clusters data in pages in the order of one of the attributes (or a concatenation of attributes) of the records, and (2) it maintains that

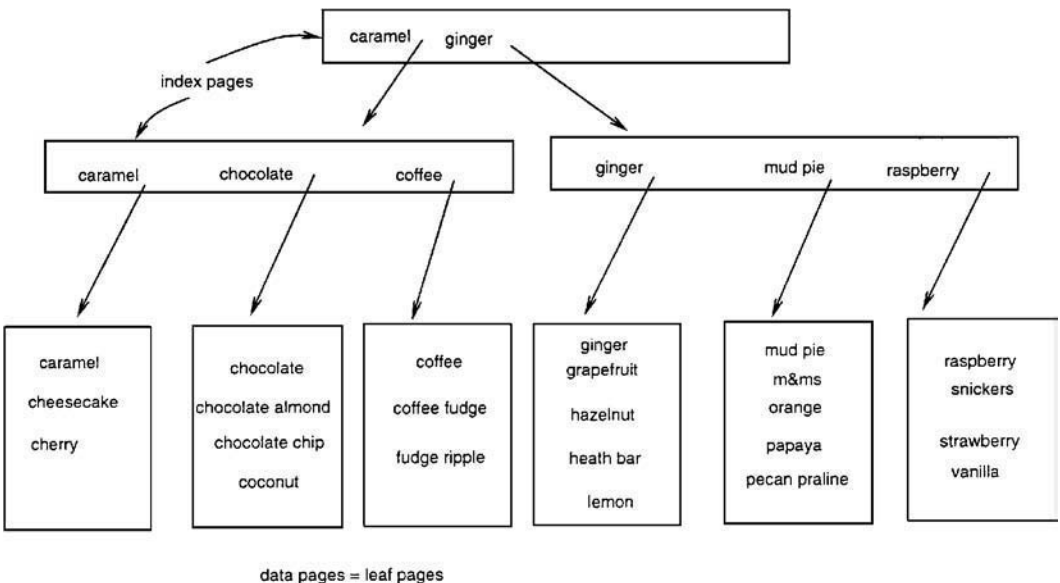

FIGURE 54.3 A B⁺-tree.

clustering dynamically, never having to be reorganized to retain disk page clustering. Thus, the B⁺-tree satisfies property 1 for good access methods: it clusters data for the anticipated queries.

Storage utilization for B⁺-trees in both index and data pages is 69% on average [Yao 1978]. Total space usage is approximately 1/0.69 times the space needed to store the data records packed in pages. All of the data is stored in the leaves of the tree. The space needed above the level of the leaves is less than 1/100 of the space needed for the leaves. Thus, the B⁺-tree satisfies property 2 for good access methods: it does not use too much total disk space.

In addition, B⁺-trees have no pathological behavior. That is, no records require many accesses to be found. Searches for a record given its key follow one path from the root of the tree to a leaf visiting only one page at each level of the tree. If the record is in the database, it is in the leaf page visited. All of the leaves are at the same level of the tree.

All records can thus be found with, at most, as many disk accesses as the height of the tree and the height of the tree is always small. The reason some records can be found with less disk accesses is that the upper levels of the tree are often still in main memory when subsequent requests for data are made. Thus, B⁺-trees satisfy property 3 for good access methods: few answer-free pages (in this case, index pages) are accessed in any search.

Insertion and deletion algorithms enable the B⁺-tree to retain its clustering and to maintain the property that all leaves are at the same level of the tree. Thus, search for one record remains efficient and search for ranges remains efficient. Insertion in a leaf that has enough empty space requires writing only one disk page. (Although this seems obvious, we will see that the R-tree discussed subsequently does not have this property.) Deletion from a page that does not require it to become sparse also writes only one disk page. The probability that more than one existing index or data page must be updated is low. In the worst case, one page is updated and a new page created at each level of the tree. This is an extremely rare event. Thus, the B⁺-tree satisfies property 4 for good access methods: the B⁺-tree has local insertion and deletion algorithms.

54.3.1.1 Fan-Out Calculations

The height of the tree is small because the **fan-out** is large. The fan-out is the ratio of the size of the data page collection to the size of the index page collection. The secret of the B⁺-tree is that each index page has hundreds of children.

Some data structure textbooks suggest a B-tree where data records are stored in all pages of the index. But when data records are stored high up in the tree, the fan-out is too small. A data record may have 100 or 200 bytes. This would limit the number of children each high-level page in the index could have. This variation has never been used for database management systems for this reason. It is also the reason we use the notation B⁺-tree, which has historically stood for the variation of B-trees, which has all of the data in the leaves, the only variation of the B-tree in use.

A disk page address is usually 4 bytes. A key value may be about 8 bytes if it is an alphanumeric key. This means each index term is 12 bytes. But there are 4096 bytes in an index page. Theoretically, each page could have $4096/12 = 341$ children. (Actually, there is some header information.) But when pages are full and they must be split as insertions are made, each new page is only half-full. An average case analysis [Yao 1978] showed that B⁺-trees are, on average, $\ell_1/2$ full, or about 69% full. Thus, this would give our average node, allowing for some header space, about 230 children.

Let us do some calculations. If the root has 230 children and each of them has 230 children and each of them is a data page, then there are 52,900 data pages. Each data page is also 4 kilobytes. This is 211,600 kilobytes or, in round numbers, about 200 megabytes. Thus, with at most three disk accesses we can find any record in a 200-megabyte relation. However, we can also fix the root in the main memory so that every record can be found in two disk accesses. If we use 231 pages of main memory space (231×4 kilobytes, or 924 kilobytes of main memory), we can store the top two levels of the tree in main memory and we have a one-disk access method.

Even if we do not specify that index pages be stored in main memory, if we use a standard least recently used (LRU) page replacement algorithm to manage the memory, it is likely that upper levels of the tree are in memory. This is because all searches must start at the root and travel down the tree.

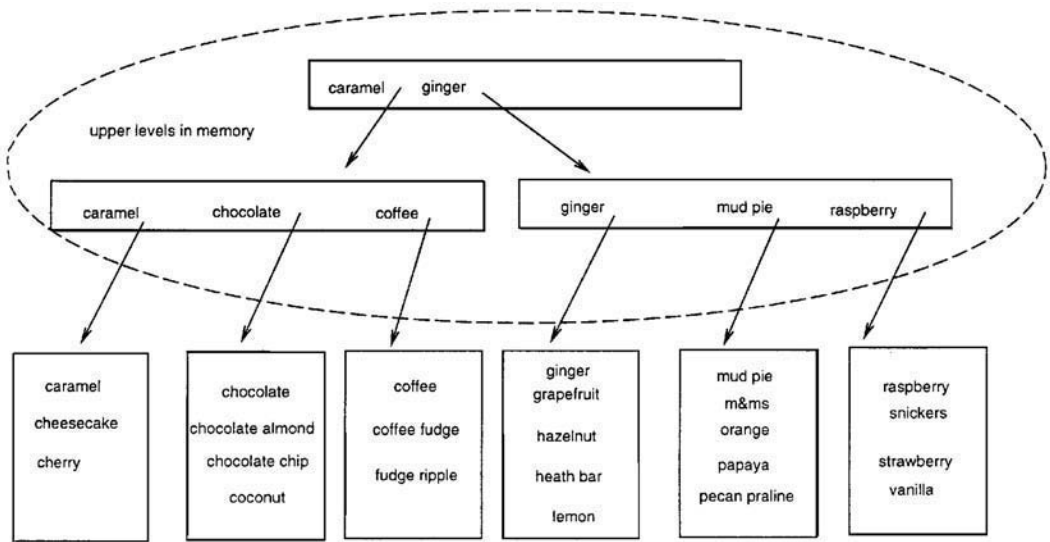

FIGURE 54.4 The number of disk accesses to find a record in a B⁺-tree depends on how much of the tree can be kept in main memory. Adding one more level, as shown here, does not necessarily add one more disk access.

The number of levels above the leaves of a tree containing n leaves is $\text{ceiling}(\log_{\text{fan-out}} n)$. The height of the tree is one more than this number. Thus, if the fan-out is 230 and the number of leaves is 50,000, there are two ($= \text{ceiling}(\log_{230} 50,000)$) levels above the leaves and the height of the tree is three. For a 4-gigabyte relation, with about 1 million leaves of 4 kilobytes each, a height of 4 is required. But in this case, the level right below the root may be small. Suppose the level below the root has only 20 pages. If each of these is a root of a subtree of height three with 50,000 leaves, we have 1 million leaves in total. But storing in memory these 20 pages at the level below the root plus the root takes up only 84 kilobytes (21×4 kilobytes). It is likely that these two levels will stay in main memory. Then, even with a height of 4, the number of disk accesses for search for one record is only two.

Thus, tree height is not the same as number of disk accesses required to find a record. The number of disk accesses required to find a record depends on what part of the top levels of the tree are already stored in main memory. This is illustrated in Figure 54.4, where we have shown the top two levels of the sample tree in main memory, making this B⁺-tree a one-disk-access method.

54.3.1.2 Key Compression and Binary Search within Pages

Because the fan-out determines the height of the tree, which in turn limits the number of disk accesses for record search, it is worthwhile to enhance fan-out. This would be particularly desirable if the size of the attributes or concatenated attributes used as the key in the B⁺-tree is large. A smaller key means a larger fan-out.

One technique often used for enhancing B⁺-tree performance is key compression. The prefix B⁺-tree [Bayer and Unterauer 1977] is used in many implementations. Here, what is stored in the index pages is not the full key but only a **separator**. A separator holds only enough characters to differentiate one page from the next. Binary search still can be used within the index pages. Separators are illustrated in Figure 54.5. (It is not true that separators must be changed when records are deleted from the database. It is probably not worthwhile to make a disk access to modify the separator when a record is deleted. The old separator still allows correct search, although it is not as short as it might be.)

Although schemes to omit some of the first characters of the key when they are shared by some of the entries have been considered, unless they are shared by *all* of the index entries in an index page, such schemes have not been used. This is because compressing prefixes of keys makes binary search impossible,

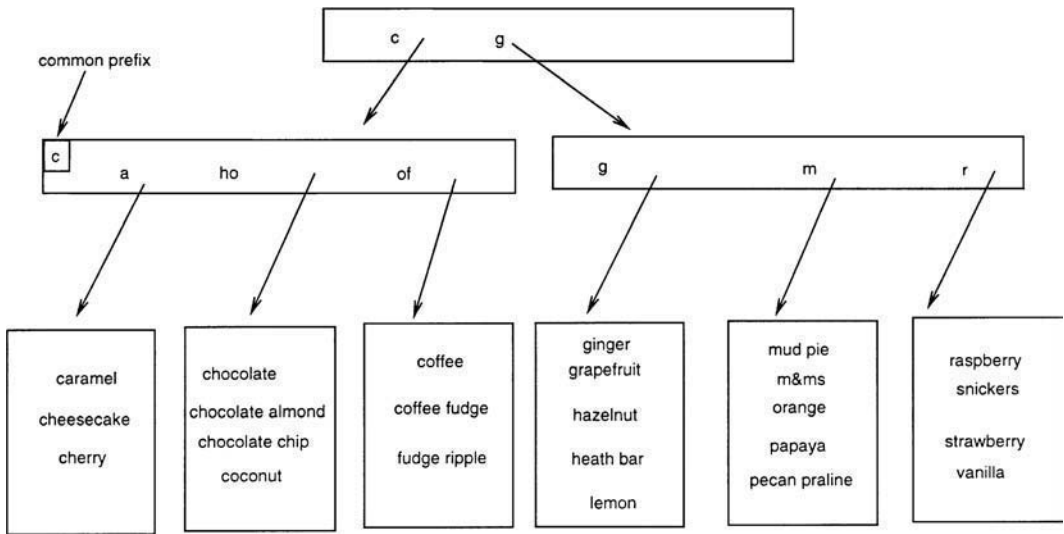

FIGURE 54.5 Separators in a prefix B⁺-tree.

and search within an index page becomes linear. Because index page search is a frequent operation, prefix compression is not worthwhile. Also, it is predicted that disk page sizes will get larger, making linear search even worse. Figure 54.5 illustrates storing a common prefix (the first few characters used in *every key in a page*) only once.

Either the index terms can be organized within index pages using a binary search tree, or they can be kept in order using an array. The usual practice for index pages is to use an array, which saves space and allows more fan-out. Index pages are updated relatively infrequently. When a new index term is inserted, the array elements after the insertion must of course be moved to a new position in the page. Binary search is performed on the array in each index page visit during a record search operation.

In data pages, the keys can be stored separately from the rest of the record, with a pointer to the rest of the record. Then the keys also can be stored in order in an array, and binary search can be used.

54.3.1.3 Insertion and Deletion

Usually, insertion of a record simply searches for the correct leaf page in the tree and updates that leaf page. Occasionally [with a probability of $2/\max(\text{recs})$ where $\max(\text{recs})$ is the maximum number of records in a leaf page], the leaf is full, and it must be split. A leaf split in a B⁺-tree is illustrated in Figure 54.6. In Figure 54.6, the record with key lime is entered in the tree of Figure 54.5. In this example, we assume that only five records can reside in a leaf. Thus, we split the leaf where lime would be inserted.

Half of the records stay in the old leaf node and half of the records are copied to a newly allocated leaf node. An entry is placed in the parent to separate the old and new nodes. With a much lower probability, the parent may need to be split as well, and this can percolate up the tree on a path to the root. The probability that an insertion causes a split of both the leaf and its parent is $(2/\max(\text{recs})) \times (2/\max(\text{index entries}))$.

For example, if records are 200 bytes and there are 4 kilobyte pages, $\max(\text{rec})$ might be 20 allowing for header space in the data page. Then, after a split, 10 more records must be inserted in the page before a split is needed again (assuming no deletes). Thus, the probability of a split is at worst 1/10. If $\max(\text{index entries})$ is equal to 300, the probability of an insertion causing an index page split is $(1/10) \times (1/150)$, or 1/1500.

For record deletion, similarly, one need only remove the record from the data page in most cases. Sometimes, pages are considered sparse and are merged with their siblings. In fact, many commercial products do not consider any pages sparse unless they are completely empty [Mohan and Levine 1992]. An analysis of this issue, which concludes that node consolidation in B⁺-trees is not useful unless the nodes are completely empty, can be found in Johnson and Shasha [1989].

FIGURE 54.6 A leaf split in a B^+ -tree.

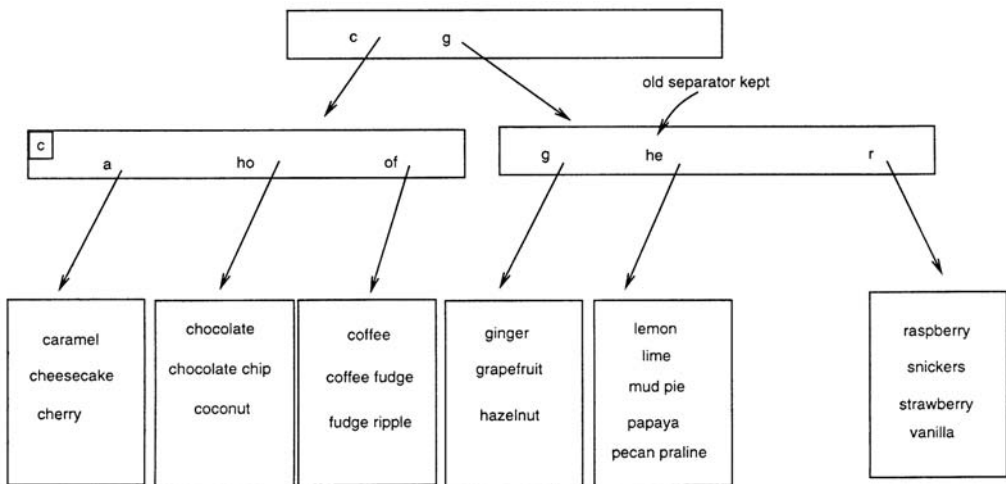

FIGURE 54.7 A B^+ -tree node consolidation.

Most textbooks, however, consider anything less than 50% to be sparse in order to maintain the property that all nodes are at least 50% full. This is not a good idea in practice, even if one does not go so far as to wait until nodes are empty before consolidating them, because it may cause **thrashing**.

If the threshold for node sparseness is 50%, so that nodes are not allowed to ever fall below 50% full, and if a record is inserted into an overflowing page, then the page is *split* to get a 50% utilization, then a record is deleted from the page, the B^+ -tree may needlessly thrash between splitting and consolidating the same node. This issue is discussed in detail in Maier and Salveter [1981].

A B^+ -tree node consolidation is pictured in Figure 54.7. (The records with keys m&ms, orange, and heath bar have been removed from Figure 54.6.) We do not change the separator *he*, although a shorter separator could have been chosen. In some cases, search will be incorrect if a new separator is chosen. Also, using the old separator makes the node consolidation algorithm *simpler*, which is an important consideration for access methods.

The case pictured deallocates a page. It also is possible to move records from a full sibling to a sparse one. In both cases, the parent must be updated to reflect the change. In rare cases, sparse node consolidation could percolate to higher levels, because deletion of an index term could cause a parent to become sparse.

54.3.1.4 Range Searches and Reorganizing

B^+ -trees are very good for small range searches. Each leaf of the tree contains all of the records whose keys are within a given range. If the range is small, it is worthwhile to use the B^+ -tree to access only a few disk pages to get all of the records wanted. However, if the range is large, it might be better to read in all of the leaf pages at once and not use the B^+ -tree to find out which ones satisfy the query.

The reason for this is that after there have been many splits of the leaves in a B^+ -tree, the leaf pages are not stored on the disk in order. Within each page, the records are in key order. But two adjacent pages in terms of key order could be in very different places on the disk. The disk arm might need to move a long distance to access the pages that were required. On the other hand, sequential reading on the disk, where the arm sits over one cylinder and reads all of the tracks on that cylinder and then moves to the next cylinder and reads all of the tracks on it and so forth, is much faster than reading the same amount of data one page at a time, moving the disk arm for each page.

Calculations in Salzberg [1988] show that in circumstances where a fairly large-size range is required (say 10% of the data), it is better to read in all of the data in no particular order than to make separate disk accesses for pages that satisfy the query. This is even worse when the B^+ -tree is used as a secondary index. The range must be quite small to make use of the index worthwhile. Here, each record in a range could be stored in a separate disk page.

Because primary B^+ -trees get out of order in this sense, it has sometimes been considered worthwhile to reorganize them. This can be done while keeping the B^+ trees online, as shown in Smith [1990], a description of an algorithm written and programmed by F. Putzolu. One leaf is written at a time. Sometimes the data in two leaves is interchanged. This is all done as a background process, and it is done transactionally (i.e., with lock protection so that searches will be correct even when reorganization is in progress).

54.3.1.5 Bounded Disorder

Efforts have been made to improve the B^+ -tree. Most of these have not been implemented in commercial systems because it is not considered worth the trouble. Mostly, the B^+ -tree is good enough. However, we will outline a particularly nice attempt in this area [Lomet 1988].

The basic idea of bounded disorder is to keep a small B^+ -tree in memory and then vary the size of the leaves, using consecutive disk pages for one leaf. To find a particular record within a leaf, a hash algorithm is used to find the correct **bucket** within the leaf holding that record. There is one hash overflow bucket stored with each leaf. In the variation we illustrate, buckets are two or three consecutive disk pages.

When a small leaf becomes full, it can be replaced with a larger leaf. (Only two different sizes for leaves are suggested, one one and one-half times bigger than the other, thus expanding the space by a factor of 1.5.) When a larger size leaf is full, it can be replaced with two smaller size leaves, thus expanding by a factor of 1.33. This gradual expansion makes the average space utilization better than that of the B^+ -tree. This follows some ideas about partial expansion found in Larson [1980].

For single record search, bounded disorder is fast because it usually requires only one disk access; the B^+ -tree in memory directs the search to the correct leaf and the hash algorithm to the bucket within the leaf. For large-range searches, it is fast because the leaves are large. For small-range searches, it is not bad; it may read in one or two large leaves and then, when they are in memory, search within each bucket for the records that are in the queried range.

Bounded disorder is illustrated in [Figure 54.8](#). Here we have assumed a hash function of $h(key) = key \bmod 5$. First, the in-memory tree is consulted. It tells the location and the size of the leaf (two or three units). Then the hash function is used to determine the bucket. If the record is not there, the overflow buckets are searched.

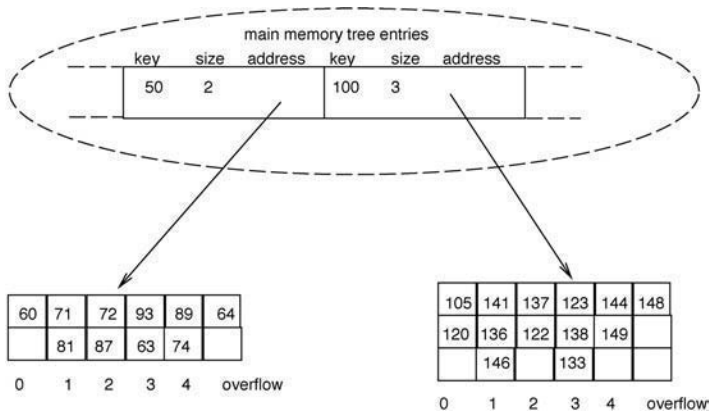

FIGURE 54.8 Bounded disorder. A small main memory B⁺-tree directs the search to a large leaf. A hash function (here $h(\text{key}) = \text{key} \bmod 5$) yields the bucket within the leaf.

54.3.1.6 Summary of the B⁺-Tree

The B⁺-tree is about as good an access method as there is. It dynamically maintains clustering, uses a reasonable total amount of disk space, never has pathological search cases, and has local insertion and deletion algorithms, usually modifying only one page. All other access methods we shall describe do not do as well.

54.3.2 Hashing

The second most used access method is **hashing**. In hashing, a function applied to a database key determines the location of the record. For example, if the set of keys were known to be the integers between 1 and 1000 and the data records all had the same size, contiguous disk space for 1000 records could be allocated, and the identity function would yield the offset from the beginning of the allocated space. However, usually database keys are not consecutive integers.

Hashing algorithms start with a function that maps a database key to a number. To make the result uniformly distributed, certain functions have been found to be especially effective. The best coverage of hashing functions can still be found in Knuth [1968].

Basically, the database key is transformed to a number N by some method such as adding together the ASCII (American Standard Code for Information Interchange) codes of the letters of the key. Then N is multiplied by a large prime number P_1 and then added to another number P_2 , and the result is taken modulo P_3 , where P_3 corresponds to the number of consecutive pages on the disk allocated for the **primary area** of the hash table. Thus, $f(N) = (N \times P_1 + P_2) \bmod P_3$. Knuth [1968] discusses how the parameters are chosen.

For a primary hashing index, the data records themselves are stored in the primary area. For a secondary hashing index, the primary area is filled with addresses of data records which are stored elsewhere. In the remainder of our discussion, we assume all indices are primary indices.

A page (or sometimes a set of consecutive pages) corresponding to one value of the hash function is called a bucket. When all records fit into their correct bucket, hashing is a one-disk-access method. The hash value gives the bucket address as an offset from the beginning of the primary area. That bucket is accessed and the record is there. The same algorithm is used to insert a new record into a bucket as long as there is room for it.

When there is no longer room in a bucket, an overflow bucket is allocated from the **overflow area**. Let us assume each overflow bucket is a disk page. When an overflow bucket is allocated, its address is placed in the primary bucket to which it corresponds (or in the last overflow bucket allocated to this hash number, forming a chain of overflow buckets for each hash value). (Most overflow chains should be empty if the average search time is to be reasonable.)

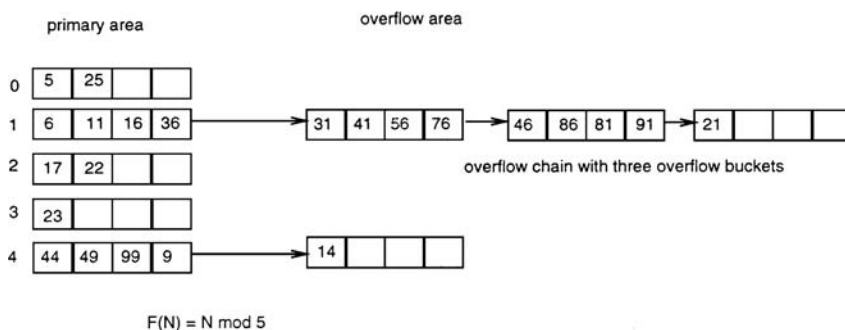

FIGURE 54.9 A hashing table with overflow buckets.

Then the search algorithm is as follows: Hash the database key to get the address of the correct bucket in the primary area. Search in the bucket. If the record is not there, search in the overflow bucket(s). A basic hashing index with overflow buckets is illustrated in Figure 54.9.

We define the **hash table fill factor** as the total space needed for the data divided by the space used by the primary area. As long as the hash table fill factor is a certain amount below one, there is not much overflow and search time is fast. For example, if buckets large enough for 50 records are used and the hash table fill factor is near 70% (which would be comparable to B⁺-tree leaf space utilization), search is very close to one disk access on average [Knuth 1968].

However, one basic drawback of hashing is that the fill factor grows as the database grows. Hashing does not adjust well to growth of the database. The database can even become several times as large as the allocated primary area. In this case, the number of disk accesses needed on average can become quite high. Even without the database becoming large, hashing functions that produced very long chains of overflow buckets are possible and have occurred. Thus, hashing does not always satisfy property 3 for good access methods (efficient search).

If hashing must be reorganized and a new table constructed because the old table is too small (which is done in most systems that use hashing), property 4 is violated: insertion is not local when massive reorganization is required.

Further, by its nature, hashing does not cluster data that is related, unless all of the records that are related have the same key. Hashing functions that effectively create a uniform distribution are never order preserving. If such an order-preserving hashing function existed, it could do sorting of n elements in $O(n)$ time, by hashing each one into its proper place in an array [Lomet 1991]. Thus, hashing does not satisfy property 1: clustering. In fact, it is virtually useless to use a hashing structure for a range query. Each possible value in the range would have to be hashed.

Because hashing does not support range queries and because it does not adjust well to growth, it is not used as often as B⁺-trees. When memories were small, a B⁺-tree access from a B⁺-tree of height 4 meant at least 3 and sometimes 4 disk accesses, because not even the root could always be kept in main memory. Now that memories are larger, single-record search in B⁺-trees is more likely to be 1 or 2 disk accesses even when the height of the tree is 4. More importantly, for most relations, a B⁺-tree of height 3 is likely to be a one-disk access method. This makes B⁺-trees competitive with hashing for single-record search.

Before leaving this topic, we look at two proposed variations on hashing to support database growth. Although many papers have been written on this topic, most are refinements of these two. Most commercial systems that provide hashing have only hashing with overflow buckets.

54.3.2.1 Linear Hashing

Linear hashing [Litwin 1980] and extendible hashing [Fagin et al. 1979] both add one new bucket to the primary area at a time. Linear hashing (in the variation we explain here) adds a new bucket when the hash table fill factor becomes too large. Extendible hashing adds one whenever an overflow bucket would otherwise occur. We explain linear hashing first.

In linear hashing, data is placed in a bucket according to the last k bits or the last $k + 1$ bits of the hash function value of the key. A pointer keeps track of the boundary between the values whose last k bits are used and the values whose last $k + 1$ bits are used. The current fill factor for the hash table is stored as the two values (bytes of data, bytes of primary space).

When the insertion of a new record causes the fill factor to go over a limit, the data in the k -bucket on the boundary between $k + 1$ and k bits is split into two buckets, each of which is placed according to the last $k + 1$ bits. There is now one more bucket in the primary area and the boundary has moved down by one bucket. When all buckets use $k + 1$ bits, an insertion causing the fill factor to go over the limit starts another expansion, so that some buckets begin to use $k + 2$ bits (k is incremented).

There is no relationship between the bucket obtaining the insertion causing the fill factor to go over the limit and the bucket that is split. Linear hashing also has overflow bucket chains.

We give an example of linear hashing in Figure 54.10. We assume that k is 2. We assume that each bucket has room for three records and the limit for the fill factor is 0.667. We show how the insertion of one record causes the fill factor limit to be exceeded and how a new bucket is added to the primary area.

The main advantage of linear hashing is that insertion never causes massive reorganization. Search can still be long if long overflow chains exist. Range searches and clustering still are not enabled. There are two main criticisms of linear hashing: (1) some of the buckets are responsible for twice as many records on average as others, causing overflow chains to be likely even when the fill factor is reasonable, and (2) in order for the addressing system to work, massive amounts of consecutive disk pages must be allocated.

Actually, the second objection is not more of a problem here than for other access methods. File systems have to allocate space for growing data collections. Usually this is done by allocating an **extent** to a relation when it is created and specifying how large new extents should be when the relation grows. Extents are large amounts of consecutive disk space. The information about the extents should be a very small table that is kept in main memory while the relation is in use. (Some file systems are not able to do this and are unsuitable for large relations.)

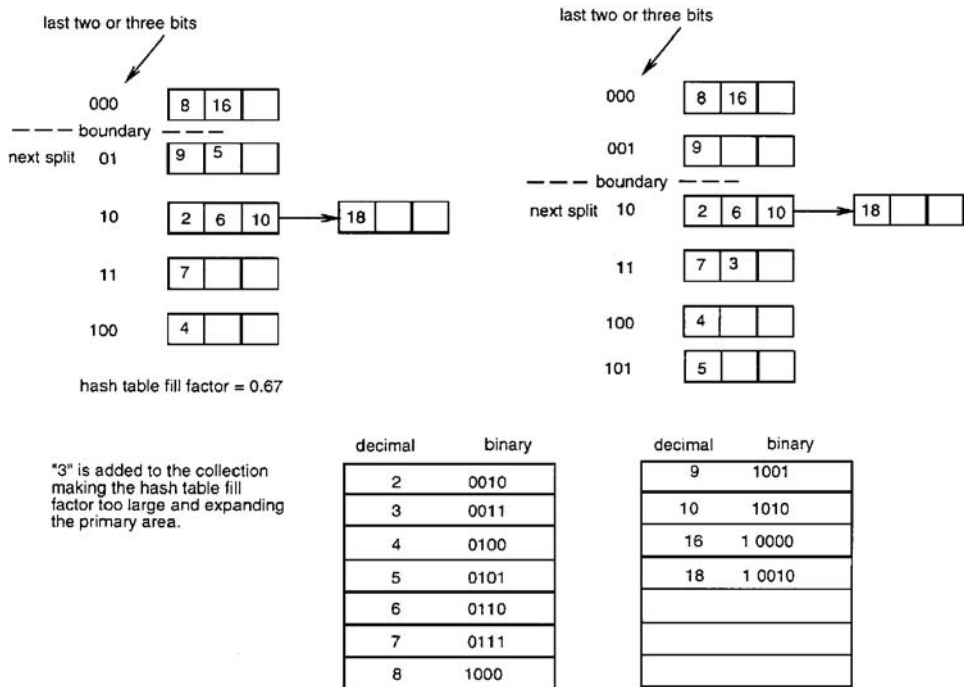

FIGURE 54.10 Linear hashing.

Many papers have been written about expanding linear hashing tables by a factor of less than 2. The basic idea here is that, for example (as was used in the bounded disorder method previously mentioned), at the first expansion, what took two units of space expands to three units of space. At the second expansion, what was in three buckets expands to four buckets. At this point, the file is twice as big as it was before the first expansion. In this way, no buckets are responsible for twice as much data as any other buckets; the factors are 1.5 or 1.33. This idea originated in Larson [1980].

54.3.2.2 Extensible Hashing

Another variant on hashing that also allows the primary area to grow one bucket at a time is called extensible hashing [Fagin et al. 1979]. Extensible hashing does not allow overflow buckets. Instead, when an insertion would cause a bucket to overflow, its contents are split between a new bucket and an old bucket and a table keeping track of where the data is updated.

The table is based on the first k bits of a hash number. A bucket B can belong to 2^j table entries, where $j < k$. In this case, all of the numbers whose first $k - j$ bits match those in the table will be in B . For example, if k is 3, there are eight entries in the table. They could refer to eight different buckets. Or two of the entries with the same two first bits could refer to the same bucket. Or four of the entries with the same first bit could refer to the same bucket. We illustrate extensible hashing in Figure 54.11.

The insertion of a new record that would cause an overflow either causes the table to double or else it causes some of the entries to be changed. For example, a bucket that was referred to by four entries might have its contents split into two buckets, each of which was referred to by two entries. Both cases are illustrated in Figure 54.11.

The advantage of extensible hashing is that it never has more than two disk accesses for any record. Often, the table will fit in memory, so that it becomes a one-disk-access method. There are no overflow chains to follow.

The main problems with this variation on hashing are total space utilization and the need for massive reorganization (of the table). Suppose the buckets can hold 50 records and there are 51 records with the identical first 13 bits in the hash number. Then there are at least $2^{14} = 16,384$ entries in the table. It does not matter how many other records there are in the database.

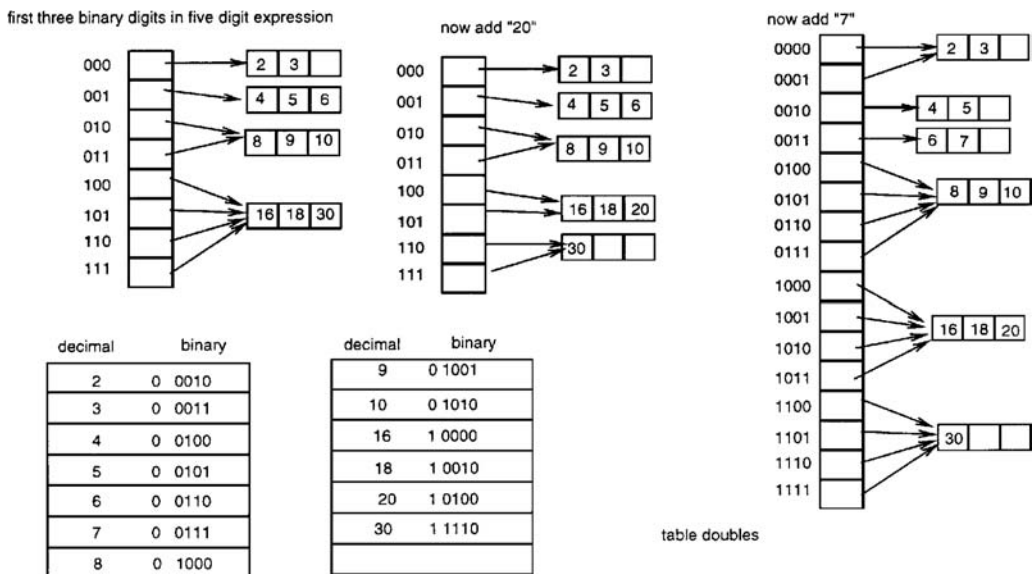

FIGURE 54.11 Extensible hashing.

Like the other variations on hashing, extendible hashing does not support range queries. All hashing starts with a *hashing function*, which will randomize the keys before applying the rest of the algorithm.

54.3.3 Spatial Methods

New application areas in geography, meteorology, astronomy, and geometry require spatial access and make nearest-neighbor queries. For spatial access methods, data should be clustered in disk pages by nearness in the application area space, for example, in latitude and longitude. Then the question: “find all of the desert areas in photographs whose center is within 100 miles of the equator” would have its answer in a smaller number of disk pages than if the data were organized alphabetically, for example, by name.

However, it is a difficult problem to organize data spatially and still maintain the four properties of good access methods. For example, one way to organize space is to make a grid and assign each cell of the grid to one disk page. However, if the data is correlated as in Figure 54.12, most of the disk pages will be empty. In this case, $O(n^k)$ disk space is needed for n records in k -dimensional space. Using a grid as an index has similar problems; only the constant in the asymptotic expression is changed. A grid index is also pictured in Figure 54.12.

A proposal was made for a grid index or *grid file* in Nievergelt et al. [1984]. Because it uses $O(n^k)$ space, in the worst case it can use too much total disk space for the index; thus, it violates property 2. Range searches can touch very many pages of the index just to find one data page; thus, it violates property 3. Insertion or deletion can cause massive reorganization; thus, it violates property 4. One major problem with the index is that it is not paginated (no specification of which disk pages correspond to which parts of the grid is made). Thus, a search over a part of it, which may even be small, can touch many disk pages of the index.

Over the past 25 years or so, researchers have proposed many spatial access methods, as surveyed in Gaede and Günther [1998]. In particular, the R-tree and Z-ordering have been used commercially, especially in geographic information systems.

54.3.3.1 R-Tree and R*-Tree

The R-tree [Guttman 1984] organizes the data in disk pages (nodes of the R-tree) corresponding to a brick or a rectangle in space. It was originally suggested for use with spatial objects. Each object is represented by the coordinates of its smallest enclosing rectangle (or brick) with sides parallel to the coordinate axes.

Correlated Data: A disk page is reserved for each cell in the grid. Many disk pages are empty.

The Grid File: A grid index where each cell in the grid has the address of a disk page containing some data. Many of the cells contain the same address. The index can become larger than the data collection.

FIGURE 54.12 A grid and a grid index.

Thus, any two-dimensional object is represented by four numbers: its lowest x -coordinate, its highest x -coordinate, its lowest y -coordinate, and its highest y -coordinate. Then when a number of such objects are collected, their smallest enclosing brick becomes the boundary of the disk page (a leaf node) containing the records (or in the case of a secondary index, pointers to the records).

At each level, the boundaries of the spaces corresponding to nodes of the R-tree can overlap. Thus, search for objects involves backtracking.

When a new item is inserted, at each level of the tree, the node where the insertion would cause the least increase in the corresponding brick is chosen. Often, the new item can be inserted in a data page without increasing the area at all.

But sometimes the area, and hence the boundaries, of nodes must change when a new data item is inserted. This is an example of a case where the insertion of an element into a leaf node, although there is room and no splits occur, causes updates of ancestors. For when the boundaries of a leaf node change, its entry in its parent must be updated. This also can affect the grandparent and so forth if further enclosing boundaries are changed. A deletion could also cause a boundary to be changed, although this could be ignored at the parent level without causing false search. The adjustment of boundaries can thus violate property 4, local insertion and deletion.

Node splits are similar to those of the B^+ -tree because, when a node splits, some of its contents are moved to a newly allocated disk page. A parent index node obtains a new entry describing the boundaries of the new child and the entry referring to the old child is updated to reflect its new boundaries. An R-tree split is illustrated in Figure 54.13.

FIGURE 54.13 An R-tree split.

Because an R-tree node can be split in many different ways, an algorithm is presented that first chooses two *seed elements* in the node to be split. One seed element is to remain in the old node, and the other seed is to be placed in the new node. After that, each remaining element is tested to see in which of the two nodes its insertion would cause the greatest increase in area (or volume). These elements are placed in the node that causes the least increase in area, until one of the nodes has reached a threshold in the number of elements. Then all remaining elements are placed in the other node.

Sparse nodes are consolidated by deallocating the sparse node, removing its reference from its parent, adjusting upward boundaries, and reinserting the orphaned elements from the sparse node (each of which requires a search, an insertion, and a possible boundary adjustment). Thus, property 4 is violated by sparse node consolidation.

Another drawback of the R-tree is its sensitivity to dimension. This is not as severe as the problems of grid files; the space usage is $O(n^k)$ because each of the $2k$ coordinates of each child must be stored in its parent. This affects the fan-out.

Keeping boundaries does have the good property of stopping searches in areas that have no points. For example, with the information in the root of the R-tree, one knows the outer boundaries of the entire data collection. A search for a point not in this space can be stopped without accessing any lower-level pages. Because the root is likely to be in main memory, this means negative searches (searches that retrieve no data) can in some cases be very efficient. The trade-off between keeping boundaries and searching in space where there are no points is a general one, not confined to the R-tree. Every search method must make a decision whether to keep boundaries of existing data in index terms, making the index larger but making negative searches more efficient, or having a smaller index but risking accessing several pages when making searches in areas where there is no data.

The main problem with the R-tree, however, is that the boundaries of space covered by nodes at a given level of the tree overlap. This means that a search for a data item could do backtracking and thus visit extra index pages and data pages that have no relevant data. This violates property 3. Attempts to decrease the amount of overlap have generated additional suggestions.

For example, the R*-tree is a collection of such suggestions [Beckmann et al. 1990]. In the R*-tree, insertion of a new element follows the path where the least new overlap of areas would occur at each level of the tree rather than the least area increase. Splits first sort the elements by lower value, and then separately by upper value, and measure the perimeter of the resulting possible splits to choose a best *axis* for the split, and then along that axis the position of least overlap is chosen.

The R*-tree also suggests forced reinsertions of elements when an insertion is made that would otherwise cause a split. This causes property 4 to be violated more seriously than in the original R-tree because one insertion of a data item may cause a number of pages to be retrieved and written. However, the claim is that there is less overlap as a result and that therefore searches require less backtracking.

54.3.3.2 hB^Π-Trees

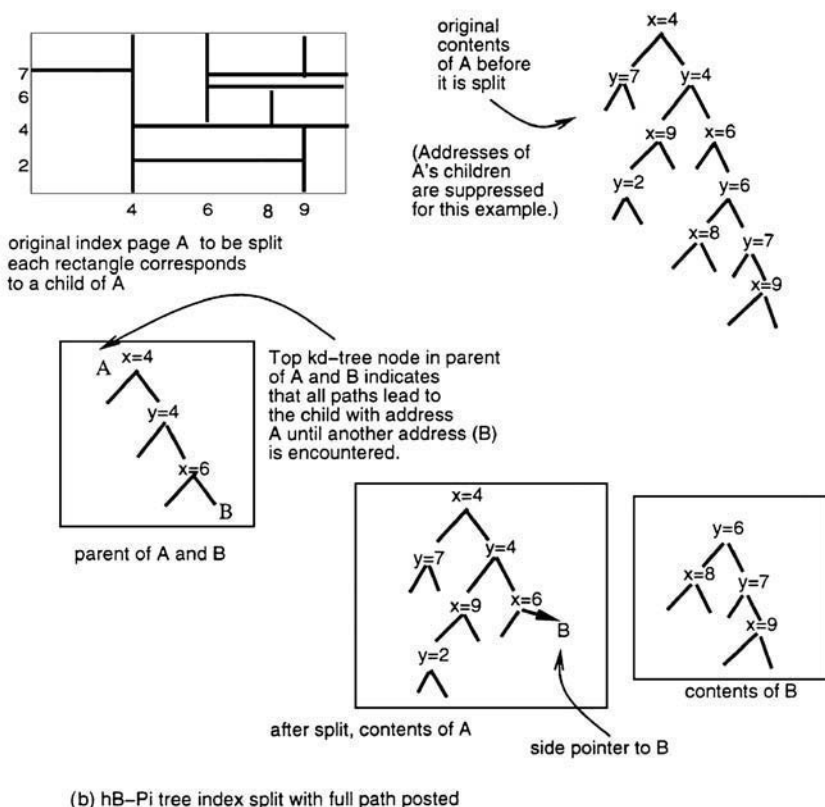

One spatial access method that has local insertion and deletion algorithms is the hB^Π-tree [Evangelidis et al. 1997]. This is a combination of the hB-tree [Lomet and Salzberg 1990a] and a concurrency method for a generalized tree called a Π-tree [Lomet and Salzberg 1992]. The method is described for point data. (Like any other point-data method, it can be used for spatial data by representing spatial elements by the coordinates of their smallest enclosing box.)

The basic idea of Π-tree concurrency is (1) to do a node split as an atomic action, locking only the node that is split, and keeping a pointer to the new sibling in the old sibling; (2) to do posting of information to the parent as a separate atomic action, locking only the parent and briefly the child to make sure the action is still necessary; and (3) to do node consolidation as a separate atomic action, locking only the parent and the two children being consolidated. Only possibly the node split is part of a database transaction. The other actions are done asynchronously. Here we concentrate on the access method aspects and not the concurrency, which is treated in another chapter of this book.

A k-d-tree [Bentley 1979] is used in index nodes to describe the spaces of its children and simultaneously to describe the spaces of the siblings it is pointing to. In data nodes, a k-d-tree also describes the space

(a) data node organization in hB-Pi tree. A local kd-tree indicates the spaces where there are record lists and the addresses of siblings that have been extracted. Here, an upper corner of the space has been split off and is in another node with disk address "H."

(b) hB-Pi tree index split with full path posted

FIGURE 54.14 An hB^{Π} -tree split.

now covered by a sibling the data node points to. An illustration of a data node in an hB^{Π} -tree is given in Figure 54.14a.

Search is as in the B^+ -tree. There is exactly one path from the root to the leaves for any point in the space. There is no backtracking. Insertion of an element never writes on more than one page if there is room for the element in the page, unlike the R-tree.

The splitting discipline of the hB^{Π} -tree is similar to the B^+ -tree or the R-tree. When a page becomes full, some of the contents are moved to a new sibling and an index term will be posted (in this case, asynchronously) in the parent. Unlike the R-tree, the spaces of the two siblings never overlap. At each level of the tree, the spaces corresponding to the pages partition the whole space.

Splitting data nodes is the same in the hB^{Π} -tree as in the hB-tree. Usually, one axis can be chosen and between one third and two thirds of the data is on one side of the hyperplane described by some one value on that axis. In Lomet and Salzberg [1990a], it is proved that, in any case, a corner can be chosen that contains between one third and two thirds of the data. The information posted to the parent

consists of at most k k -d-tree nodes and usually only one. The hB^{Π} -tree is not as sensitive to increases in dimension as the R-tree (and transitively, much less sensitive to increases in dimension than the grid file).

Several variations on splitting index nodes and posting are suggested in Evangelidis et al. [1997]. We briefly describe *full paths* and *split anywhere*. Split anywhere is the split policy of the hB -tree [Lomet and Salzberg 1990a]. Index nodes contain k -d-trees. Index nodes contain no data. To split an index node, one follows the path from the root to a subtree having more than two thirds of the total contents of the node. The split is made there. The subtree is moved to a newly allocated disk page. All of the k -d-tree nodes on the path from the root of the original k -d-tree to the extracted subtree are copied to the parent(s). (This is the full path.) A split of an hB^{Π} -tree index node with full path posting is illustrated in Figure 54.14b. In this figure, we begin with a full index node A containing a k -d-tree. A subtree is extracted and placed in a newly allocated sibling node B .

The choice of not keeping boundaries of existing data elements, but instead partitioning the space, means that searches for ranges outside the areas where data exist can touch several pages containing no data. This seems to be a general trade-off: if boundaries of existing data are kept, as in the R-tree, the total space usage of the access structure grows at least linearly in the number of dimensions of the space, and the insertion and deletion algorithms become nonlocal. But some searches (especially those that retrieve no data) will be more efficient.

54.3.3.3 Z-Ordering

A tried-and-true method for spatial access is bit interleaving, or Z-ordering. Here, the bits of each coordinate of a data point are interleaved to form one number. Then the record corresponding to that point is inserted into a B^+ -tree according to that number. Z-ordering is illustrated in Figure 54.15. One reference for Z-ordering is Orenstein and Merrett [1984].

The Z-ordering forms a path in space. Points are entered into the B^+ -tree in the order of that path. Leaves of the B^+ -tree correspond to connected segments of the path. Thus, clustering is good, although some points that are far apart in space may be clustered together when the path jumps to another area, and some close-by points in space are far apart on the path. The disk space usage is also good because each point is stored once and a standard B^+ -tree is used. Insertion and deletion and exact-match search are also efficient. In addition, because a well-known method (the B^+ -tree) is used, existing software in file systems and databases can be adapted to this method.

There are two problems. One is that the bits chosen for bit interleaving can have patterns that inhibit good clustering. For example, the first 13 bits of the first attribute could be identical in 95% of the records. Then, if two attributes are used, clustering is good only for the second attribute.

The other problem is the range query. Ranges correspond to many disjoint segments of the path and many different B^+ -tree leaves. How can these segments be determined? In Orenstein and Merrett [1984], a recursive algorithm finds all segments completely contained in the search area and then obtains all B -tree leaves intersecting those segments. (This may require visiting a number of index pages and data pages that may, in fact, have no points in the search area, but this is true of all spatial access methods as pages whose space intersects the border of the query space may or may not contain answers to the query.)

54.3.4 Temporal Methods

To do *data mining*, for example, to discover trends in buying patterns, or for many legal and financial applications, all old versions of records are maintained. This is in contrast to the usual policy in databases of replacing records with their new versions, or *updating in place*. To maintain a database of current and old versions of records, special access structures are necessary.

In this chapter, we look only at record versions that are marked with a timestamp associated to the transaction that created the version. This is called *transaction time*. Transaction time has the interesting and useful property that it is monotonically increasing. Newly created record versions have more recent timestamps than older versions.

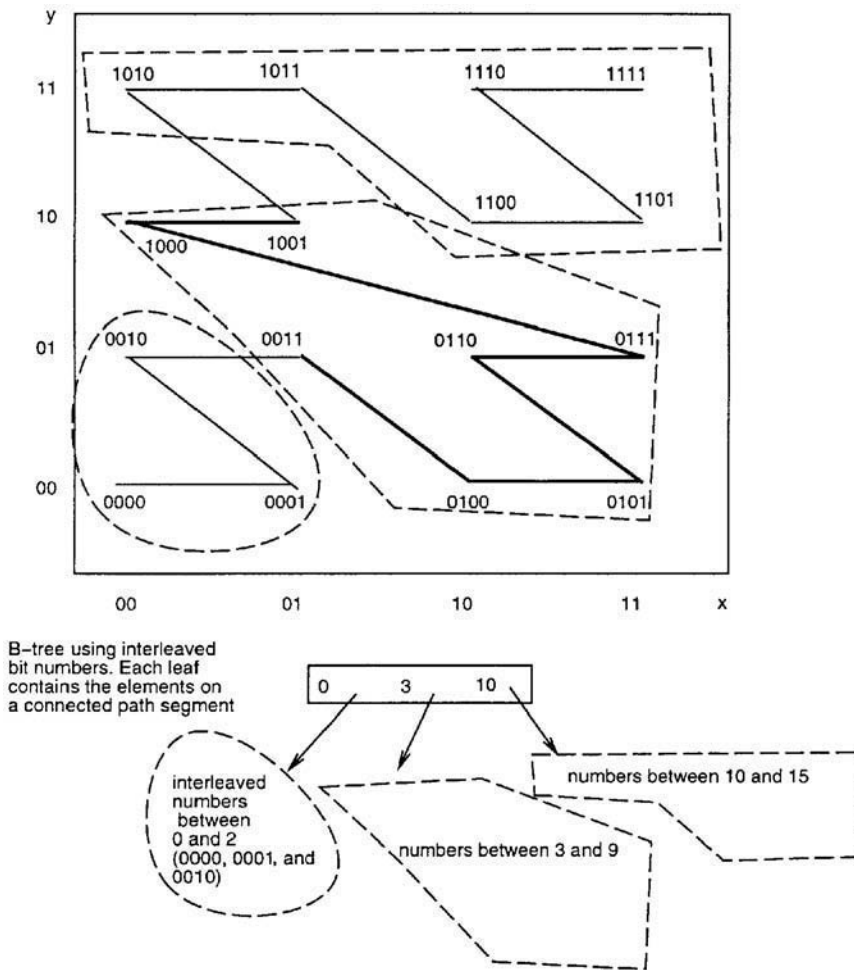

FIGURE 54.15 Z-ordering.

We also assume that each version of a record is assumed valid until a new version is created or until the record with that key is deleted from the database. Thus, to find the version of a record valid at time T , one finds the most recent version created at or before T .

As before, we discuss the indices as if they were primary indices, although, as usual, they can all be regarded as secondary indices if records are replaced with references to records. Thus, our indices will determine the placement of the records in disk pages.

We assume four canonical queries:

1. *Time slice*: Find all records as of time T .
2. *Exact match*: Find the record with key K at time T .
3. *Key range/time slice*: Find records with keys in range (K_1, K_2) valid at time T .
4. *Past versions*: Find all past versions of this record.

A survey of recent temporal access methods appears in Salzberg and Tsotras [1999]. Here, because we assume key ranges are of interest, we look only at access methods that cluster by time and by key range in disk pages. We will in addition restrict ourselves to methods that partition the time-key space rather than allowing overlapping of time-key rectangles. The access methods we outline here are all variations on the write-once B-tree.

FIGURE 54.16 A time-key rectangle covered by a data page. Line segments represent distinct record versions. At time instant 5, a new version with key *c* is created. At time instant 6, a record with key *g* is inserted. (From Salzberg, B. 1994. On indexing spatial and temporal data. *Information Systems*, 19(6):447–465. Elsevier Science Ltd. With permission.)

54.3.4.1 The Write-Once B-Tree

The write-once B-tree (WOBT) [Easton 1986] was described as an access method for write-once read-many (WORM) optical disks. It can of course be used without modification on erasable optical or magnetic disks. WORM disks have the property that once a sector of about 1 kilobyte (1024 bytes) is written, with its associated error correcting checksum, no further writing can be made on the sector. In particular, if say one record is written to the disk, no other records can be subsequently written in the same sector.

(The original specification of the WOBT had the property that many sectors contained only one record each, and therefore much space was wasted. We discuss a WOBT without this restriction, to illustrate the basic idea.)

Basically, data pages or nodes in a WOBT span a key-time rectangle. Such a key-time rectangle on the data level is pictured in Figure 54.16. The set of all of the pages on a given level of the WOBT partition the key-time space. The WOBT has good clustering for the canonical queries. It satisfies property 1.

Search for a record with key *K* and time *T* follows exactly one path down the tree to the one data page where *K* is in the key range and *T* is in the time range. Only one page on each level is visited. The WOBT satisfies property 3 of good access methods.

The WOBT splits as a B⁺-tree. Assume a new record version is to be inserted in a data page, including its key and the current time. All of the current record versions in that page are then copied to one or two newly allocated pages. Only one page is used if the number of current records in the page falls below a threshold. Two pages are used if the number of record versions in the page that are still valid is large. If two pages are used, they are distinguished by key range: all of the current records with key value over or equal to some value *K*₀ are placed in one page and those with key value less than *K*₀ are placed in the other page. WOBT data node splits are illustrated in Figure 54.17a (by time) and Figure 54.18a (by time, then by key).

Index nodes are split the same way. They refer to children with a time-key range rectangle. The current children references are copied to the one or two new index nodes. Note that this makes the WOBT a directed acyclic graph (DAG), and not a tree. In particular, current nodes have more than one parent.

When a current node splits, its split time is only in the time-key rectangle of its most recent parent. So the most recent parent is the only one that needs to be updated. The new index term indicates the split time and the address of the new node(s) containing the copies of the current records. In case of a (time-and-) key split, two index terms are posted. The WOBT satisfies property 4, local insertion and deletion algorithms.

However, old data cannot be moved because that would involve updating several parents referring to the old time-key rectangle. (Imagine a long-lived data page whose parents have split many times.) This means that older data cannot be moved to an archive.

In addition, sometimes it does not make sense to make a time split before every key split. This makes unnecessary copies of data. These two problems of the WOBT were addressed by the TSB-tree.

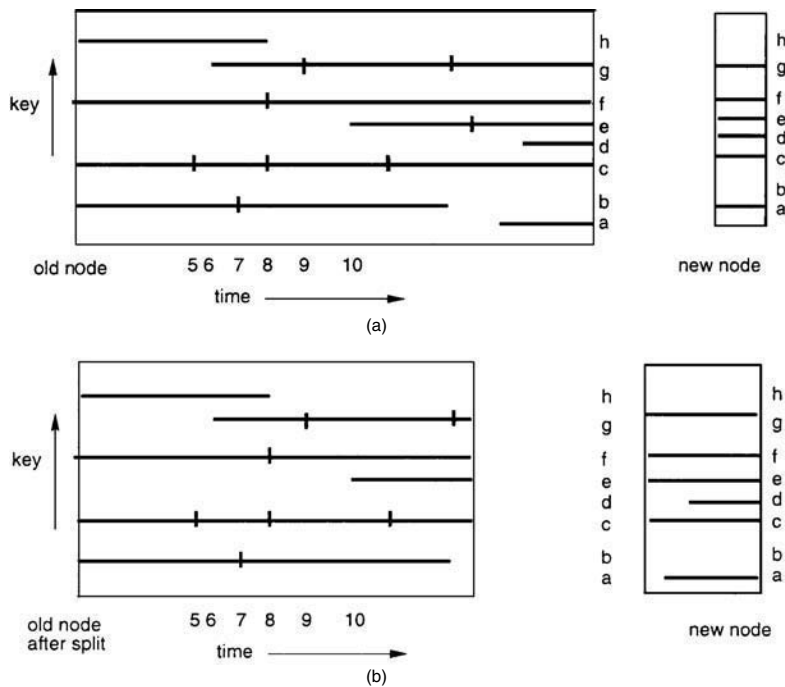

FIGURE 54.17 WOBT and TSB-tree time splits. (a) The WOBT splits at current time, copying current records into a new node. (b) The TSB tree can choose other times to split. (From Salzberg, B. 1994. On indexing spatial and temporal data. *Information Systems*, 19(6):447–465. Elsevier Science Ltd. With permission.)

54.3.4.2 The TSB-Tree

The time-split B-tree (TSB-tree) [Lomet and Salzberg 1989] modifies the splitting algorithms of the WOBT. It allows pure key splits (so that a node may split by key without splitting first by time) and it allows data nodes to split at any time, not just the current time. Data node splits of the TSB-tree are indicated in Figure 54.17b and Figure 54.18b.

In the TSB-tree, index nodes may split only by a time before or at the earliest begin time of any current child. This way, current children have only one parent and old data can be migrated to an archive. Key splits for index nodes must be by a key boundary of a current child. This is also needed to ensure that current children have only one parent. TSB-tree index node splits are illustrated in Figure 54.19.

The total space utilization of the TSB-tree is significantly smaller than that of the WOBT. This is important because all past versions of records are kept and because copies of records are made. An analysis of the space usage is in Lomet and Salzberg [1990b]. Both the TSB-tree and the WOBT use $O(N)$ space, where N is the number of distinct versions. The constant is smaller for the TSB-tree. However, this sometimes comes at a price. Because pure key splits are allowed, it is possible to split a data node so that in some of the earlier time instants not many record versions are valid in one or both of the new nodes. This is illustrated in Figure 54.18b.

Both TSB-tree and the WOBT have no node-consolidation algorithm. This problem is solved by two other extensions of the WOBT.

54.3.4.3 Other Extensions of the Write-Once B-Tree

The persistent B-tree [Lanka and Mays 1991] does time splits by current time only, as does the WOBT. It specifies a node consolidation algorithm by splitting a sparse current node and one of its siblings at current time and copying the combined current record versions to a new node. If there are too many of

FIGURE 54.18 WOBT and TSB-tree key splits. (a) The WOBT splits data nodes first by time and then sometimes also by key. (b) The TSB-tree can split by key alone. (From Salzberg, B. 1994. On indexing spatial and temporal data. *Information Systems*, 19(6):447–465. Elsevier Science Ltd. With permission.)

them, two new nodes can be used instead. It makes the mistake we discussed earlier with the B^+ -tree of having a 50% threshold for node consolidation, thereby allowing thrashing.

It also has two features that are not useful in general: (1) extra nodes on the path from the root to the leaves and (2) an unbalanced overall structure caused by having a *superroot* called *root**. Having a superroot usually increases the average height of the tree. (The WOBT, but not the TSB-tree, also has a superroot.)

The multiversion B-tree [Becker et al. 1993] eliminates the extra nodes in the search path and uses a smaller than 50% threshold for node consolidation but does not eliminate the superroot.

Both the persistent B-tree and the multiversion B-tree always split by current time. This implies that a lower limit on the number of record versions valid at a given time in a node's time interval can be guaranteed, but old record versions cannot be migrated to an archive.

A good compromise of all of the previous methods would be to allow pure-key splitting, as in the TSB-tree, but only when the resulting minimum number of valid records in the time intervals of each new node is above a certain level. Index nodes should be split by earliest begin time of current children, as in the TSB-tree. (This includes the case when they are split for node consolidation.) Node consolidation should be supported as in the persistent B-tree, but with a lower threshold to avoid thrashing as in the multiversion B-tree.

54.3.5 Spatio-Temporal Methods

Recently, with the advances in areas such as mobile computing, GPS technology, and cellular communications, the field of efficiently indexing and querying spatio-temporal objects has received much attention.

FIGURE 54.19 TSB-tree index-node splits. (From Salzberg, B. 1994. On indexing spatial and temporal data. *Information Systems*, 19(6):447–465. Elsevier Science Ltd. With permission.)

An object has both spatial attributes and temporal attributes. Spatio-temporal access methods need to efficiently support the following selection queries — the *region-timeslice query*: “find all objects that are in region R at time t ” and the *region-interval query*: “find all objects that are in region R at some time during time interval I .”

To efficiently support the region-timeslice query, theoretically we could store a separate R-tree for every time instant. However, the space utilization is prohibitively expensive. Also, region-interval queries will not be supported efficiently because many R-trees need to be browsed.

The **Partially Persistent R-tree (PPR-tree)** [Kollios et al. 2001, Tao and Papadias 2001] is an access method that has asymptotically the same efficiency for timeslice queries as the theoretical approach described in the previous paragraph, while it has linear storage cost. The idea is as follows. Two consecutive versions of ephemeral R-trees are quite similar. Thus we combine the common parts of the ephemeral R-trees and only store separately the difference. This, of course, requires us to store a time interval along with each record specifying all the versions that share it. Here, an index is *partially persistent* if a query can be performed on any version while an update can be performed only on the current version.

The PPR-tree is a directed acyclic graph of pages. This graph embeds many R-trees and has a number of root pages. Each root is responsible for providing access to a subsequent part of the ephemeral R-tree data objects. Each record stored in the PPR-tree is thus extended to also include a time interval. This interval represents both the *start* time when the object was inserted into the database and the *end* time when the object was deleted.

A record is called *alive* at time t if t is in the time interval associated with the record. Similarly, a tree node is called *alive* at t if t is in the time interval associated with the index entry referencing the node. To ensure query efficiency, for any time t that a page is alive, we require the page (with the exception of root) to have at least D records that are alive at t . This requirement enables clustering of the alive objects at a given time in a small number of pages, which in turn will minimize the query I/O.

To insert a new object at time t , by examining the latest state of the ephemeral R-tree (omit all nodes whose time interval does not contain t), we find the leaf page where the object should be inserted using the R-tree insertion algorithm. The object is stored in the page, and the time interval associated with it is $[t, \infty)$. If the number of records is more than the page capacity, an *overflow* happens. Another case that needs special care is at deletion time. Because we keep old versions, we do not physically delete the object. Instead, we change the *end* time of the record's time interval from ∞ to the deletion time t . Although the number of records in the page remains the same, the number of records alive at t (or some later time instant) is reduced by one. If this number is smaller than D , we say a *weak-version underflow* happens. To handle overflow or weak-version underflow at time t , a *time-split* is performed on the target page P as follows. All alive records in P are copied to a new page. The *end* time of P is changed to t . If the new page has too many records, it is split into two. If the new page has too few records, alive records from some sibling page of P are copied to the new page.

To perform a timeslice query with respect to region R and time t , we start with the root page alive at t . The tree is searched in a top-down fashion, as in a regular R-tree. The time interval of every record traversed should contain t , while the record's MBR should intersect S . To perform a query with respect to region S and time interval I , the algorithm is similar. First, all roots with intervals intersecting I are found, and so on. Because the PPR-tree is a graph, some nodes can be accessed multiple times. We can keep a list of accessed pages to avoid browsing the same page multiple times.

54.4 Research Issues and Summary

Good access methods should cluster data according to anticipated queries, use only a reasonable amount of total disk space, be efficient in search, and have local insertion and deletion algorithms. We have seen that for one-dimensional data, usually used in business applications, the B^+ -tree has all of these properties. As a result, it is the most used access method today.

Hashing can be very fast, especially for a large and nearly static collection of data. However, as hashed databases grow, they require massive reorganization to regain their good performance. In addition, they do not support range queries. Hashing is the second most used access method today.

The requirements of spatial and temporal indexing, on the other hand, lead to subtle problems. Grid-style solutions tend to take up too much space, especially in large dimensions. R-tree-like solutions with overlapping can have poor search performance due to backtracking. R-trees are also somewhat sensitive to larger dimensions as all boundary coordinates of each child are stored in their parent. Access methods based on interleaved bits depend on the bit patterns of the data. Methods such as the hB^+ -tree, which is not sensitive to increases in dimension but where index terms do not keep boundaries of existing data in children, may cause searches to visit too many data nodes without data in the query area.

Temporal methods (using transaction time) trade off total space usage (numbers of copies of records) with efficiency of search. Some variation of the WOBT, which allows pure key splits some of the time, does node consolidation, and splits index nodes by earliest begin time of current children, is a good compromise solution to the problem.

To index objects with both spatial attributes and temporal attributes, we can use the partially persistent R-tree. It can be thought as many R-trees, one for each time instant. However, by combining the common parts of adjacent versions into one record along with a time interval describing the versions, the partially persistent R-tree has good space utilization as well.

Defining Terms

- Arm:** The part of a disk drive that moves back and forth toward and away from the center of the disks.
- Bucket:** One or several consecutive disk pages corresponding to one value of a hashing function.
- Clustering index:** A commercial term often used to denote a secondary index that is used for data placement only when the data is loaded in the database. After initial loading, the index can be used for record placement only when there is still space left in the correct page. Records never move from the page where they are originally placed. Clustering indices tend not to be clustering after a number of insertions in the database. *This term is avoided in this chapter for this reason.*
- Cylinder:** The set of tracks on a collection of disks on a disk drive that are the same distance from the center of the disks. (One track on each side of each disk.) Reading information that is stored on the same cylinder of a disk drive is fast because the disk arm does not have to move.
- Data page:** A disk page in an access method that contains data records.
- Dense index:** A secondary index.
- Disk access:** The act of transferring information from a magnetic disk to the main memory of a computer, or the reverse. This involves the mechanical movement of the disk arm so that it is placed at the correct cylinder and the rotation of the disk so that the correct disk page falls under a read/write head on the disk arm.
- Disk page:** The smallest unit of transfer from (or to) a disk to (or from) main memory. In most systems today, this is 4 kilobytes, or 4096 bytes. It is expected that the size of a disk page will grow in the future so that many systems may begin to have 8-kilobyte disk pages, or even 32-kilobyte disk pages. The reason for the size increase is that main memory space and CPU speed are increasing faster than disk access speed.
- Extent:** The large amount of consecutive disk space assigned to a relation when it is created and subsequent such chunks of consecutive disk space assigned to the relation as it grows. Some file systems cannot assign extents and thus are unsuitable for many access methods.
- Fan-out:** The ratio of the size of the data page collection to the size of the index page collection. In B⁺-tree N-like access methods, this is approximately the average number of children of an index node, and sometimes fan-out is used in this sense.
- Hash table fill factor:** The total space needed for the data divided by the space used by the primary area.
- Hashing:** In hashing, a function maps a database key to the location (address) of the record having that key. (A secondary hashing method maps the database key to the location containing the address of the record.)
- Head:** The head on a disk arm is where the bits are moved off and onto the disk (read and write). Much effort has been made to allow disk head placement to be more precise so that the density of bits on the disk (number of bits per track and number of tracks per disk of a fixed diameter) can become larger.
- Index page:** A disk page in an access method or indexing method that does not contain any data records.
- Overflow area:** That part of a hashing access method where records are placed when there is no room for them in the correct bucket in the primary area.
- Primary area:** That part of the disk that holds the buckets of a hashing method accessible with one disk access, using the hashing function.
- Primary index:** A primary index determines the physical placement of records. It does not contain references to individual records. A primary index can be converted to a secondary index by replacing all of the data records with references to data records. Many database systems have no primary indices.
- Reference:** A reference to an index page or to a data page is a disk address. A reference to a data record can be (1) just the address of the disk page where the record is, with the understanding that some other criteria will be used to locate the record; (2) a disk page address and a slot number within that disk page; or (3) some collection of attribute values from the record that can be used in another index to find the record.

Secondary index: An index that contains a reference to every data record. Secondary indices do not determine data record placement. Sometimes, secondary indices refer to data that is placed in the database in insertion order. Sometimes, secondary indices refer to data that is placed in the database according to a separate primary index based on other attributes of the record. Sometimes, secondary indices refer to data that is loaded into the database originally in the same order as specified by the secondary index but not thereafter. Many database management systems have only secondary indices.

Separator: A prefix of a (possibly former) database key that is long enough to differentiate one page on a lower level of a B⁺-tree from the next. These are used instead of database keys in the index pages of a B⁺-tree.

Sparse index: A primary index.

Thrashing: When repeated deletions and insertions of records cause the same data page to be repeatedly split and then consolidated, the access method is said to be thrashing. Commercial database systems prevent thrashing by setting the threshold for B⁺-tree node consolidation at 0% full; only empty nodes are considered sparse and are consolidated with their siblings.

Track: A circle on one side of one disk with its center in the middle of the disk. Tracks tend to hold on the order of 100,000 bytes. The set of tracks at the same distance from the center, but on different disks or on different sides of the disk, form a cylinder on a given disk drive.

Further Information

To build a solid background on access methods on or before 1998, please refer to the survey paper on spatial access methods [Gaede and Günther 1998] and the survey paper on temporal access methods [Salzberg and Tsotras 1999].

The best information about new access methods for new applications can be obtained by attending top database conferences and reading their proceedings. The best database conferences include: (1) ACM International Conference for Special Interest Group on Management of Data (SIGMOD); (2) International Conference on Very Large Data Bases (VLDB); (3) IEEE International Conference on Data Engineering (ICDE); and (4) International Conference on Extending Database Technology (EDBT). Another top conference is the ACM Symposium on Principles of Database Systems (PODS), which is held annually together with SIGMOD. The papers in PODS generally are more theoretical. For more information on the conferences (e.g., to download research papers), one can visit the following URL: <http://www.informatik.uni-trier.de/~ley/db/index.html>.

Important database events (e.g., upcoming database conferences or submission deadlines) will be announced in the newsgroup dbworld. To subscribe to dbworld, send a message by e-mail to listproc@cs.wisc.edu with the words “subscribe dbworld” and your full name. The reason to attend conferences in person is that you will hear information that is not published and you will get an impression of which articles are the best ones to read in detail.

Although in the database field, conference papers are more important than journal papers, there are some journals worth reading: (1) *ACM Transactions on Database Systems (TODS)*, (2) *The VLDB Journal*; and (3) *IEEE Transactions on Knowledge and Data Engineering (TKDE)*.

There are several excellent textbooks that contain information on access methods: (1) *Transaction Processing: Techniques and Concepts* by Jim Gray and Andreas Reuter has chapters on file structures and access methods in a modern setting. This book was published in 1993 by Morgan Kaufmann. (2) The first author of this chapter, Betty Salzberg, has written a textbook entitled *File Structures: An Analytic Approach*. Many topics touched upon in this chapter are elaborated with exercises and examples. This book was published in 1988 by Prentice Hall. (3) *Database Principles, Programming, and Performance (second edition)* by Patrick E. O'Neil and Elizabeth J. O'Neil, published by Morgan Kaufmann in 2000. (4) *Database Management Systems (third edition)* by Raghu Ramakrishnan and Johannes Gehrke, published by McGraw-Hill in 2001.

55.1 Introduction

Imagine yourself standing in front of an exquisite buffet filled with numerous delicacies. Your goal is to try them all out, but you need to decide in what order. What order of tastes will maximize the overall pleasure of your palate?

Although much less pleasurable and subjective, that is the type of problem that query optimizers are called to solve. Given a query, there are many plans that a database management system (DBMS) can follow to process it and produce its answer. All plans are equivalent in terms of their final output but vary in their cost, i.e., the amount of time that they need to run. What is the plan that needs the least amount of time?

Such *query optimization* is absolutely necessary in a DBMS. The cost difference between two alternatives can be enormous. For example, consider the following database schema, which will be used throughout this chapter:

```
emp(name,age,sal,dno)
dept(dno,dname,floor,budget,mgr,ano)
acct(ano,type,balance,bno)
bank(bno,bname,address)
```

Further, consider the following very simple SQL query:

```
select name, floor
from emp, dept
where emp.dno=dept.dno and sal>100 K
```

TABLE 55.1 Characteristics of a Sample Database

Parameter Description	Parameter Value
Number of emp pages	20,000
Number of emp tuples	100,000
Number of emp tuples with sal > 100 K	10
Number of dept pages	10
Number of dept tuples	100
Indices of emp	Clustered B+-tree on emp.sal (3 levels deep)
Indices of dept	Clustered hashing on dept.dno (average bucket length of 1.2 pages)
Number of buffer pages	3
Cost of one disk page access	20 ms

Assume the characteristics in Table 55.1 for the database contents, structure, and run-time environment: Consider the following three different plans:

- P1**: Through the B+-tree find all tuples of emp that satisfy the selection on emp.sal. For each one, use the hashing index to find the corresponding dept tuples. (Nested loops, using the index on both relations.)
- P2**: For each dept page, scan the entire emp relation. If an emp tuple agrees on the dno attribute with a tuple on the dept page and satisfies the selection on emp.sal, then the emp–dept tuple pair appears in the result. (Page-level nested loops, using no index.)
- P3**: For each dept tuple, scan the entire emp relation and store all emp–dept tuple pairs. Then, scan this set of pairs and, for each one, check if it has the same values in the two dno attributes and satisfies the selection on emp.sal. (Tuple-level formation of the cross product, with subsequent scan to test the join and the selection.)

Calculating the expected I/O costs of these three plans shows the tremendous difference in efficiency that equivalent plans may have. P1 needs 0.32 s, P2 needs a bit more than an hour, and P3 needs more than a whole day. Without query optimization, a system may choose plan P2 or P3 to execute this query, with devastating results. Query optimizers, however, examine “all” alternatives, so they should have no trouble choosing P1 to process the query.

The path that a query traverses through a DBMS until its answer is generated is shown in [Figure 55.1](#). The system modules through which it moves have the following functionality:

- The *Query Parser* checks the validity of the query and then translates it into an internal form, usually a relational calculus expression or something equivalent
- The *Query Optimizer* examines all algebraic expressions that are equivalent to the given query and chooses the one that is estimated to be the cheapest
- The *Code Generator* or the *Interpreter* transforms the access plan generated by the optimizer into calls to the query processor
- The *Query Processor* actually executes the query

Queries are posed to a DBMS by interactive users or by programs written in general-purpose programming languages (e.g., C/C++, Fortran, PL/I) that have queries embedded in them. An interactive (ad hoc) query goes through the entire path shown in Figure 55.1. On the other hand, an embedded query goes through the first three steps only once, when the program in which it is embedded is compiled (*compile time*). The code produced by the Code Generator is stored in the database and is simply

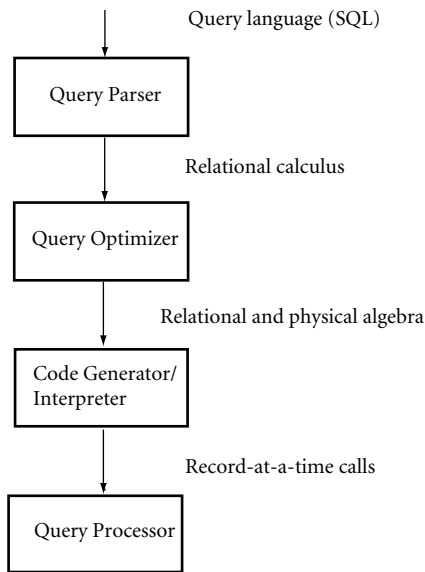

FIGURE 55.1 Query flow through a DBMS.

invoked and executed by the Query Processor whenever control reaches that query during the program execution (*run time*). Thus, independent of the number of times an embedded query needs to be executed, optimization is not repeated until database updates make the access plan invalid (e.g., index deletion) or highly suboptimal (e.g., extensive changes in database contents). There is no real difference between optimizing interactive or embedded queries, so we make no distinction between the two in this chapter.

The area of query optimization is very large within the database field. It has been studied in a great variety of contexts and from many different angles, giving rise to several diverse solutions in each case. The purpose of this chapter is to primarily discuss the core problems in query optimization and their solutions and only touch upon the wealth of results that exist beyond that. More specifically, we concentrate on optimizing a single *flat SQL query* with “and” as the only Boolean connective in its qualification (also known as *conjunctive query*, *select–project–join query*, or *nonrecursive Horn clause*) in a centralized relational DBMS, assuming that full knowledge of the run-time environment exists at compile time. Likewise, we make no attempt to provide a complete survey of the literature, in most cases providing only a few example references. More extensive surveys can be found elsewhere [Jarke and Koch 1984, Mannino et al. 1988].

The rest of the chapter is organized as follows. [Section 55.2](#) presents a modular architecture for a query optimizer and describes the role of each module in it. [Section 55.3](#) analyzes the choices that exist in the shapes of relational query access plans, and the restrictions usually imposed by current optimizers to make the whole process more manageable. [Section 55.4](#) focuses on the dynamic programming search strategy used by commercial query optimizers and briefly describes alternative strategies that have been proposed. [Section 55.5](#) defines the problem of estimating the sizes of query results and/or the frequency distributions of values in them and describes in detail histograms, which represent the statistical information typically used by systems to derive such estimates. [Section 55.6](#) discusses query optimization in noncentralized environments, i.e., parallel and distributed DBMSs. [Section 55.7](#) briefly touches upon several advanced types of query optimization that have been proposed to solve some hard problems in the area. Finally, [Section 55.8](#) summarizes the chapter and raises some questions related to query optimization that still have no good answer.

55.2 Query Optimizer Architecture

55.2.1 Overall Architecture

In this section, we provide an abstraction of the query optimization process in a DBMS. Given a database and a query on it, several execution plans exist that can be employed to answer the query. In principle, all the alternatives need to be considered so that the one with the best estimated performance is chosen. An abstraction of the process of generating and testing these alternatives is shown in Figure 55.2, which is essentially a modular architecture of a query optimizer. Although one could build an optimizer based on this architecture, in real systems the modules shown do not always have boundaries so clear-cut as in Figure 55.2. Based on Figure 55.2, the entire query optimization process can be seen as having two stages: *rewriting* and *planning*. There is only one module in the first stage, the *Rewriter*, whereas all other modules are in the second stage. The functionality of each of the modules in Figure 55.2 is analyzed below.

55.2.2 Module Functionality

55.2.2.1 Rewriter

This module applies transformations to a given query and produces equivalent queries that are hopefully more efficient, e.g., replacement of views with their definition, flattening out of nested queries, etc. The transformations performed by the Rewriter depend only on the declarative, i.e., static, characteristics of queries and do not take into account the actual query costs for the specific DBMS and database concerned. If the rewriting is known or assumed to always be beneficial, the original query is discarded; otherwise, it is sent to the next stage as well. By the nature of the rewriting transformations, this stage operates at the *declarative* level.

55.2.2.2 Planner

This is the main module of the ordering stage. It examines all possible execution plans for each query produced in the previous stage and selects the overall cheapest one to be used to generate the answer of the original query. It employs a *search strategy*, which examines the space of execution plans in a particular fashion. This space is determined by two other modules of the optimizer, the *Algebraic Space* and the *Method-Structure Space*. For the most part, these two modules and the search strategy determine the cost, i.e., running time, of the optimizer itself, which should be as low as possible. The execution plans examined by the Planner are compared based on estimates of their cost so that the cheapest may be chosen. These costs are derived by the last two modules of the optimizer, the *Cost Model* and the *Size-Distribution Estimator*.

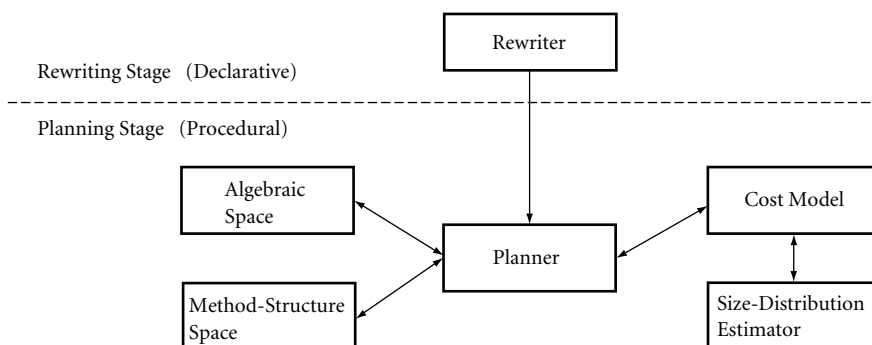

FIGURE 55.2 Query optimizer architecture.

55.2.2.3 Algebraic Space

This module determines the action execution orders that are to be considered by the Planner for each query sent to it. All such series of actions produce the same query answer but usually differ in performance. They are usually represented in relational algebra as formulas or in tree form. Because of the algorithmic nature of the objects generated by this module and sent to the Planner, the overall planning stage is characterized as operating at the *procedural* level.

55.2.2.4 Method–Structure Space

This module determines the implementation choices that exist for the execution of each ordered series of actions specified by the Algebraic Space. This choice is related to the available join methods for each join (e.g., nested loops, merge scan, and hash join), if supporting data structures are built on the fly, if/when duplicates are eliminated, and other implementation characteristics of this sort, which are predetermined by the DBMS implementation. This choice is also related to the available indices for accessing each relation, which is determined by the physical schema of each database stored in its catalogs. Given an algebraic formula or tree from the Algebraic Space, this module produces all corresponding complete execution plans, which specify the implementation of each algebraic operator and the use of any indices.

55.2.2.5 Cost Model

This module specifies the arithmetic formulas that are used to estimate the cost of execution plans. For every different join method, for every different index type access, and in general for every distinct kind of step that can be found in an execution plan, there is a formula that gives its cost. Given the complexity of many of these steps, most of these formulas are simple approximations of what the system actually does and are based on certain assumptions regarding issues like buffer management, disk–CPU overlap, sequential vs random I/O, etc. The most important input parameters to a formula are the size of the buffer pool used by the corresponding step, the sizes of relations or indices accessed, and possibly various distributions of values in these relations. While the first one is determined by the DBMS for each query, the other two are estimated by the Size-Distribution Estimator.

55.2.2.6 Size-Distribution Estimator

This module specifies how the sizes (and possibly frequency distributions of attribute values) of database relations and indices as well as (sub)query results are estimated. As mentioned above, these estimates are needed by the Cost Model. The specific estimation approach adopted in this module also determines the form of statistics that need to be maintained in the catalogs of each database, if any.

55.2.3 Description Focus

Of the six modules of [Figure 55.2](#), three are not discussed in any detail in this chapter: the Rewriter, the Method–Structure Space, and the Cost Model. The Rewriter is a module that exists in some commercial DBMSs (e.g., DB2-Client/Server and Illustra), although not in all of them. Most of the transformations normally performed by this module are considered an advanced form of query optimization and not part of the core (planning) process. The Method–Structure Space specifies alternatives regarding join methods, indices, etc., which are based on decisions made outside the development of the query optimizer and do not really affect much of the rest of it. For the Cost Model, for each alternative join method, index access, etc., offered by the Method–Structure Space, either there is a standard straightforward formula that people have devised by simple accounting of the corresponding actions (e.g., the formula for the tuple-level nested-loop join) or there are numerous variations of formulas that people have proposed and used to approximate these actions (e.g., formulas for finding the tuples in a relation having a random value in an attribute). In either case, the derivation of these formulas is not considered an intrinsic part of the query optimization field. For these reasons, we do not discuss these three modules any further until [Section 55.7](#), where some Rewriter transformations are described. The following three sections provide a detailed description of the Algebraic Space, the Planner, and the Size-Distribution Estimator modules, respectively.

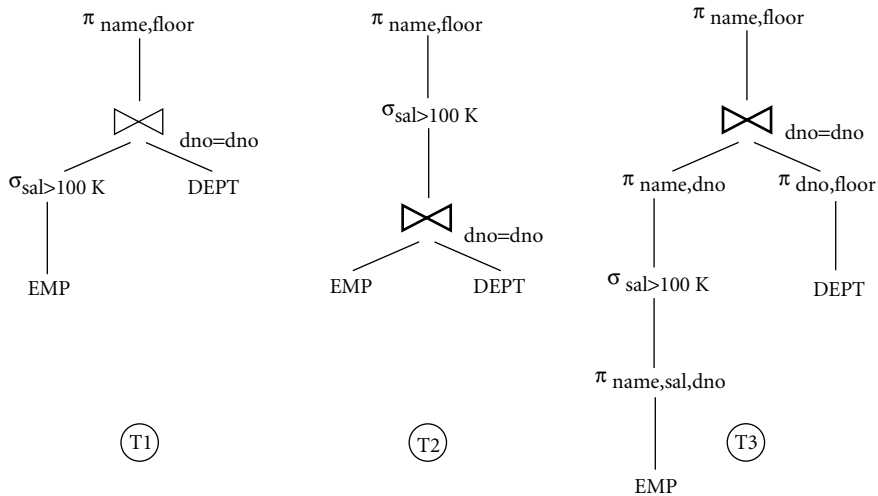

FIGURE 55.3 Examples of general query trees.

55.3 Algebraic Space

As mentioned above, a flat SQL query corresponds to a select–project–join query in relational algebra. Typically, such an algebraic query is represented by a *query tree* whose leaves are database relations and nonleaf nodes are algebraic operators like selections (denoted by σ), projections (denoted by π), and joins* (denoted by \bowtie). An intermediate node indicates the application of the corresponding operator on the relations generated by its children, the result of which is then sent further up. Thus, the edges of a tree represent data flow from bottom to top, i.e., from the leaves, which correspond to data in the database, to the root, which is the final operator producing the query answer. Figure 55.3 gives three examples of query trees for the query

```

select name, floor
from emp, dept
where emp.dno=dept.dno and sal > 100 K

```

For a complicated query, the number of all query trees may be enormous. To reduce the size of the space that the search strategy has to explore, DBMSs usually restrict the space in several ways. The first typical restriction deals with selections and projections:

- R1: Selections and projections are processed on the fly and almost never generate intermediate relations. Selections are processed as relations are accessed for the first time. Projections are processed as the results of other operators are generated.

For example, plan P1 of Section 55.1 satisfies restriction R1: the index scan of emp finds emp tuples that satisfy the selection on emp.sal on the fly and attempts to join only those; furthermore, the projection on the result attributes occurs as the join tuples are generated. For queries with no join, R1 is moot. For queries with joins, however, it implies that all operations are dealt with as part of join execution. Restriction R1 eliminates only suboptimal query trees, since separate processing of selections and projections incurs additional costs. Hence, the Algebraic Space module specifies alternative query trees with join operators only, selections and projections being implicit.

*For simplicity, we think of the cross-product operator as a special case of a join with no join qualification.

Given a set of relations to be combined in a query, the set of all alternative join trees is determined by two algebraic properties of join: commutativity ($R_1 \bowtie R_2 \equiv R_2 \bowtie R_1$) and associativity ($[(R_1 \bowtie R_2) \bowtie R_3] \equiv R_1 \bowtie (R_2 \bowtie R_3)$). The first determines which relation will be inner and which outer in the join execution. The second determines the order in which joins will be executed. Even with the R1 restriction, the alternative join trees that are generated by commutativity and associativity are very large, $\Omega(N!)$ for N relations. Thus, DBMSs usually further restrict the space that must be explored. In particular, the second typical restriction deals with cross products.

R2: Cross products are never formed, unless the query itself asks for them. Relations are combined always through joins in the query.

For example, consider the following query:

```

select name, floor, balance
from emp, dept, acnt
where emp.dno=dept.dno and dept.ano=acnt.ano
  
```

Figure 55.4 shows the three possible join trees (modulo join commutativity) that can be used to combine the emp, dept, and acnt relations to answer the query. Of the three trees in the figure, tree T3 has a cross product, since its lower join involves relations emp and acnt, which are not explicitly joined in the query. Restriction R2 almost always eliminates suboptimal join trees due to the large size of the results typically generated by cross products. The exceptions are very few and are cases where the relations forming cross products are extremely small. Hence, the algebraic-space module specifies alternative join trees that involve no cross product. The exclusion of unnecessary cross products reduces the size of the space to be explored, but that still remains very large. Although some systems restrict the space no further (e.g., Ingres and DB2-Client/Server), others require an even smaller space (e.g., DB2/MVS). In particular, the third typical restriction deals with the shape of join trees:

R3: The inner operand of each join is a database relation, never an intermediate result.

For example, consider the following query:

```

select name, floor, balance, address
from emp, dept, acnt, bank
where emp.dno=dept.dno and dept.ano=acnt.ano and acnt.bno=bank.bno
  
```

Figure 55.5 shows three possible cross-product-free join trees that can be used to combine the emp, dept, acnt, and bank relations to answer the query. Tree T1 satisfies restriction R3, whereas trees T2 and T3 do not, since they have at least one join with an intermediate result as the inner relation. Because of their shape (Figure 55.5), join trees that satisfy restriction R3, e.g., tree T1, are called *left-deep*. Trees that have their outer relation always being a database relation, e.g., tree T2, are called *right-deep*. Trees with at least one join between two intermediate results, e.g., tree T3, are called *bushy*. Restriction R3 is of a more heuristic nature than R1 and R2 and may well eliminate the optimal plan in some cases. It has been claimed that

FIGURE 55.4 Examples of join trees; T3 has a cross product.

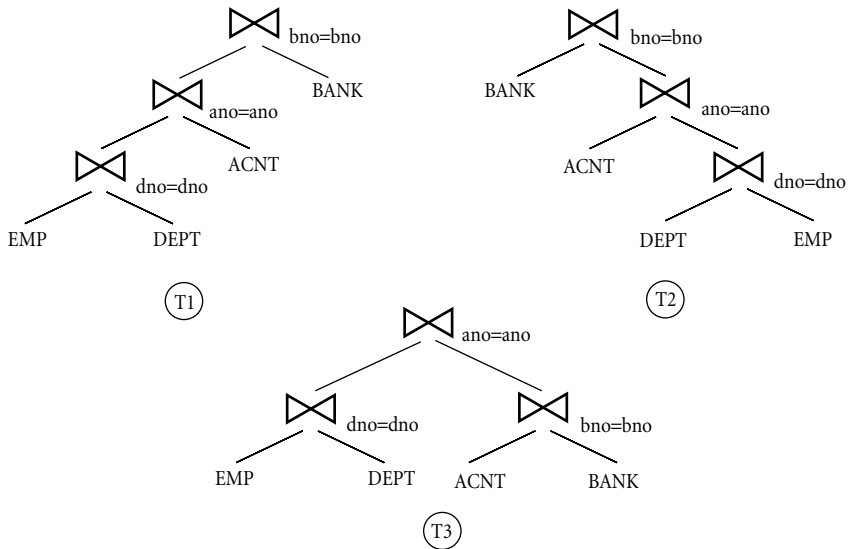

FIGURE 55.5 Examples of left-deep (T1), right-deep (T2), and bushy (T3) join trees.

most often the optimal left-deep tree is not much more expensive than the optimal tree overall. The typical arguments used are two:

- Having original database relations as inners increases the use of any preexisting indices.
- Having intermediate relations asouters allows sequences of nested-loops joins to be executed in a pipelined fashion.*

Both index usage and pipelining reduce the cost of join trees. Moreover, restriction R3 significantly reduces the number of alternative join trees to $O(2^N)$ for many queries with N relations. Hence, the Algebraic Space module of the typical query optimizer specifies only join trees that are left-deep.

In summary, typical query optimizers make restrictions R1, R2, and R3 to reduce the size of the space they explore. Hence, unless otherwise noted, our descriptions follow these restrictions as well.

55.4 Planner

The role of the Planner is to explore the set of alternative execution plans, as specified by the Algebraic Space and the Method–Structure Space, and find the cheapest one, as determined by the Cost Model and the Size-Distribution Estimator. The following three subsections deal with different types of search strategies that the Planner may employ for its exploration. The first one focuses on the most important strategy, dynamic programming, which is the one used by essentially all commercial systems. The second one discusses a promising approach based on randomized algorithms, and the third one talks about other search strategies that have been proposed.

55.4.1 Dynamic Programming Algorithms

Dynamic programming was first proposed as a query optimization search strategy in the context of System R [Astrahan et al. 1976] by Selinger et al. [1979]. Commercial systems have since used it in various forms and with various extensions. We present this algorithm pretty much in its original form [Selinger et al. 1979], only ignoring details that do not arise in flat SQL queries, which are our focus.

*A similar argument can be made in favor of right-deep trees regarding sequences of hash joins.

The algorithm is essentially a dynamically pruning, exhaustive search algorithm. It constructs all alternative join trees (that satisfy restrictions R1–R3) by iterating on the number of relations joined so far, always pruning trees that are known to be suboptimal. Before we present the algorithm in detail, we need to discuss the issue of *interesting order*. One of the join methods that is usually specified by the Method–Structure–Space module is *merge scan*. Merge scan first sorts the two input relations on the corresponding join attributes and then merges them with a synchronized scan. If any of the input relations, however, is already sorted on its join attribute (e.g., because of earlier use of a B+-tree index or sorting as part of an earlier merge-scan join), the sorting step can be skipped for the relation. Hence, given two partial plans during query optimization, one cannot compare them based on their cost only and prune the more expensive one; one has to also take into account the sorted order (if any) in which their result comes out. One of the plans may be more expensive but may generate its result sorted on an attribute that will save a sort in a subsequent merge-scan execution of a join. To take into account these possibilities, given a query, one defines its *interesting orders* to be orders of intermediate results on any relation attributes that participate in joins. (For more general SQL queries, attributes in order-by and group-by clauses give rise to interesting orders as well.) For example, in the query of [Section 55.3](#), orders on the attributes emp.dno, dept.dno, dept.ano, acnt.ano, acnt.bno, and bank.bno are interesting. During optimization of this query, if any intermediate result comes out sorted on any of these attributes, then the partial plan that gave this result must be treated specially.

Using the above, we give below a detailed English description of the dynamic programming algorithm optimizing a query of N relations:

Step 1: For each relation in the query, all possible ways to access it, i.e., via all existing indices and including the simple sequential scan, are obtained. (Accessing an index takes into account any query selection on the index key attribute.) These partial (single-relation) plans are partitioned into equivalence classes based on any interesting order in which they produce their result. An additional equivalence class is formed by the partial plans whose results are in no interesting order. Estimates of the costs of all plans are obtained from the Cost Model module, and the cheapest plan in each equivalence class is retained for further consideration. However, the cheapest plan of the no-order equivalence class is not retained if it is not cheaper than all other plans.

Step 2: For each pair of relations joined in the query, all possible ways to evaluate their join using all relation access plans retained after step 1 are obtained. Partitioning and pruning of these partial (two-relation) plans proceeds as above.

⋮

Step i : For each set of $i - 1$ relations joined in the query, the cheapest plans to join them for each interesting order are known from the previous step. In this step, for each such set, all possible ways to join one more relation with it without creating a cross product are evaluated. For each set of i relations, all generated (partial) plans are partitioned and pruned as before.

⋮

Step N : All possible plans to answer the query (the unique set of N relations joined in the query) are generated from the plans retained in the previous step. The cheapest plan is the final output of the optimizer to be used to process the query.

For a given query, the above algorithm is guaranteed to find the optimal plan among those satisfying restrictions R1–R3. It often avoids enumerating all plans in the space by being able to dynamically prune suboptimal parts of the space as partial plans are generated. In fact, although in general still exponential, there are query forms for which it generates only $O(N^3)$ plans [Ono and Lohman 1990].

An example that shows dynamic programming in its full detail takes too much space. We illustrate its basic mechanism by showing how it would proceed on the simple query below:

```
select name, mgr
from emp, dept
where emp.dno=dept.dno and sal>30 K and floor=2
```

TABLE 55.2 Entire Set of Alternatives Appropriately Partitioned

Relation	Interesting Order	Plan Description	Cost
emp	emp.dno	Access through B+-tree on emp.dno.	700
	—	Access through B+-tree on emp.sal.	200
		Sequential scan.	600
dept	—	Access through hashing on dept.floor.	50
		Sequential scan.	200

TABLE 55.3 Entire Set of Alternatives for the Last Step of the Algorithm

Join Method	Outer/Inner	Plan Description	Cost	
Nested loops	emp/dept	• For each emp tuple obtained through the B+-tree on emp.sal, scan dept through the hashing index on dept.floor to find tuples matching on dno.	1800	
		• For each emp tuple obtained through the B+-tree on emp.dno and satisfying the selection on emp.sal, scan dept through the hashing index on dept.floor to find tuples matching on dno.	3000	
	dept/emp	• For each dept tuple obtained through the hashing index on dept.floor, scan emp through the B+-tree on emp.sal to find tuples matching on dno.	2500	
		• For each dept tuple obtained through the hashing index on dept.floor, probe emp through the B+-tree on emp.dno using the value in dept.dno to find tuples satisfying the selection on emp.sal.	1500	
Merge scan	—	• Sort the emp tuples resulting from accessing the B+-tree on emp.sal into L_1 .	2300	
		• Sort the dept tuples resulting from accessing the hashing index on dept.floor into L_2 .		
		• Merge L_1 and L_2 .		
		• Sort the dept tuples resulting from accessing the hashing index on dept.floor into L_2 .		2000
		• Merge L_2 and the emp tuples resulting from accessing the B+-tree on emp.dno and satisfying the selection on emp.sal.		

Assume that there is a B+-tree index on emp.sal, a B+-tree index on emp.dno, and a hashing index on dept.floor. Also assume that the DBMS supports two join methods: nested loops and merge scan. (Both types of information should be specified in the Method–Structure–Space module.) Note that, based on the definition, potential interesting orders are those on emp.dno and dept.dno, since these are the only join attributes in the query. The algorithm proceeds as follows:

Step 1: All possible ways to access emp and dept are found. The only interesting order arises from accessing emp via the B+-tree on emp.dno, which generates the emp tuples sorted and ready for the join with dept. The entire set of alternatives, appropriately partitioned, is shown in Table 55.2. Each partial plan is associated with some hypothetical cost; in reality, these costs are obtained from the Cost-Model module. Within each equivalence class, only the cheapest plan is retained for the next step, as indicated by the boxes surrounding the corresponding costs in the table.

Step 2: Since the query has two relations, this is the last step of the algorithm. All possible ways to join emp and dept are found, using both supported join methods and all partial plans for individual relation access retained from step 1. For the nested-loops method, which relation is inner and which is outer is also specified. Since this is the last step of the algorithm, there is no issue of interesting orders. The entire set of alternatives is shown in Table 55.3 in a way similar to step 1. Based on hypothetical costs for each of the plans, the optimizer produces as output the plan indicated by the box surrounding the corresponding cost in the table.

As the above example illustrates, the choices offered by the Method–Structure Space in addition to those of the Algebraic Space result in an extraordinary number of alternatives that the optimizer must search through. The memory requirements and running time of dynamic programming grow exponentially with query size (i.e., number of joins) in the worst case, since all viable partial plans generated in each step must be stored to be used in the next one. In fact, many modern systems place a limit on the size of queries that can be submitted (usually around fifteen joins), because for larger queries the optimizer crashes due to its very high memory requirements. Nevertheless, most queries seen in practice involve less than ten joins, and the algorithm has proved to be very effective in such contexts. It is considered the standard in query optimization search strategies.

55.4.2 Randomized Algorithms

To address the inability of dynamic programming to cope with really large queries, which appear in several novel application fields, several other algorithms have been proposed recently. Of these, randomized algorithms, i.e., algorithms that “flip coins” to make decisions, appear very promising.

The most important class of these optimization algorithms is based on plan transformations instead of the plan construction of dynamic programming, and includes algorithms like *Simulated Annealing*, *Iterative Improvement*, and *Two-Phase Optimization*. These are generic algorithms that can be applied to a variety of optimization problems and are briefly described below as adapted to query optimization. They operate by searching a graph whose nodes are all the alternative execution plans that can be used to answer a query. Each node has a cost associated with it, and the goal of the algorithm is to find a node with the globally minimum cost. Randomized algorithms perform *random walks* in the graph via a series of *moves*. The nodes that can be reached in one move from a node *S* are called the *neighbors* of *S*. A move is called *uphill* move (*downhill*) if the cost of the source node is lower (higher) than the cost of the destination node. A node is a *global minimum* if it has the lowest cost among all nodes. It is a *local minimum* if, in all paths starting at that node, any downhill move comes after at least one uphill move.

55.4.2.1 Algorithm Description

Iterative Improvement (II) [Nahar et al. 1986, Swami 1989, Swami and Gupta 1988] performs a large number of *local optimizations*. Each one starts at a random node and repeatedly accepts random downhill moves until it reaches a local minimum. II returns the local minimum with the lowest cost found.

Simulated Annealing (SA) performs a continuous random walk, accepting downhill moves always and uphill moves with some probability, trying to avoid being caught in a high-cost local minimum [Ioannidis and Kang 1990, Ioannidis and Wong 1987, Kirkpatrick et al. 1983]. This probability decreases as time progresses and eventually becomes zero, at which point execution stops. Like II, SA returns the node with the lowest cost visited.

The *Two-Phase Optimization* (2PO) algorithm is a combination of II and SA [Ioannidis and Kang 1990]. In phase 1, II is run for a small period of time, i.e., a few local optimizations are performed. The output of that phase, which is the best local minimum found, is the initial node of the next phase. In phase 2, SA is run starting from a low probability for uphill moves. Intuitively, the algorithm chooses a local minimum and then searches the area around it, still being able to move in and out of local minima, but practically unable to climb up very high hills.

55.4.2.2 Results

Given a finite amount of time, these randomized algorithms have performance that depends on the characteristics of the cost function over the graph and the connectivity of the latter as determined by the neighbors of each node. They have been studied extensively for query optimization, being mutually compared and also compared against dynamic programming [Ioannidis and Kang 1990, Ioannidis and Wong 1987, Kang 1991, Swami 1989, Swami and Gupta 1988]. The specific results of these comparisons vary depending on the choices made regarding issues of the algorithms’ implementation and setup, but

also choices made in other modules of the query optimizer, i.e., the Algebraic Space, the Method–Structure Space, and the Cost Model. In general, however, the conclusions are as follows. First, up to about ten joins, dynamic programming is preferred over the randomized algorithms because it is faster and it guarantees finding the optimal plan. For larger queries, the situation is reversed, and despite the probabilistic nature of the randomized algorithms, their efficiency makes them the algorithms of choice. Second, among randomized algorithms, II usually finds a reasonable plan very quickly, while given enough time, SA is able to find a better plan than II. 2PO gets the best of both worlds and is able to find plans that are as good as those of SA, if not better, in much shorter time.

55.4.3 Other Search Strategies

To complete the picture on search strategies we briefly describe several other algorithms that people have proposed in the past, deterministic, heuristic, or randomized. Ibaraki and Kameda were the ones that proved that query optimization is an NP-complete problem even if considering only the nested-loops join method [Ibaraki and Kameda 1984]. Given that result, there have been several efforts to obtain algorithms that solve important subcases of the query optimization problem and run in polynomial time. Ibaraki and Kameda themselves presented an algorithm (referred to as IK here) that takes advantage of the special form of the cost formula for nested loops and optimizes a tree query of N joins in $O(N^2 \log N)$ time. They also presented an algorithm that is applicable to even cyclic queries and finds a good (but not always optimal) plan in $O(N^3)$ time.

The KBZ algorithm uses essentially the same techniques, but it is more general and more sophisticated and runs in $O(N^2)$ time for tree queries [Krishnamurthy et al. 1986]. As with IK, the applicability of KBZ depends on the cost formulas for joins to be of a specific form. Nested loops and hash join satisfy this requirement but, in general, merge scan does not.

The AB algorithm mixes deterministic and randomized techniques and runs in $O(N^4)$ time [Swami and Iyer 1993]. It uses KBZ as a subroutine, which needs $O(N^2)$ time, and essentially executes it $O(N^2)$ times on randomly selected spanning trees of the query graph. Through an interesting separation of the cost of merge scan into a part that affects optimization and a part that does not, AB is applicable to all join methods despite the dependence on KBZ.

In addition to SA, II, and 2PO, *Genetic Algorithms* [Goldberg 1989] form another class of generic randomized optimization algorithms that have been applied to query optimization. These algorithms simulate a biological phenomenon: a random set of solutions to the problem, each with its own cost, represents an initial population; pairs of solutions from that population are matched (*cross over*) to generate offspring that obtain characteristics from both parents, and the new children may also be randomly changed in small ways (*mutation*); between the parents and the children, those with the least cost (*most fit*) survive in the next generation. The algorithm ends when the entire population consists of copies of the same solution, which is considered to be optimal. Genetic algorithms have been implemented for query optimization with promising results [Bennett et al. 1991].

Another interesting randomized approach to query optimization is pure, uniformly random generation of access plans [Galindo-Legaria et al. 1994]. Truly uniform generation is a hard problem but has been solved for tree queries. With an efficient implementation of this step, experiments with the algorithm have shown good potential, since there is no dependence on plan transformations or random walks.

In the artificial intelligence community, the A^* heuristic algorithm is extensively used for complex search problems. A^* has been proposed for query optimization as well and can be seen as a direct extension to the traditional dynamic programming algorithm [Yoo and Lafortune 1989]. Instead of proceeding in steps and using all plans with n relations to generate all plans with $n + 1$ relations together, A^* proceeds by expanding one of the generated plans at hand at a time, based on its expected proximity to the optimal plan. Thus, A^* generates a full plan much earlier than dynamic programming and is able to prune more aggressively in a branch-and-bound mode. A^* has been proposed for query optimization and has been shown quite successful for not very large queries.

Finally, in the context of extensible DBMSs, several unique search strategies have been proposed, which are all rule-based. Rules are defined on how plans can be constructed or modified, and the Planner follows the rules to explore the specified plan space. The most representative of these efforts are those of Starburst [Haas et al. 1990, Lohman 1988] and Volcano/Exodus [Graefe and DeWitt 1987, Graefe and McKenna 1993]. The Starburst optimizer employs constructive rules, whereas the Volcano/Exodus optimizers employ transformation rules.

55.5 Size-Distribution Estimator

The final module of the query optimizer that we examine in detail is the Size-Distribution Estimator. Given a query, it estimates the sizes of the results of (sub)queries and the frequency distributions of values in attributes of these results.

Before we present specific techniques that have been proposed for estimation, we use an example to clarify the notion of frequency distribution. Consider the simple relation *OLYMPIAN* on the left in Table 55.4, with the frequency distribution of the values in its Department attribute on the right.

One can generalize the above and discuss distributions of frequencies of combinations of arbitrary numbers of attributes. In fact, to calculate/estimate the size of any query that involves multiple attributes from a single relation, multiattribute joint frequency distributions or their approximations are required. Practical DBMSs, however, deal with frequency distributions of individual attributes only, because considering all possible combinations of attributes is very expensive. This essentially corresponds to what is known as the *attribute value independence assumption*, and, although rarely true, it is adopted by all current DBMSs.

Several techniques have been proposed in the literature to estimate query result sizes and frequency distributions, most of them contained in the extensive survey by Mannino et al. [1988] and elsewhere [Christodoulakis 1989]. Most commercial DBMSs (e.g., DB2, Informix, Ingres, Sybase, Microsoft SQL server) base their estimation on *histograms*, so our description mostly focuses on those. We then briefly summarize other techniques that have been proposed.

55.5.1 Histograms

In a *histogram* on attribute *a* of relation *R*, the domain of *a* is partitioned into *buckets*, and a uniform distribution is assumed within each bucket. That is, for any bucket *b* in the histogram, if a value $v_i \in b$, then the frequency f_i of v_i is approximated by $\sum_{v_j \in b} f_j / |b|$. A histogram with a single bucket generates the same approximate frequency for all attribute values. Such a histogram is called *trivial* and corresponds to making the *uniform distribution assumption* over the entire attribute domain. Note that, in principle,

TABLE 55.4 The Relation Olympian with the Frequency Distribution of the Values in its Department Attribute

Name	Salary	Department	Department	Frequency
Zeus	100 K	General Management	General Management	2
Poseidon	80 K	Defense	Defense	2
Pluto	80 K	Justice	Education	1
Aris	50 K	Defense	Domestic Affairs	2
Ernis	60 K	Commerce	Agriculture	1
Apollo	60 K	Energy	Commerce	1
Hefestus	50 K	Energy	Justice	1
Hera	90 K	General Management	Energy	3
Athena	70 K	Education		
Aphrodite	60 K	Domestic Affairs		
Demeter	60 K	Agriculture		
Hestia	50 K	Domestic Affairs		
Artemis	60 K	Energy		

TABLE 55.5 An Example of Two Histograms on the Department Attribute

Department	Histogram H1		Histogram H2	
	Frequency in Bucket	Approximate Frequency	Frequency in Bucket	Approximate Frequency
Agriculture	1	1.5	1	1.33
Commerce	1	1.5	1	1.33
Defense	2	1.5	2	1.33
Domestic Affairs	2	1.5	2	2.5
Education	1	1.75	1	1.33
Energy	3	1.75	3	2.5
General Management	2	1.75	2	1.33
Justice	1	1.75	1	1.33

any arbitrary subset of an attribute’s domain may form a bucket and not necessarily consecutive ranges of its natural order.

Continuing with the example of the *OLYMPIAN* relation, we present in Table 55.5 two different histograms on the Department attribute, both with two buckets. For each histogram, we first show which frequencies are grouped in the same bucket by enclosing them in the same shape (box or circle), and then we show the resulting approximate frequency, i.e., the average of all frequencies enclosed by identical shapes.

There are various classes of histograms that systems use or researchers have proposed for estimation. Most of the earlier prototypes, and still some of the commercial DBMSs, use trivial histograms, i.e., make the uniform distribution assumption [Selinger et al. 1979]. That assumption, however, rarely holds in real data, and estimates based on it usually have large errors [Christodoulakis 1984, Ioannidis and Christodoulakis 1991]. Excluding trivial ones, the histograms that are typically used belong to the class of *equiwidth* histograms [Kooi 1980]. In those, the number of consecutive attribute values or the size of the range of attribute values associated with each bucket is the same, independent of the frequency of each attribute value in the data. Since these histograms store a lot more information than trivial histograms (they typically have 10–20 buckets), their estimations are much better. Histogram H1 above is equiwidth, since the first bucket contains four values starting from A–D and the second bucket contains also four values starting from E–Z.

Although we are not aware of any system that currently uses histograms in any other class than those mentioned above, several more advanced classes have been proposed and are worth discussing. *Equidepth* (or *equiheight*) histograms are essentially duals of equiwidth histograms [Kooi 1980, Piatetsky-Shapiro and Connell 1984]. In those, the sum of the frequencies of the attribute values associated with each bucket is the same, independent of the number of those attribute values. Equiwidth histograms have a much higher worst-case and average error for a variety of selection queries than equidepth histograms. Muralikrishna and DeWitt [1988] extended the above work for multidimensional histograms that are appropriate for multiattribute selection queries.

In *serial* histograms [Ioannidis and Christodoulakis 1993], the frequencies of the attribute values associated with each bucket are either all greater or all less than the frequencies of the attribute values associated with any other bucket. That is, the buckets of a serial histogram group frequencies that are close to each other with no interleaving. Histogram H1 in Table 55.5 is not serial, as frequencies 1 and 3 appear in one bucket and frequency 2 appears in the other, while histogram H2 is. Under various optimality criteria, serial histograms have been shown to be optimal for reducing the worst-case and the average error

in equality selection and join queries [Ioannidis 1993, Ioannidis and Christodoulakis 1993, Ioannidis and Poosala 1995].

Identifying the optimal histogram among all serial ones takes exponential time in the number of buckets. Moreover, since there is usually no order correlation between attribute values and their frequencies, storage of serial histograms essentially requires a regular index that will lead to the approximate frequency of every individual attribute value. Because of all these complexities, the class of *end-biased* histograms has been introduced. In those, some number of the highest frequencies and some number of the lowest frequencies in an attribute are explicitly and accurately maintained in separate individual buckets, and the remaining (middle) frequencies are all approximated together in a single bucket. End-biased histograms are serial, since their buckets group frequencies with no interleaving. Identifying the optimal end-biased histogram, however, takes only slightly over linear time in the number of buckets. Moreover, end-biased histograms require little storage, since usually most of the attribute values belong in a single bucket and do not have to be stored explicitly. Finally, in several experiments it has been shown that most often the errors in the estimates based on end-biased histograms are not too far off from the corresponding (optimal) errors based on serial histograms. Thus, as a compromise between optimality and practicality, it has been suggested that the optimal end-biased histograms should be used in real systems.

55.5.2 Other Techniques

In addition to histograms, several other techniques have been proposed for query result size estimation [Christodoulakis 1989, Mannino et al. 1988]. Those that, like histograms, store information in the database typically approximate a frequency distribution by a parametrized mathematical distribution or a polynomial. Although requiring very little overhead, these approaches are typically inaccurate because most often real data do not follow any mathematical function. On the other hand, those based on *sampling* primarily operate at run time [Haas and Swami 1992, 1995, Lipton et al. 1990, Olken and Rotem 1986] and compute their estimates by collecting and possibly processing random samples of the data. Although producing highly accurate estimates, sampling is quite expensive, and therefore its practicality in query optimization is questionable, especially since optimizers need query result size estimations frequently.

55.6 Noncentralized Environments

The preceding discussion focuses on query optimization for sequential processing. This section touches upon issues and techniques related to optimizing queries in noncentralized environments. The focus is on the Method–Structure–Space and Planner modules of the optimizer, as the remaining ones are not significantly different from the centralized case.

55.6.1 Parallel Databases

Among all parallel architectures, the shared-nothing and the shared-memory paradigms have emerged as the most viable ones for database query processing. Thus, query optimization research has concentrated on these two. The processing choices that either of these paradigms offers represent a huge increase over the alternatives offered by the Method–Structure–Space module in a sequential environment. In addition to the sources of alternatives that we discussed earlier, the Method–Structure–Space module offers two more: the number of processors that should be given to each database operation (*intraoperator parallelism*) and placing operators into groups that should be executed simultaneously by the available processors (*interoperator parallelism*, which can be further subdivided into *pipelining* and *independent parallelism*). The *scheduling* alternatives that arise from these two questions add at least another superexponential factor to the total number of alternatives and make searching an even more formidable task. Thus, most systems and research prototypes adopt various heuristics to avoid dealing with a very large search space. In the two-stage approach [Hong and Stonebraker 1991], given a query, one first identifies the optimal sequential

plan for it using conventional techniques like those discussed in [Section 55.4](#), and then one identifies the optimal parallelization/scheduling of that plan. Various techniques have been proposed in the literature for the second stage, but none of them claims to provide a complete and optimal answer to the scheduling question, which remains an open research problem. In the segmented execution model, one considers only schedules that process memory-resident right-deep segments of (possibly bushy) query plans one-at-a-time (i.e., no independent interoperator parallelism). Shekita et al. [1993] combined this model with a novel heuristic search strategy with good results for shared-memory. Finally, one may be restricted to deal with right-deep trees only [Schneider and DeWitt 1990].

In contrast to all the search-space reduction heuristics, Lanzelotte et al. [1993] dealt with both deep and bushy trees, considering schedules with independent parallelism, where all the pipelines in an execution are divided into phases, pipelines in the same phase are executed in parallel, and each phase starts only after the previous phase ended. The search strategy that they used was a randomized algorithm, similar to 2PO, and proved very effective in identifying efficient parallel plans for a shared-nothing architecture.

55.6.2 Distributed Databases

The difference between distributed and parallel DBMSs is that the former are formed by a collection of independent, semiautonomous processing sites that are connected via a network that could be spread over a large geographic area, whereas the latter are individual systems controlling multiple processors that are in the same location, usually in the same machine room. Many prototypes of distributed DBMSs have been implemented [Bernstein et al. 1981, Mackert and Lohman 1986], and several commercial systems are offering distributed versions of their products as well (e.g., DB2, Informix, Sybase, Oracle).

Other than the necessary extensions of the Cost-Model module, the main differences between centralized and distributed query optimization are in the Method-Structure-Space module, which offers additional processing strategies and opportunities for transmitting data for processing at multiple sites. In early distributed systems, where the network cost was dominating every other cost, a key idea was using semijoins for processing in order to only transmit tuples that would certainly contribute to join results [Bernstein et al. 1981, Mackert and Lohman 1986]. An extension of that idea is using Bloom filters, which are bit vectors that approximate join columns and are transferred across sites to determine which tuples *might* participate in a join so that only these may be transmitted [Mackert and Lohman 1986].

55.7 Advanced Types of Optimization

In this section, we attempt to provide a brief glimpse of advanced types of optimization that researchers have proposed over the past few years. The descriptions are based on examples only; further details may be found in the references provided. Furthermore, there are several issues that are not discussed at all due to lack of space, although much interesting work has been done on them, e.g., nested query optimization, rule-based query optimization, query optimizer generators, object-oriented query optimization, optimization with materialized views, heterogeneous query optimization, recursive query optimization, aggregate query optimization, optimization with expensive selection predicates, and query-optimizer validation.

55.7.1 Semantic Query Optimization

Semantic query optimization is a form of optimization mostly related to the Rewriter module. The basic idea lies in using integrity constraints defined in the database to rewrite a given query into *semantically equivalent* ones [King 1981]. These can then be optimized by the Planner as regular queries, and the most efficient plan among all can be used to answer the original query. As a simple example, using a hypothetical SQL-like syntax, consider the following integrity constraint:

```
assert sal-constraint on emp:  
  sal > 100 K where job = "Sr. Programmer".
```

Also consider the following query:

```
select name, floor
from emp, dept
where emp.dno=dept.dno and job="Sr. Programmer".
```

Using the above integrity constraint, the query can be rewritten into a semantically equivalent one to include a selection on sal:

```
select name, floor
from emp, dept
where emp.dno=dept.dno and job="Sr. Programmer" and sal>100 K.
```

Having the extra selection could help tremendously in finding a fast plan to answer the query if the only index in the database is a B+-tree on emp.sal. On the other hand, it would certainly be a waste if no such index exists. For such reasons, all proposals for semantic query optimization present various heuristics or rules on which rewritings have the potential of being beneficial and should be applied and which should not.

55.7.2 Global Query Optimization

So far, we have focused our attention to optimizing individual queries. Quite often, however, multiple queries become available for optimization at the same time, e.g., queries with unions, queries from multiple concurrent users, queries embedded in a single program, or queries in a deductive system. Instead of optimizing each query separately, one may be able to obtain a global plan that, although possibly suboptimal for each individual query, is optimal for the execution of all of them as a group. Several techniques have been proposed for global query optimization [Sellis 1988]. As a simple example of the problem of global optimization consider the following two queries:

```
select name, floor
from emp, dept
where emp.dno=dept.dno and job="Sr. Programmer,"
select name
from emp, dept
where emp.dno=dept.dno and budget>1 M.
```

Depending on the sizes of the emp and dept relations and the selectivities of the selections, it may well be that computing the entire join once and then applying separately the two selections to obtain the results of the two queries is more efficient than doing the join twice, each time taking into account the corresponding selection. Developing Planner modules that would examine all the available global plans and identify the optimal one is the goal of global/multiple query optimizers.

55.7.3 Parametric/Dynamic Query Optimization

As mentioned earlier, embedded queries are typically optimized once at compile time and are executed multiple times at run time. Because of this temporal separation between optimization and execution, the values of various parameters that are used during optimization may be very different during execution. This may make the chosen plan invalid (e.g., if indices used in the plan are no longer available) or simply not optimal (e.g., if the number of available buffer pages or operator selectivities has changed, or if new indices have become available). To address this issue, several techniques [Cole and Graefe 1994, Graefe and Ward 1989, Ioannidis et al. 1992] have been proposed that use various search strategies (e.g., randomized algorithms [Ioannidis et al. 1992] or the strategy of Volcano [Cole and Graefe 1994]) to optimize queries as much as possible at compile time, taking into account all possible values that interesting parameters may have at run time. These techniques use the actual parameter values at run time and simply pick the plan that was found optimal for them with little or no overhead. Of a drastically different flavor is the technique

of Rdb/VMS [Antoshenkov 1993], where by dynamically monitoring how the probability distribution of plan costs changes, plan switching may actually occur during query execution.

55.8 Summary

To a large extent, the success of a DBMS lies in the quality, functionality, and sophistication of its query optimizer, since that determines much of the system's performance. In this chapter, we have given a bird's-eye view of query optimization. We have presented an abstraction of the architecture of a query optimizer and focused on the techniques currently used by most commercial systems for its various modules. In addition, we have provided a glimpse of advanced issues in query optimization, whose solutions have not yet found their way into practical systems, but could certainly do so in the future.

Although query optimization has existed as a field for more than twenty years, it is very surprising how fresh it remains in terms of being a source of research problems. In every single module of the architecture of Figure 55.2, there are many questions for which we do not have complete answers, even for the most simple, single-query, sequential, relational optimizations. When is it worthwhile to consider bushy trees instead of just left-deep trees? How can one model buffering effectively in the system's cost formulas? What is the most effective means of estimating the cost of operators that involve random access to relations (e.g., nonclustered index selection)? Which search strategy can be used for complex queries with confidence, providing consistent plans for similar queries? Should optimization and execution be interleaved in complex queries so that estimate errors do not grow very large? Of course, we do not even attempt to mention the questions that arise in various advanced types of optimization.

We believe that the next twenty years will be as active as the previous twenty and will bring many advances to query optimization technology, changing many of the approaches currently used in practice. Despite its age, query optimization remains an exciting field.

56.1 Introduction

Many service-oriented businesses and organizations, such as banks, airlines, catalog retailers, hospitals, etc., have grown to depend on fast, reliable, and correct access to their “mission-critical” data on a constant basis. In many cases, particularly for global enterprises, 7×24 access is required; that is, the data must be available seven days a week, twenty-four hours a day. *Database management systems* (DBMSs) are often employed to meet these stringent performance, availability, and reliability demands. As a result, two of the core functions of a DBMS are (1) to protect the data stored in the database and (2) to provide correct and highly available access to those data in the presence of concurrent access by large and diverse user populations, despite various software and hardware failures. The responsibility for these functions resides in the **concurrency control** and **recovery** components of the DBMS software. *Concurrency control* ensures that individual users see consistent states of the database even though operations on behalf of many users may be interleaved by the database system. *Recovery* ensures that the database is fault-tolerant; that is, that the database state is not corrupted as the result of a software, system, or media failure. The existence of this functionality in the DBMS allows applications to be written without explicit concern for concurrency and fault tolerance. This freedom provides a tremendous increase in programmer productivity and allows new applications to be added more easily and safely to an existing system.

For database systems, correctness in the presence of concurrent access and/or failures is tied to the notion of a **transaction**. A transaction is a unit of work, possibly consisting of multiple data accesses and updates, that must **commit** or **abort** as a single atomic unit. When a transaction *commits*, all updates it performed on the database are made permanent and visible to other transactions. In contrast, when a transaction *aborts*, all of its updates are removed from the database and the database is restored (if necessary) to the state it would have been in if the aborting transaction had never been executed. Informally, transaction executions are said to respect the **ACID properties** [Gray and Reuter 1993]:

Atomicity: This is the “all-or-nothing” aspect of transactions discussed above — either all operations of a transaction complete successfully, or none of them do. Therefore, after a transaction has completed (i.e., committed or aborted), the database will not reflect a partial result of that transaction.

Consistency: Transactions preserve the consistency of the data — a transaction performed on a database that is internally consistent will leave the database in an internally consistent state. Consistency is typically expressed as a set of declarative *integrity constraints*. For example, a constraint may be that the salary of an employee cannot be higher than that of his or her manager.

Isolation: A transaction's behavior is not impacted by the presence of other transactions that may be accessing the same database concurrently. That is, a transaction sees only a state of the database that could occur if that transaction were the only one running against the database and produces only results that it could produce if it was running alone.

Durability: The effects of *committed* transactions survive failures. Once a transaction commits, its updates are guaranteed to be reflected in the database even if the contents of volatile (e.g., main memory) or nonvolatile (e.g., disk) storage are lost or corrupted.

Of these four transaction properties, the concurrency control and recovery components of a DBMS are primarily concerned with preserving *atomicity*, *isolation*, and *durability*. The preservation of the *consistency* property typically requires additional mechanisms such as compile-time analysis or run-time triggers in order to check adherence to integrity constraints.* For this reason, this chapter focuses primarily on the A, I, and D of the ACID transaction properties.

Transactions are used to structure complex processing tasks which consist of multiple data accesses and updates. A traditional example of a transaction is a money transfer from one bank account (say account A) to another (say B). This transaction consists of a withdrawal from A and a deposit into B and requires four accesses to account information stored in the database: a read and write of A and a read and write of B. The data accesses of this transaction are as follows:

```
TRANSFER( )
  01 A_bal := Read(A)
  02 A_bal := A_bal - $50
  03 Write(A, A_bal)
  04 B_bal := Read(B)
  05 B_bal := B_bal + $50
  06 Write(B, B_bal)
```

The value of A in the database is read and decremented by \$50, then the value of B in the database is read and incremented by \$50. Thus, TRANSFER preserves the invariant that the sum of the balances of A and B prior to its execution must equal the sum of the balances after its execution, regardless of whether the transaction commits or aborts.

Consider the importance of the atomicity property. At several points during the TRANSFER transaction, the database is in a temporarily inconsistent state. For example, between the time that account A is updated (statement 3) and the time that account B is updated (statement 6) the database reflects the decrement of A but not the increment of B, so it appears as if \$50 has disappeared from the database. If the transaction reaches such a point and then is unable to complete (e.g., due to a failure or an unresolvable conflict, etc.), then the system must ensure that the effects of the partial results of the transaction (i.e., the update to A) are removed from the database — otherwise the database state will be incorrect. The durability property, in contrast, only comes into play in the event that the transaction successfully commits. Once the user is notified that the transfer has taken place, he or she will assume that account B contains the transferred funds and may attempt to use those funds from that point on. Therefore, the DBMS must ensure that the results of the transaction (i.e., the transfer of the \$50) remain reflected in the database state even if the system crashes.

Atomicity, consistency, and durability address correctness for **serial execution** of transactions, where only a single transaction at a time is allowed to be in progress. In practice, however, database management systems typically support **concurrent execution**, in which the operations of multiple transactions can

*In the case of triggers, the recovery mechanism is typically invoked to abort an offending transaction.

TRANSFER	REPORTSUM
01 A_bal := Read (A)	
02 A_bal := A_bal - \$50	
03 Write (A,A_bal)	
	01 A_bal := Read (A) /* value is \$250 */
	02 B_bal := Read (B) /* value is \$200 */
	03 Print(A_bal + B_bal) /* result = \$450 */
04 B_bal := Read (B)	
05 B_bal := B_bal + \$50	
06 Write (B,B_bal)	

FIGURE 56.1 An incorrect interleaving of TRANSFER and REPORTSUM.

be executed in an interleaved fashion. The motivation for concurrent execution in a DBMS is similar to that for multiprogramming in operating systems, namely, to improve the utilization of system hardware resources and to provide multiple users a degree of fairness in access to those resources. The *isolation* property of transactions comes into play when concurrent execution is allowed.

Consider a second transaction that computes the sum of the balances of accounts A and B:

```
REPORTSUM( )
  01 A_bal := Read(A)
  02 B_bal := Read(B)
  03 Print(A_bal + B_bal)
```

Assume that initially, the balance of account A is \$300 and the balance of account B is \$200. If a REPORTSUM transaction is executed on this state of the database, it will print a result of \$500. In a database system restricted to *serial execution* of transactions, REPORTSUM will also produce the same result if it is executed after a TRANSFER transaction. The atomicity property of transactions ensures that if the TRANSFER aborts, all of its effects are removed from the database (so REPORTSUM would see A = \$300 and B = \$200), and the durability property ensures that if it commits, then all of its effects remain in the database state (so REPORTSUM would see A = \$250 and B = \$250).

Under concurrent execution, however, a problem could arise if the isolation property is not enforced. As shown in Figure 56.1, if REPORTSUM were to execute after TRANSFER has updated account A but before it has updated account B, then REPORTSUM could see an inconsistent state of the database. In this case, the execution of REPORTSUM sees a state of the database in which \$50 has been withdrawn from account A but has not yet been deposited in account B, resulting in a total of \$450 — it seems that \$50 has disappeared from the database. This result is not one that could be obtained in any serial execution of TRANSFER and REPORTSUM transactions. It occurs because in this example, REPORTSUM accessed the database when it was in a temporarily inconsistent state. This problem is sometimes referred to as the *inconsistent retrieval* problem. To preserve the isolation property of transactions the DBMS must prevent the occurrence of this and other potential anomalies that could arise due to concurrent execution. The formal notion of correctness for concurrent execution in database systems is known as **serializability** and is described in [Section 56.2](#).

Although the transaction processing literature often traces the history of transactions back to antiquity (such as Sumerian tax records) or to early contract law [Gray 1981, Gray and Reuter 1993, Korth 1995], the roots of the transaction concept in information systems are typically traced back to the early 1970s and the work of Bjork [1973] and Davies [1973]. Early systems such as IBM's IMS addressed related issues, and a systematic treatment and understanding of ACID transactions was developed several years later by members of the IBM System R group [Gray et al. 1975, Eswaran et al. 1976] and others [e.g., Rosenkrantz et al. 1977, Lomet 1977]. Since that time, many techniques for implementing ACID transactions have been proposed and a fairly well accepted set of techniques has emerged. The remainder of this chapter contains an overview of the basic theory that has been developed as well as a survey of the more widely known implementation techniques for concurrency control and recovery. A brief discussion of work on extending the simple transaction model is presented at the end of the chapter.

It should be noted that issues related to those addressed by concurrency control and recovery in database systems arise in other areas of computing systems as well, such as file systems and memory systems. There are, however, two salient aspects of the ACID model that distinguish transactions from other approaches. First is the incorporation of both isolation (concurrency control) and fault-tolerance (recovery) issues. Second is the concern with treating arbitrary groups of *write* and/or *read* operations on multiple data items as atomic, isolated units of work. While these aspects of the ACID model provide powerful guarantees for the protection of data, they also can induce significant systems implementation complexity and performance overhead. For this reason, the notion of ACID transactions and their associated implementation techniques have remained largely within the DBMS domain, where the provision of highly available and reliable access to “mission critical” data is a primary concern.

56.2 Underlying Principles

56.2.1 Concurrency Control

56.2.1.1 Serializability

As stated in the previous section, the responsibility for maintaining the isolation property of ACID transactions resides in the concurrency-control portion of the DBMS software. The most widely accepted notion of correctness for concurrent execution of transactions is *serializability*. Serializability is the property that an (possibly interleaved) execution of a group of transactions has the same effect on the database, and produces the same output, as some serial (i.e., noninterleaved) execution of those transactions. It is important to note that serializability does not specify any *particular* serial order, but rather, only that the execution is equivalent to *some* serial order. This distinction makes serializability a slightly less intuitive notion of correctness than transaction initiation time or commit order, but it provides the DBMS with significant additional flexibility in the scheduling of operations. This flexibility can translate into increased responsiveness for end users.

A rich theory of database concurrency control has been developed over the years [see Papadimitriou 1986, Bernstein et al. 1987, Gray and Reuter 1993], and serializability lies at the heart of much of this theory. In this chapter we focus on the simplest models of concurrency control, where the operations that can be performed by transactions are restricted to *read(x)*, *write(x)*, *commit*, and *abort*. The operation *read(x)* retrieves the value of a data item from the database, *write(x)* modifies the value of a data item in the database, and *commit* and *abort* indicate successful or unsuccessful transaction completion respectively (with the concomitant guarantees provided by the ACID properties). We also focus on a specific variant of serializability called *conflict serializability*. Conflict serializability is the most widely accepted notion of correctness for concurrent transactions because there are efficient, easily implementable techniques for detecting and/or enforcing it. Another well-known variant is called *view serializability*. View serializability is less restrictive (i.e., it allows more legal schedules) than conflict serializability, but it and other variants are primarily of theoretical interest because they are impractical to implement. The reader is referred to Papadimitriou [1986] for a detailed treatment of alternative serializability models.

56.2.1.2 Transaction Schedules

Conflict serializability is based on the notion of a **schedule** of transaction operations. A schedule for a set of transaction executions is a partial ordering of the operations performed by those transactions, which shows how the operations are interleaved. The ordering defined by a schedule can be partial in the sense that it is only required to specify two types of dependencies:

- All operations of a given transaction for which an order is specified by that transaction must appear in that order in the schedule. For example, the definition of REPORTSUM above specifies that account A is read before account B.
- The ordering of all **conflicting operations** from different transactions must be specified. Two operations are said to conflict if they both operate on the same data item and at least one of them is a *write()*.

The concept of a schedule provides a mechanism to express and reason about the (possibly) concurrent execution of transactions. A *serial* schedule is one in which all the operations of each transaction appear consecutively. For example, the serial execution of TRANSFER followed by REPORTSUM is represented by the following schedule:

$$r_0[A] \rightarrow w_0[A] \rightarrow r_0[B] \rightarrow w_0[B] \rightarrow c_0 \rightarrow r_1[A] \rightarrow r_1[B] \rightarrow c_1 \quad (56.1)$$

In this notation, each operation is represented by its initial letter, the subscript of the operation indicates the *transaction number* of the transaction on whose behalf the operation was performed, and a capital letter in brackets indicates a specific data item from the database (for read and write operations). A transaction number (tn) is a unique identifier that is assigned by the DBMS to an execution of a transaction. In the example above, the execution of TRANSFER was assigned tn 0 and the execution of REPORTSUM was assigned tn 1. A right arrow (\rightarrow) between two operations indicates that the left-hand operation is ordered before the right-hand one. The ordering relationship is transitive; the orderings implied by transitivity are not explicitly drawn.

For example, the interleaved execution of TRANSFER and REPORTSUM shown in Figure 56.1 would produce the following schedule:

$$r_0[A] \rightarrow w_0[A] \rightarrow r_1[A] \rightarrow r_1[B] \rightarrow c_1 \rightarrow r_0[B] \rightarrow w_0[B] \rightarrow c_0 \quad (56.2)$$

The formal definition of serializability is based on the concept of equivalent schedules. Two schedules are said to be *equivalent* (\equiv) if:

- They contain the same transactions and operations, and
- They order all conflicting operations of nonaborting transactions in the same way.

Given this notion of equivalent schedules, *a schedule is said to be serializable if and only if it is equivalent to some serial schedule*. For example, the following concurrent schedule is serializable because it is equivalent to Schedule 56.1:

$$r_0[A] \rightarrow w_0[A] \rightarrow r_1[A] \rightarrow r_0[B] \rightarrow w_0[B] \rightarrow c_0 \rightarrow r_1[B] \rightarrow c_1 \quad (56.3)$$

In contrast, the interleaved execution of Schedule 56.2 is *not* serializable. To see why, notice that in any serial execution of TRANSFER and REPORTSUM either *both* writes of TRANSFER will precede *both* reads of REPORTSUM or vice versa. However, in schedule (56.2) $w_0[A] \rightarrow r_1[A]$ but $r_1[B] \rightarrow w_0[b]$. Schedule 56.2, therefore, is not equivalent to any possible serial schedule of the two transactions so it is not serializable. This result agrees with our intuitive notion of correctness, because recall that Schedule 56.2 resulted in the apparent loss of \$50.

56.2.1.3 Testing for Serializability

A schedule can easily be tested for serializability through the use of a *precedence graph*. A precedence graph is a directed graph that contains a vertex for each *committed* transaction execution in a schedule (noncommitted executions can be ignored). The graph contains an edge from transaction execution T_i to transaction execution T_j ($i \neq j$) if there is an operation in T_i that is constrained to precede an operation of T_j in the schedule. A schedule is serializable if and only if its precedence graph is *acyclic*. Figure 56.2(a) shows the precedence graph for Schedule 56.2. That graph has an edge $T_0 \rightarrow T_1$ because the schedule

FIGURE 56.2 Precedence graphs for (a) nonserializable and (b) serializable schedules.

contains $w_0[A] \rightarrow r_1[A]$ and an edge $T_1 \rightarrow T_0$ because the schedule contains $r_1[B] \rightarrow w_0[b]$. The cycle in the graph shows that the schedule is nonserializable. In contrast, Figure 56.2(b) shows the precedence graph for Schedule 56.1. In this case, all ordering constraints are from T_0 to T_1 , so the precedence graph is acyclic, indicating that the schedule is serializable.

There are a number of practical ways to implement conflict serializability. These and other implementation issues are addressed in Section 56.3. Before discussing implementation issues, however, we first survey the basic principles underlying database recovery.

56.2.2 Recovery

56.2.2.1 Coping with Failures

Recall that the responsibility for the atomicity and durability properties of ACID transactions lies in the recovery component of the DBMS. For recovery purposes it is necessary to distinguish between two types of storage: (1) **volatile storage**, such as main memory, whose state is lost in the event of a system crash or power outage, and (2) **nonvolatile storage**, such as magnetic disks or tapes, whose contents persist across such events. The recovery subsystem is relied upon to ensure correct operation in the presence of three different types of failures (listed in order of likelihood):

- *Transaction failure*: When a transaction that is in progress reaches a state from which it cannot successfully commit, all updates that it made must be removed from the database in order to preserve the atomicity property. This is known as *transaction rollback*.
- *System failure*: If the system fails in a way that causes the loss of volatile memory contents, recovery must ensure that: (1) the updates of all transactions that had committed prior to the crash are reflected in the database and (2) all updates of other transactions (aborted or in progress at the time of the crash) are removed from the database.
- *Media failure*: In the event that data are lost or corrupted on the nonvolatile storage (e.g., due to a disk-head crash), then the on-line version of the data is lost. In this case, the database must be restored from an archival version of the database and brought up to date using operation logs.

In this chapter we focus on the issues of rollback and crash recovery, the most frequent uses of the DBMS recovery subsystem. Recovery from media crashes requires substantial additional mechanisms and complexity beyond what is covered here. Media recovery is addressed in the recovery-related references listed at the end of this chapter.

56.2.2.2 Buffer Management Issues

The process of removing the effects of an incomplete or aborted transaction for preserving atomicity is known as *UNDO*. The process of reinstating the effects of a committed transaction for durability is known as *REDO*. The amount of work that a recovery subsystem must perform for either of these functions depends on how the DBMS buffer manager handles data that are updated by in-progress and/or committing transactions [Haerder and Reuter 1983, Bernstein et al. 1987]. Recall that the buffer manager is the DBMS component that is responsible for coordinating the transfer of data between main memory (i.e., volatile storage) and disk (i.e., nonvolatile storage). The unit of storage that can be written atomically to nonvolatile storage is called a *page*. Updates are made to copies of pages in the (volatile) buffer pool, and those copies are written out to nonvolatile storage at a later time. If the buffer manager allows an update made by an *uncommitted* transaction to overwrite the most recent committed value of a data item on nonvolatile storage, it is said to support a *STEAL* policy (the opposite is called *NO-STEAL*). If the buffer manager ensures that all updates made by a transaction are reflected on nonvolatile storage before the transaction is allowed to commit, then it is said to support a *FORCE* policy (the opposite is *NO-FORCE*).

Support for the *STEAL* policy implies that in the event that a transaction needs to be rolled back (due to transaction failure or system crash), *UNDO*ing the transaction will involve restoring the values of any nonvolatile copies of data that were overwritten by that transaction back to their previous committed state.

In contrast, a NO-STEAL policy guarantees that the data values on nonvolatile storage are valid, so they do not need to be restored. A NO-FORCE policy raises the possibility that some committed data values may be lost during a system crash because there is no guarantee that they have been placed on nonvolatile storage. This means that substantial REDO work may be required to preserve the durability of committed updates. In contrast, a FORCE policy ensures that the committed updates *are* placed on nonvolatile storage, so that in the event of a system crash, the updates will still be reflected in the copy of the database on nonvolatile storage.

From the above discussion, it should be apparent that a buffer manager that supports the combination of NO-STEAL and FORCE would place the fewest demands on UNDO and REDO recovery. However, these policies may negatively impact the performance of the DBMS during normal operation (i.e., when there are no crashes or rollbacks) because they restrict the flexibility of the buffer manager. NO-STEAL obligates the buffer manager to retain updated data in memory until a transaction commits or to write those data to a temporary location on nonvolatile storage (e.g., a swap area). The problem with a FORCE policy is that it can impose significant disk write overhead during the critical path of a committing transaction. For these reasons, many buffer managers support the STEAL and NO-FORCE (**STEAL/NO-FORCE**) policies.

56.2.2.3 Logging

In order to deal with the UNDO and REDO requirements imposed by the STEAL and NO-FORCE policies respectively, database systems typically rely on the use of a **log**. A log is a sequential file that stores information about transactions and the state of the system at certain instances. Each entry in the log is called a **log record**. One or more log records are written for each update performed by a transaction. When a log record is created, it is assigned a **log sequence number** (LSN) which serves to uniquely identify that record in the log. LSNs are typically assigned in a monotonically increasing fashion so that they provide an indication of relative position in the log. When an update is made to a data item in the buffer, a log record is created for that update. Many systems write the LSN of this new log record into the page containing the updated data item. Recording LSNs in this fashion allows the recovery system to relate the state of a data page to logged updates in order to tell if a given log record is reflected in a given state of a page.

Log records are also written for transaction management activities such as the commit or abort of a transaction. In addition, log records are sometimes written to describe the state of the system at certain periods of time. For example, such log records are written as part of the **checkpointing** process. Checkpoints are taken periodically during normal operation to help bound the amount of recovery work that would be required in the event of a crash. Part of the checkpointing process involves the writing of one or more *checkpoint records*. These records can include information about the contents of the buffer pool and the transactions that are currently active, etc. The particular contents of these records depend on the method of checkpointing that is used. Many different checkpointing methods have been developed, some of which involve quiescing the system to a consistent state, while others are less intrusive. A particularly nonintrusive type of checkpointing is used by the ARIES recovery method [Mohan et al. 1992] that is described in [Section 56.3](#).

For transaction update operations there are two basic types of logging: *physical* and *logical* [Gray and Reuter 1993]. Physical log records typically indicate the location (e.g., position on a particular page) of modified data in the database. If support for UNDO is provided (i.e., a STEAL policy is used), then the value of the item prior to the update is recorded in the log record. This is known as the *before image* of the item. Similarly the *after image* (i.e., the new value of the item after the update), is logged if REDO support is provided. Thus, physical log records in a DBMS with STEAL/NO-FORCE buffer management contain both the old and new data values of items. Recovery using physical log records has the property that recovery actions (i.e., UNDOs or REDOs) are *idempotent*, meaning that they have the same effect no matter how many times they are applied. This property is important if recovery is invoked multiple times, as will occur if a system fails repeatedly (e.g., due to a power problem or a faulty device).

Logical logging (sometimes referred to as *operational logging*) records only high-level information about operations that are performed, rather than recording the actual changes to items (or storage locations) in the database. For example, the insertion of a new tuple into a relation might require many physical changes to the database such as space allocation, index updates, and reorganization, etc. Physical logging would

require log records to be written for all of these changes. In contrast, logical logging would simply log the fact that the insertion had taken place, along with the value of the inserted tuple. The REDO process for a logical logging system must determine the set of actions that are required to fully reinstate the insert. Likewise, the UNDO logic must determine the set of actions that make up the inverse of the logged operation.

Logical logging has the advantage that it minimizes the amount of data that must be written to the log. Furthermore, it is inherently appealing because it allows many of the implementation details of complex operations to be hidden in the UNDO/REDO logic. In practice however, recovery based on logical logging is difficult to implement because the actions that make up the logged operation are not performed atomically. That is, when a system is restarted after a crash, the database may not be in an *action consistent* state with respect to a complex operation — it is possible that only a subset of the updates made by the action had been placed on nonvolatile storage prior to the crash. As a result, it is difficult for the recovery system to determine which portions of a logical update are reflected in the database state upon recovery from a system crash. In contrast, physical logging does not suffer from this problem, but it can require substantially higher logging activity.

In practice, systems often implement a compromise between physical and logical approaches that has been referred to as *physiological logging* [Gray and Reuter 1993]. In this approach log records are constrained to refer to a single page, but may reflect logical operations on that page. For example, a physiological log record for an insert on a page would specify the value of the new tuple that is added to the page, but would not specify any free-space manipulation or reorganization of data on the page resulting from the insertion; the REDO and UNDO logic for insertion would be required to infer the necessary operations. If a tuple insert required updates to multiple pages (e.g., data pages plus multiple index pages), then a separate physiological log record would be written for each page updated. Physiological logging avoids the action consistency problem of logical logging, while reducing, to some extent, the amount of logging that would be incurred by physical logging. The ARIES recovery method is one example of a recovery method that uses physiological logging.

56.2.2.4 Write-Ahead Logging (WAL)

A final recovery principle to be addressed in this section is the **write-ahead logging** (WAL) protocol. Recall that the contents of volatile storage are lost in the event of a system crash. As a result, any log records that are not reflected on nonvolatile storage will also be lost during a crash. WAL is a protocol that ensures that in the event of a system crash, the recovery log contains sufficient information to perform the necessary UNDO and REDO work when a STEAL/NO-FORCE buffer management policy is used. The WAL protocol ensures that:

1. All log records pertaining to an updated page are written to nonvolatile storage before the page itself is allowed to be overwritten in nonvolatile storage
2. A transaction is not considered to be committed until all of its log records (including its commit record) have been written to stable storage

The first point ensures that UNDO information required due to the STEAL policy will be present in the log in the event of a crash. Similarly, the second point ensures that any REDO information required due to the NO-FORCE policy will be present in the nonvolatile log. The WAL protocol is typically enforced with special support provided by the DBMS buffer manager.

56.3 Best Practices

56.3.1 Concurrency Control

56.3.1.1 Two-Phase Locking

The most prevalent implementation technique for concurrency control is locking. Typically, two types of locks are supported, *shared* (S) locks and *exclusive* (X) locks. The compatibility of these locks is defined by the *compatibility matrix* shown in [Table 56.1](#). The compatibility matrix shows that two different transactions

TABLE 56.1 Compatibility Matrix for S and X Locks

	S	X
S	y	n
X	n	n

are allowed to hold S locks simultaneously on the same data item, but that X locks cannot be held on an item simultaneously with any other locks (by other transactions) on that item. S locks are used for protecting *read* access to data (i.e., multiple concurrent readers are allowed), and X locks are used for protecting *write* access to data. As long as a transaction is holding a lock, no other transaction is allowed to obtain a conflicting lock. If a transaction requests a lock that cannot be granted (due to a lock conflict), that transaction is *blocked* (i.e., prohibited from proceeding) until all the conflicting locks held by other transactions are released.

S and X locks as defined in Table 56.1 directly model the semantics of conflicts used in the definition of conflict serializability. Therefore, locking can be used to enforce serializability. Rather than testing for serializability after a schedule has been produced (as was done in the previous section), the blocking of transactions due to lock conflicts can be used to prevent nonserializable schedules from *ever* being produced.

A transaction is said to be **well formed** with respect to *reads* if it always holds an S or an X lock on an item while reading it, and well formed with respect to *writes* if it always holds an X lock on an item while writing it. Unfortunately, restricting all transactions to be well formed is not sufficient to guarantee serializability. For example, a nonserializable execution such as that of Schedule 56.2 is still possible using well formed transactions. Serializability can be enforced, however, through the use of **two-phase locking (2PL)**. Two-phase locking requires that all transactions be well formed and that they respect the following rule: *Once a transaction has released a lock, it is not allowed to obtain any additional locks*. This rule results in transactions that have two phases:

1. A *growing phase* in which the transaction is acquiring locks
2. A *shrinking phase* in which locks are released

The two-phase rule dictates that the transaction shifts from the growing phase to the shrinking phase at the instant it first releases a lock.

To see how 2PL enforces serializability, consider again Schedule 56.2. Recall that the problem arises in this schedule because $w_0[A] \rightarrow r_1[A]$ but $r_1[B] \rightarrow w_0[B]$. This schedule could not be produced under 2PL, because transaction 1 (REPORTSUM) would be blocked when it attempted to read the value of A because transaction 0 would be holding an X lock on it. Transaction 0 would not be allowed to release this X lock before obtaining its X lock on B, and thus it would either abort or perform its update of B before transaction 1 is allowed to progress. In contrast, note that Schedule 56.1 (the serial schedule) would be allowed in 2PL. 2PL would also allow the following (serializable) interleaved schedule:

$$r_1[A] \rightarrow r_0[A] \rightarrow r_1[B] \rightarrow c_1 \rightarrow w_0[A] \rightarrow r_0[B] \rightarrow w_0[B] \rightarrow c_0 \quad (56.4)$$

It is important to note, however, that two-phase locking is sufficient but not necessary for implementing serializability. In other words, there are schedules that are serializable but would not be allowed by two-phase locking. Schedule 56.3 is an example of such a schedule.

In order to implement 2PL, the DBMS contains a component called a *lock manager*. The lock manager is responsible for granting or blocking lock requests, for managing queues of blocked transactions, and for unblocking transactions when locks are released. In addition, the lock manager is also responsible for dealing with **deadlock** situations. A deadlock arises when a set of transactions is blocked, each waiting for another member of the set to release a lock. In a deadlock situation, none of the transactions involved can

make progress. Database systems deal with deadlocks using one of two general techniques: avoidance or detection. Deadlock avoidance can be achieved by imposing an order in which locks can be obtained on data, by requiring transactions to predeclare their locking needs, or by aborting transactions rather than blocking them in certain situations.

Deadlock detection, on the other hand, can be implemented using *timeouts* or explicit checking. Timeouts are the simplest technique; if a transaction is blocked beyond a certain amount of time, it is assumed that a deadlock has occurred. The choice of a timeout interval can be problematic, however. If it is too short, then the system may infer the presence of a deadlock that does not truly exist. If it is too long, then deadlocks may go undetected for too long a time. Alternatively the system can explicitly check for deadlocks using a structure called a *waits-for graph*. A waits-for graph is a directed graph with a vertex for each active transaction. The lock manager constructs the graph by placing an edge from a transaction T_i to a transaction T_j ($i \neq j$) if T_i is blocked waiting for a lock held by T_j . If the waits-for graph contains a cycle, all of the transactions involved in the cycle are waiting for each other, and thus they are deadlocked. When a deadlock is detected, one or more of the transactions involved is rolled back. When a transaction is rolled back its locks are automatically released, so the deadlock will be broken.

56.3.1.2 Isolation Levels

As should be apparent from the previous discussion, transaction isolation comes at a cost in potential concurrency. Transaction blocking can add significantly to transaction response time.* As stated previously, serializability is typically implemented using two-phase locking, which requires locks to be held at least until all necessary locks have been obtained. Prolonging the holding time of locks increases the likelihood of blocking due to data contention.

In some applications, however, serializability is not strictly necessary. For example, a data analysis program that computes aggregates over large numbers of tuples may be able to tolerate some inconsistent access to the database in exchange for improved performance. The concept of *degrees of isolation* or *isolation levels* has been developed to allow transactions to trade concurrency for consistency in a controlled manner [Gray et al. 1975, Gray and Reuter 1993, Berenson et al. 1995]. In their 1975 paper, Gray et al. defined four degrees of consistency using characterizations based on locking, dependencies, and anomalies (i.e., results that could not arise in a serial schedule). The degrees were named degree 0–3, with degree 0 being the least consistent, and degree 3 intended to be equivalent to serializable execution.

The original presentation has served as the basis for understanding relaxed consistency in many current systems, but it has become apparent over time that the different characterizations in that paper were not specified to an equal degree of detail. As pointed out in a recent paper by Berenson et al. [1995], the SQL-92 standard suffers from a similar lack of specificity. Berenson et al. have attempted to clarify the issue, but it is too early to determine if they have been successful. In this section we focus on the locking-based definitions of the isolation levels, as they are generally acknowledged to have “stood the test of time” [Berenson et al. 1995]. However, the definition of the degrees of consistency requires an extension to the previous description of locking in order to address the *phantom problem*.

An example of the phantom problem is the following: assume a transaction T_i reads a set of tuples that satisfy a query predicate. A second transaction T_j inserts a new tuple that satisfies the predicate. If T_i then executes the query again, it will see the new item, so that its second answer differs from the first. This behavior could never occur in a serial schedule, as a “phantom” tuple appears in the midst of a transaction; thus, this execution is anomalous. The phantom problem is an artifact of the transaction model, consisting of reads and writes to *individual* data that we have used so far. In practice, transactions include *queries* that dynamically define sets based on predicates. When a query is executed, all of the tuples that satisfy the predicate at that time can be locked as they are accessed. Such individual locks, however, do not protect against the later addition of further tuples that satisfy the predicate.

*Note that other, non-blocking approaches discussed later in this section also suffer from similar problems.

One obvious solution to the phantom problem is to lock predicates instead of (or in addition to) individual items [Eswaran et al. 1976]. This solution is impractical to implement, however, due to the complexity of detecting the overlap of a set of arbitrary predicates. Predicate locking can be approximated using techniques based on locking clusters of data or ranges of index values. Such techniques, however, are beyond the scope of this chapter. In this discussion we will assume that predicates can be locked without specifying the technical details of how this can be accomplished (see Gray and Reuter [1993] and Mohan et al. [1992] for detailed treatments of this topic).

The locking-oriented definitions of the isolation levels are based on whether or not read and/or write operations are well formed (i.e., protected by the appropriate lock), and if so, whether those locks are *long duration* or *short duration*. Long-duration locks are held until the end of a transaction (EOT) (i.e., when it commits or aborts); short-duration locks can be released earlier. Long-duration write locks on data items have important benefits for recovery, namely, they allow recovery to be performed using *before images*. If long-duration write locks are not used, then the following scenario could arise:

$$w_0[A] \rightarrow w_1[A] \rightarrow a_0 \quad (56.5)$$

In this case restoring A with T_0 's before image of it will be incorrect because it would overwrite T_1 's update. Simply ignoring the abort of T_0 is also incorrect. In that case, if T_1 were to subsequently abort, installing its before image would reinstate the value written by T_0 . For this reason and for simplicity, locking systems typically hold long-duration locks on data items. This is sometimes referred to as *strict* locking [Bernstein et al. 1987].

Given these notions of locks, the degrees of isolation presented in the SQL-92 standard can be obtained using different lock protocols. In the following, all levels are assumed to be well formed with respect to writes and to hold long duration *write* (i.e., exclusive) locks on updated data items. Four levels are defined (from weakest to strongest):*

READ UNCOMMITTED: This level, which provides the weakest consistency guarantees, allows transactions to read data that have been written by other transactions that have not committed. In a locking implementation this level is achieved by being ill formed with respect to reads (i.e., not obtaining read locks). The risks of operating at this level include (in addition to the risks incurred at the more restrictive levels) the possibility of seeing updates that will eventually be rolled back and the possibility of seeing some of the updates made by another transaction but missing others made by that transaction.

READ COMMITTED: This level ensures that transactions only see updates that have been made by transactions that have committed. This level is achieved by being well formed with respect to reads on individual data items, but holding the read locks only as short-duration locks. Transactions operating at this level run the risk of seeing *nonrepeatable* reads (in addition to the risks of the more restrictive levels). That is, a transaction T_0 could read a data item twice and see two different values. This anomaly could occur if a second transaction were to update the item and commit in between the two reads by T_0 .

REPEATABLE READ: This level ensures that reads to individual data items are repeatable, but does not protect against the phantom problem described previously. This level is achieved by being well formed with respect to reads on individual data items, and holding those locks for long duration.

SERIALIZABLE: This level protects against all of the problems of the less restrictive levels, including the phantom problem. It is achieved by being well formed with respect to reads on *predicates* as well as on individual data items and holding all locks for long duration.

*It should be noted that two-phase locks can be substituted for the long-duration locks in these definitions without impacting the consistency provided. Long-duration locks are typically used, however, to avoid the recovery-related problems described previously.

A key aspect of this definition of degrees of isolation is that as long as all transactions execute at the READ UNCOMMITTED level or higher, they are able to obtain at least the degree of isolation they desire without interference from any transactions running at lower degrees. Thus, these degrees of isolation provide a powerful tool that allows application writers or users to trade off consistency for improved concurrency. As stated earlier, the definition of these isolation levels for concurrency-control methods that are not based on locking has been problematic. This issue is addressed in depth in Berenson et al. [1995].

It should be noted that the discussion of locking so far has ignored an important class of data that is typically present in databases, namely, *indexes*. Because indexes are auxiliary information, they can be accessed in a non-two-phase manner without sacrificing serializability. Furthermore, the hierarchical structure of many indexes (e.g., B-trees) makes them potential concurrency bottlenecks due to high contention at the upper levels of the structure. For this reason, significant effort has gone into developing methods for providing highly concurrent access to indexes. Pointers to some of this work can be found in the Further Information section at the end of this chapter.

56.3.1.3 Hierarchical Locking

The examples in the preceding discussions of concurrency control primarily dealt with operations on a single granularity of data items (e.g., tuples). In practice, however, the notions of conflicts and locks can be applied at many different granularities. For example, it is possible to perform locking at the granularity of a page, a relation, or even an entire database. In choosing the proper granularity at which to perform locking there is a fundamental tradeoff between potential concurrency and locking overhead. Locking at a fine granularity, such as an individual tuple, allows for maximum concurrency, as only transactions that are truly accessing the same tuple have the potential to conflict. The downside of such fine-grained locking, however, is that a transaction that accesses a large number of tuples will have to acquire a large number of locks. Each lock request requires a call to the lock manager. This overhead can be reduced by locking at a coarser granularity, but coarse granularity raises the potential for *false conflicts*. For example, two transactions that update different tuples residing on the same page would conflict under page-level locking but not under tuple-level locking.

The notion of hierarchical or multigranular locking was introduced to allow concurrent transactions to obtain locks at different granularities in order to optimize the above tradeoff [Gray et al. 1975]. In hierarchical locking, a lock on a granule at a particular level of the granularity hierarchy implicitly locks all items included in that granule. For example, an S-lock on a relation implicitly locks all pages and tuples in that relation. Thus, a transaction with such a lock can read any tuple in the relation without requesting additional locks. Hierarchical locking introduces additional lock modes beyond S and X. These additional modes allow transactions to declare their *intention* to perform an operation on objects at lower levels of the granularity hierarchy. The new modes are IS, IX, and SIX for *intention shared*, *intention exclusive*, and *shared with intention exclusive*. An IS (or IX) lock on a granule provides no privileges on that granule, but indicates that the holder intends to obtain S (or X) locks on one or more finer granules. An SIX lock combines an S lock on the entire granule with an IX lock. SIX locks support the common access pattern of scanning the items in a granule (e.g., tuples in a relation) and choosing to update a fraction of them based on their values.

Similarly to S and X locks, these lock modes can be described using a compatibility matrix. The compatibility matrix for these modes is shown in Table 56.2. In order for transactions locking at different granularities to coexist, all transactions must follow the same hierarchical locking protocol starting from the root of the granularity hierarchy. This protocol is shown in Table 56.3. For example, to read a single record, a transaction would obtain IS locks on the database, relation, and page, followed by an S lock on the specific tuple. If a transaction wanted to read all or most tuples on a page, then it could obtain IS locks on the database and relation, followed by an S lock on the entire page. By following this uniform protocol, potential conflicts between transactions that ultimately obtain S and/or X locks at different granularities can be detected.

A useful extension to hierarchical locking is known as *lock escalation*. Lock escalation allows the DBMS to automatically adjust the granularity at which transactions obtain locks, based on their behavior. If the

TABLE 56.2 Compatibility Matrix for Regular and Intention Locks

	IS	IX	S	SIX	X
IS	y	y	y	y	n
IX	y	y	n	n	n
S	y	n	y	n	n
SIX	y	n	n	n	n
X	n	n	n	n	n

TABLE 56.3 Hierarchical Locking Rules

To Get	Must Have on All Ancestors
IS or S	IS or IX
IX, SIX, or X	IX or SIX

system detects that a transaction is obtaining locks on a large percentage of the granules that make up a larger granule, it can attempt to grant the transaction a lock on the larger granule so that no additional locks will be required for subsequent accesses to other objects in that granule. Automatic escalation is useful because the access pattern that a transaction will produce is often not known until run time.

56.3.1.4 Other Concurrency Control Methods

As stated previously, two-phase locking is the most generally accepted technique for ensuring serializability. Locking is considered to be a *pessimistic* technique because it is based on the assumption that transactions are likely to interfere with each other and takes measures (e.g., blocking) to ensure that such interference does not occur. An important alternative to locking is **optimistic concurrency control**. Optimistic methods [e.g., Kung and Robinson 1981] allow transactions to perform their operations without obtaining any locks. To ensure that concurrent executions do not violate serializability, transactions must perform a *validation phase* before they are allowed to commit. Many optimistic protocols have been proposed. In the algorithm of Kung and Robinson [1981], the validation process ensures that the reads and writes performed by a validating transaction did not conflict with any other transactions with which it ran concurrently. If during validation it is determined a conflict had occurred, the validating transaction is aborted and restarted.

Unlike locking, which depends on *blocking* transactions to ensure isolation, optimistic policies depend on transaction *restart*. As a result, although they don't perform any blocking, the performance of optimistic policies can be hurt by data contention (as are pessimistic schemes) — a high degree of data contention will result in a large number of unsuccessful transaction executions. The performance tradeoffs between optimistic and pessimistic have been addressed in numerous studies [see Agrawal et al. 1987]. In general, locking is likely to be superior in resource-limited environments because blocking does not consume cpu or disk resources. In contrast, optimistic techniques may have performance advantages in situations where resources are abundant, because they allow more executions to proceed concurrently. If resources are abundant, then the resource consumption of restarted transactions will not significantly hurt performance. In practice, however resources are typically limited, and thus concurrency control in most commercial database systems is based on locking.

Another class of concurrency control techniques is known as **multiversion concurrency control** [e.g., Reed 1983]. As updating transactions modify data items, these techniques retain the previous versions of the items on line. Read-only transactions (i.e., transactions that perform no updates) can then be provided with access to these older versions, allowing them to see a consistent (although possibly somewhat out-of-date) snapshot of the database. Optimistic, multiversion, and other concurrency control techniques (e.g., timestamping) are addressed in further detail in Bernstein et al. [1987].

56.3.2 Recovery

The recovery subsystem is generally considered to be one of the more difficult parts of a DBMS to design for two reasons: First, recovery is required to function in failure situations and must correctly cope with a huge number of possible system and database states. Second, the recovery system depends on the behavior of many other components of the DBMS, such as concurrency control, buffer management, disk management, and query processing. As a result, few recovery methods have been described in the literature in detail. One exception is the ARIES recovery system developed at IBM [Mohan et al. 1992]. Many details about the ARIES method have been published, and the method has been included in a number of DBMSs. Furthermore, the ARIES method involves only a small number of basic concepts. For these reasons, we focus on the ARIES method in the remainder of this section. The ARIES method is related to many other recovery methods such as those described in Bernstein et al. [1987] and Gray and Reuter [1993]. A comparison with other techniques appears in Mohan et al. [1992].

56.3.2.1 Overview of ARIES

ARIES is a fairly recent refinement of the write-ahead-logging (WAL) protocol. Recall that the WAL protocol enables the use of a STEAL/NO FORCE buffer management policy, which means that pages on stable storage can be overwritten at any time and that data pages do not need to be forced to disk in order to commit a transaction. As with other WAL implementations, each page in the database contains a log sequence number (LSN) which uniquely identifies the log record for the latest update that was applied to the page. This LSN (referred to as the *pageLSN*) is used during recovery to determine whether or not an update for a page must be redone. LSN information is also used to determine the point in the log from which the REDO pass must commence during restart from a system crash. LSNs are often implemented using the physical address of the log record in the log to enable the efficient location of a log record given its LSN.

Much of the power and relative simplicity of the ARIES algorithm is due to its REDO paradigm of *repeating history*, in which it redoes updates for *all* transactions — including those that will eventually be undone. Repeating history enables ARIES to employ a variant of the *physiological logging* technique described earlier: it uses *page-oriented REDO* and a form of *logical UNDO*. Page-oriented REDO means that REDO operations involve only a single page and that the affected page is specified in the log record. This is part of physiological logging. In the context of ARIES, logical UNDO means that the operations performed to undo an update do not need to be the exact inverses of the operations of the original update.

In ARIES, logical UNDO is used to support fine-grained (i.e., tuple-level) locking and high-concurrency index management. For an example of the latter issue, consider a case in which a transaction T1 updates an index entry on a given page P1. Before T1 completes, a second transaction T2 could split P1, causing the index entry to be moved to a new page (P2). If T1 must be undone, a physical, page-oriented approach would fail because it would erroneously attempt to perform the UNDO operation on P1. Logical UNDO solves this problem by using the index structure to find the index entry, and then applying the UNDO operation to it in its new location. In contrast to UNDO, page-oriented REDO can be used because the repeating history paradigm ensures that REDO operations will always find the index entry on the page referenced in the log record — any operations that had affected the location of the index operation at the time the log record was created will be replayed before that log record is redone.

ARIES uses a three-pass algorithm for restart recovery. The first pass is the *analysis* pass, which processes the log forward from the most recent checkpoint. This pass determines information about dirty pages and active transactions that is used in the subsequent passes. The second pass is the *REDO* pass, in which history is repeated by processing the log forward from the earliest log record that could require REDO, thus ensuring that all logged operations have been applied. The third pass is the *UNDO* pass. This pass proceeds backwards from the end of the log, removing from the database the effects of all transactions that had not committed at the time of the crash. These passes are shown in [Figure 56.3](#). (Note that the relative ordering of the starting point for the REDO pass, the endpoint for the UNDO pass, and the checkpoint can be different than that shown in the figure.) The three passes are described in more detail below.

ARIES maintains two important data structures during normal operation. The first is the *transaction table*, which contains status information for each transaction that is currently running. This information

FIGURE 56.3 The three passes of ARIES restart.

includes a field called the *lastLSN*, which is the LSN of the most recent log record written by the transaction. The second data structure, called the *dirty-page table*, contains an entry for each “dirty” page. A page is considered to be dirty if it contains updates that are not reflected on stable storage. Each entry in the dirty-page table includes a field called the *recoveryLSN*, which is the LSN of the log record that caused the associated page to become dirty. Therefore, the *recoveryLSN* is the LSN of the earliest log record that might need to be redone for the page during restart. Log records belonging to the same transaction are linked backwards in time using a field in each log record called the *prevLSN* field. When a new log record is written for a transaction, the value of the *lastLSN* field in the transaction-table entry is placed in the *prevLSN* field of the new record and the new record’s LSN is entered as the *lastLSN* in the transaction-table entry.

During normal operation, checkpoints are taken periodically. ARIES uses a form of fuzzy checkpoints which are extremely inexpensive. When a checkpoint is taken, a checkpoint record is constructed which includes the contents of the transaction table and the dirty-page table. Checkpoints are efficient, since no operations need be quiesced and no database pages are flushed to perform a checkpoint. However, the effectiveness of checkpoints in reducing the amount of the log that must be maintained is limited in part by the earliest *recoveryLSN* of the dirty pages at checkpoint time. Therefore, it is helpful to have a background process that periodically writes dirty pages to non-volatile storage.

56.3.2.2 Analysis

The job of the analysis pass of restart recovery is threefold: (1) it determines the point in the log at which to start the REDO pass, (2) it determines which pages could have been dirty at the time of the crash in order to avoid unnecessary I/O during the REDO pass, and (3) it determines which transactions had not committed at the time of the crash and will therefore need to be undone.

The analysis pass begins at the most recent checkpoint and scans forward to the end of the log. It reconstructs the transaction table and dirty-page table to determine the state of the system as of the time of the crash. It begins with the copies of those structures that were logged in the checkpoint record. Then, the contents of the tables are modified according to the log records that are encountered during the forward scan. When a log record for a transaction that does not appear in the transaction table is encountered, that transaction is added to the table. When a log record for the commit or the abort of a transaction is encountered, the corresponding transaction is removed from the transaction table. When a log record for an update to a page that is not in the dirty-page table is encountered, that page is added to the dirty-page table, and the LSN of the record which caused the page to be entered into the table is recorded as the *recoveryLSN* for that page. At the end of the analysis pass, the dirty-page table is a conservative (since some pages may have been flushed to nonvolatile storage) list of all database pages that could have been dirty at the time of the crash, and the transaction table contains entries for those transactions that will actually require undo processing during the UNDO phase. The earliest *recoveryLSN* of all the entries in the dirty-page table, called the *firstLSN*, is used as the spot in the log from which to begin the REDO phase.

56.3.2.2.1 REDO

As stated earlier, ARIES employs a redo paradigm called *repeating history*. That is, it redoes updates for *all* transactions, committed or otherwise. The effect of repeating history is that at the end of the REDO pass, the database is in the same state with respect to the logged updates that it was in at the time that

the crash occurred. The REDO pass begins at the log record whose LSN is the *firstLSN* determined by analysis and scans forward from there. To redo an update, the logged action is reapplied and the *pageLSN* on the page is set to the LSN of the redone log record. No logging is performed as the result of a redo. For each log record the following algorithm is used to determine if the logged update must be redone:

- If the affected page is not in the dirty-page table, then the update does *not* require redo.
- If the affected page is in the dirty-page table, but the *recoveryLSN* in the page's table entry is *greater than* the LSN of the record being checked, then the update does *not* require redo.
- Otherwise, the LSN stored on the page (the *pageLSN*) must be checked. This may require that the page be read in from disk. If the *pageLSN* is *greater than or equal to* the LSN of the record being checked, then the update does *not* require redo. Otherwise, the update *must* be redone.

56.3.2.2.2 UNDO

The UNDO pass scans backwards from the end of the log. During the UNDO pass, all transactions that had not committed by the time of the crash must be undone. In ARIES, undo is an *unconditional* operation. That is, the *pageLSN* of an affected page is not checked, because it is always the case that the undo must be performed. This is due to the fact that the *repeating of history* in the REDO pass ensures that all logged updates have been applied to the page.

When an update is undone, the undo operation is applied to the page and is logged using a special type of log record called a *compensation log record* (CLR). In addition to the undo information, a CLR contains a field called the *UndoNextLSN*. The *UndoNextLSN* is the LSN of the next log record that must be undone for the transaction. It is set to the value of the *prevLSN* field of the log record being undone. The logging of CLR's in this fashion enables ARIES to avoid ever having to undo the effects of an undo (e.g., as the result of a system crash during an abort), thereby limiting the amount of work that must be undone and bounding the amount of logging done in the event of multiple crashes. When a CLR is encountered during the backward scan, no operation is performed on the page, and the backward scan continues at the log record referenced by the *UndoNextLSN* field of the CLR, thereby jumping over the undone update and all other updates for the transaction that have already been undone (the case of multiple transactions will be discussed shortly). An example execution is shown in Figure 56.4.

In Figure 56.4, a transaction logged three updates (LSNs 10, 20, and 30) before the system crashed for the first time. During REDO, the database was brought up to date with respect to the log (i.e., 10, 20, and/or 30 were redone if they weren't on nonvolatile storage), but since the transaction was in progress at the time of the crash, they must be undone. During the UNDO pass, update 30 was undone, resulting in the writing of a CLR with LSN 40, which contains an *UndoNextLSN* value that points to 20. Then, 20 was undone, resulting in the writing of a CLR (LSN 50) with an *UndoNextLSN* value that points to 10. However, the system then crashed for a second time before 10 was undone. Once again, history is repeated during REDO, which brings the database back to the state it was in after the application of LSN 50 (the CLR for 20). When UNDO begins during this second restart, it will first examine the log record 50. Since the record is a CLR, no modification will be performed on the page, and UNDO will skip to the record whose LSN is stored in the *UndoNextLSN* field of the CLR (i.e., LSN 10). Therefore, it will continue by undoing the

FIGURE 56.4 The use of CLR's for UNDO.

update whose log record has LSN 10. This is where the UNDO pass was interrupted at the time of the second crash. Note that no extra logging was performed as a result of the second crash.

In order to undo multiple transactions, restart UNDO keeps a list containing the next LSN to be undone for each transaction being undone. When a log record is processed during UNDO, the *prevLSN* (or *UndoNxtLSN*, in the case of a CLR) is entered as the next LSN to be undone for that transaction. Then the UNDO pass moves on to the log record whose LSN is the most recent of the next LSNs to be redone. UNDO continues backward in the log until all of the transactions in the list have been undone up to and including their first log record. UNDO for *transaction rollback* works similarly to the UNDO pass of the restart algorithm as described above. The only difference is that during transaction rollback, only a single transaction (or part of a transaction) must be undone. Therefore, rather than keeping a list of LSNs to be undone for multiple transactions, rollback can simply follow the backward chain of log records for the transaction to be rolled back.

56.4 Research Issues and Summary

The model of ACID transactions that has been described in this chapter has proven to be quite durable in its own right, and serves as the underpinning for the current generation of database and transaction processing systems. This chapter has focused on the issues of concurrency control and recovery in a centralized environment. It is important to note, however, that the basic model is used in many types of distributed and parallel DBMS environments and the mechanisms described here have been successfully adapted for use in these more complex systems. Additional techniques, however, are needed in such environments. One important technique is *two-phase commit*, which is a protocol for ensuring that all participants in a distributed transaction agree on the decision to commit or abort that transaction.

While the basic transaction model has been a clear success, its limitations have also been apparent for quite some time [e.g., Gray 1981]. Much of the ongoing research related to concurrency control and recovery is aimed at addressing some of these limitations. This research includes the development of new implementation techniques, as well as the investigation of new and extended transaction models.

The ACID transaction model suffers from a lack of flexibility and the inability to model many types of interactions that arise in complex systems and organizations. For example, in collaborative work environments, strict isolation is not possible or even desirable [Korth 1995]. Workflow management systems are another example where the ACID model, which works best for relatively simple and short transactions, is not directly appropriate. For these types of applications, a richer, multilevel notion of transactions is required.

In addition to the problems raised by complex application environments, there are also many computing environments for which the ACID model is not fully appropriate. These include environments such as mobile wireless networks, where large periods of disconnection are expected, and loosely coupled wide-area networks (the Net is an extreme example) in which the availability of systems is relatively low. The techniques that have been developed for supporting ACID transactions must be adjusted to cope with such highly variable situations. New techniques must also be developed to provide concurrency control and recovery in nontraditional environments such as heterogeneous systems, dissemination-oriented environments, and others.

A final limitation of ACID transactions in their simplest form is that they are a general mechanism, and hence, do not exploit the semantics of data and/or applications. Such knowledge could be used to significantly improve system performance. Therefore, the development of concurrency control and recovery techniques that can exploit application-specific properties is another area of active research.

As should be obvious from the preceding discussion, there is still a significant amount of work that remains to be done in the areas of concurrency control and recovery for database systems. The basic concepts, however, such as serializability theory, two-phase locking, write-ahead logging, etc., will continue to be a fundamental technology, both in their own right and as building blocks for the development of more sophisticated and flexible information systems.

Acknowledgment

Conf. on Management of Data (SIGMOD'92)*, San Diego, June 1992. © 1992 by the Association for Computing Machinery, Inc. (ACM).

Defining Terms

Abort: The process of rolling back an uncommitted transaction. All changes to the database state made by that transaction are removed.

ACID properties: The transaction properties of atomicity, consistency, isolation, and durability that are upheld by the DBMS.

Checkpointing: An action taken during normal system operation that can help limit the amount of recovery work required in the event of a system crash.

Commit: The process of successfully completing a transaction. Upon commit, all changes to the database state made by a transaction are made permanent and visible to other transactions.

Concurrency control: The mechanism that ensures that individual users see consistent states of the database even though operations on behalf of many users may be interleaved by the database system.

Concurrent execution: The (possibly) interleaved execution of multiple transactions simultaneously.

Conflicting operations: Two operations are said to conflict if they both operate on the same data item and at least one of them is a *write()*.

Deadlock: A situation in which a set of transactions is blocked, each waiting for another member of the set to release a lock. In such a case none of the transactions involved can make progress.

Log: A sequential file that stores information about transactions and the state of the system at certain instances.

Log record: An entry in the log. One or more log records are written for each update performed by a transaction.

Log sequence number (LSN): A number assigned to a log record, which serves to uniquely identify that record in the log. LSNs are typically assigned in a monotonically increasing fashion so that they provide an indication of relative position.

Multiversion concurrency control: A concurrency control technique that provides read-only transactions with conflict-free access to previous versions of data items.

Nonvolatile storage: Storage, such as magnetic disks or tapes, whose contents persist across power failures and system crashes.

Optimistic concurrency control: A concurrency control technique that allows transactions to proceed without obtaining locks and ensures correctness by validating transactions upon their completion.

Recovery: The mechanism that ensures that the database is fault-tolerant; that is, that the database state is not corrupted as the result of a software, system, or media failure.

Schedule: A schedule for a set of transaction executions is a partial ordering of the operations performed by those transactions, which shows how the operations are interleaved.

Serial execution: The execution of a single transaction at a time.

Serializability: The property that a (possibly interleaved) execution of a group transactions has the same effect on the database, and produces the same output, as some serial (i.e., non-interleaved) execution of those transactions.

STEAL/NO-FORCE: A buffer management policy that allows committed data values to be overwritten on nonvolatile storage and does not require committed values to be written to nonvolatile storage. This policy provides flexibility for the buffer manager at the cost of increased demands on the recovery subsystem.

Transaction: A unit of work, possibly consisting of multiple data accesses and updates, that must commit or abort as a single atomic unit. Transactions have the ACID properties of *atomicity*, *consistency*, *isolation*, and *durability*.

Two-phase locking (2PL): A locking protocol that is a sufficient but not a necessary condition for serializability. Two-phase locking requires that all transactions be well formed and that once a transaction has released a lock, it is not allowed to obtain any additional locks.

Volatile storage: Storage, such as main memory, whose state is lost in the event of a system crash or power outage.

Well formed: A transaction is said to be well formed with respect to reads if it always holds a shared or an exclusive lock on an item while reading it, and well formed with respect to writes if it always holds an exclusive lock on an item while writing it.

Write-ahead logging: A protocol that ensures all log records required to correctly perform recovery in the event of a crash are placed on nonvolatile storage.

Further Information

For many years, what knowledge that existed in the public domain about concurrency control and recovery was passed on primarily through the use of multiple-generation copies of a set of lecture notes written by Jim Gray in the late seventies (“Notes on Database Operating Systems” in *Operating Systems: An Advanced Course* published by Springer-Verlag, Berlin, 1978). Fortunately, this state of affairs has been supplanted by the publication of *Transaction Processing: Concepts and Techniques* by Jim Gray and Andreas Reuter (Morgan Kaufmann, San Mateo, CA, 1993). This latter book contains a detailed treatment of all of the topics covered in this chapter, plus many others that are crucial for implementing transaction processing systems.

An excellent treatment of concurrency control and recovery theory and algorithms can be found in *Concurrency Control and Recovery in Database Systems* by Phil Bernstein, Vassos Hadzilacos, and Nathan Goodman (Addison-Wesley, Reading, MA, 1987). Another source of valuable information on concurrency control and recovery implementation is the series of papers on the ARIES method by C. Mohan and others at IBM, some of which are referenced in this chapter. The book *The Theory of Database Concurrency Control* by Christos Papadimitriou (Computer Science Press, Rockville, MD, 1986) covers a number of serializability models.

The performance aspects of concurrency control and recovery techniques have been only briefly addressed in this chapter. More information can be found in the recent books *Performance of Concurrency Control Mechanisms in Centralized Database Systems* edited by Vijay Kumar (Prentice-Hall, Englewood Cliffs, NJ, 1996) and *Recovery in Database Management Systems*, edited by Vijay Kumar and Meichun Hsu (Prentice-Hall, Englewood Cliffs, NJ, in press). Also, the performance aspects of transactions are addressed in *The Benchmark Handbook: For Database and Transaction Processing Systems* (2nd ed.), edited by Jim Gray (Morgan Kaufmann, San Mateo, CA, 1993).

Finally, extensions to the ACID transaction model are discussed in *Database Transaction Models*, edited by Ahmed Elmagarmid (Morgan Kaufmann, San Mateo, CA, 1993). Papers containing the most recent work on related topics appear regularly in the ACM SIGMOD Conference and the International Conference on Very Large Databases (VLDB), among others.

57.1 Introduction

“Six thousand years ago the Sumerians invented writing for transaction processing” [Gray and Reuter 1993], but the same goal can be accomplished today with a few clicks of the mouse.

The discussion of transaction processing concepts in this chapter is somewhat abbreviated, because aspects of transaction processing are covered in chapters on *Concurrency Control and Recovery* (Chapter 56) and *Distributed and Parallel Database Systems* (Chapter 58). Enough material is included here to make this chapter self-complete. In this section we review the fundamentals of transaction processing, its infrastructure, and distributed transaction processing.

Section 57.2 is an introduction to the cryptography required for e-commerce. The emphasis is on the protocols rather than the mathematical aspects of *cryptography*, which is the title of Chapter 9. This is followed by transaction processing on the Web, better known as Web Services, in Section 57.3.

Section 57.4 is a review of concurrency control methods to reduce the level of data contention in high-contention environments. This discussion is motivated by the increase in the volume of transactions made possible by electronic shopping. With the rapid increase in computing power, it is data rather than hardware resource contention that may become the bottleneck, unless the software is carefully designed not to thrash under high levels of lock contention. Such behavior was observed as part of a benchmarking study of an

e-commerce application with a mySQL DBMS (DBMS = database management system) [Elnikety et al. 2003].

Section 57.5 discusses performance analysis for transaction processing, taking both hardware resource contention and data contention into account. Transactions tend to have stringent response time requirements, so it is important to understand the factors affecting transaction performance. We are not concerned here with software performance engineering, whose role is to predict performance as the software is being developed. Conclusions are given in Section 57.6.

57.1.1 Transaction Processing Preliminaries

Transactions can be described by four **ACID properties** as follows:

1. **Atomicity:** all or nothing property.
2. **Consistency:** a transaction's modification of a consistent database will lead to another consistent database state. Consistency can be enforced by **integrity constraints**, which provide a notification when a constraint is violated; for example, the salary of an employee, after a raise, exceeds his manager's salary (a company policy) [Ramakrishnan and Gehrke 2003].
3. **Isolation:** it is as if a transaction is executing by itself, although there are other transactions being processed concurrently.
4. **Durability:** the updates made by a **committed** transaction will endure system failures.

Transaction commit is the declaration that a transaction has completed successfully, so that it cannot be rolled back and that its updates have been made durable. It is reassuring to know this when making a bank deposit. Transaction **abort** can be self-induced due to an internal error condition, or the user who initiated a transaction can abort it in the middle, or the system can initiate the abort to resolve a deadlock (such transactions are automatically restarted by the system).

The ACID properties are required for pragmatic reasons. Transaction updates are first applied to database pages residing in the **database buffer** in volatile main memory, whose content may be lost due to power outages, but also system crashes, software failures, and operator errors. Most DBMSs use the **NO-FORCE** policy, so that the pages modified by a transaction do not have to be propagated to disk as part of transaction commit. This policy is a necessity in high-performance transaction processing systems, because writing to disk of certain frequently updated database pages would result in unnecessary disk traffic.

The **STEAL** policy allows dirty pages of *uncommitted* transactions to be written to disk. Atomicity and durability in a centralized database are implemented by the **recovery** component of the DBMS, which ensures both by **logging** appropriate information onto **non-volatile storage (NVS)**. As far as the NO-FORCE policy is concerned, logging writes the **after-images** or modifications made by the transaction. As far as the STEAL policy is concerned, the logging process writes the **before-image** of modified data to disk. This allows the database to be returned to its original state in case the transaction which made the change is aborted.

Checkpointing, which is invoked periodically, writes (committed) dirty pages to disk with the intent of reducing **recovery time** when the system is restarted after a failure occurs. This is because database pages on disk may not be up-to-date because of the NO-FORCE policy. A recovery method, such as ARIES, uses the log to bring disk pages to a consistent state, so that they reflect updates by committed transactions and no modifications made by aborted transactions. This ensures transaction atomicity.

Concurrent execution of transactions or **multiprogramming** is a system requirement for transaction processing systems (see Section 57.5 for more details). **Concurrency control** methods are required to ensure that transaction updates do not result in an incorrect execution; for example, the updates of one transaction overwrite another's update. In fact, concurrency control methods ensure both consistency *and* isolation.

Strict two-phase locking (2PL) is the dominant concurrency control method in commercial DBMSs. Strict 2PL ensures **serializability**, that is, *the concurrent execution of a set of transactions is considered correct as long as it corresponds to a serial execution schedule*. While this definition is the *de facto* standard, certain specialized applications, such as stock trading, may have more stringent requirements.

Commercial DBMSs do not strictly adhere to strict 2PL, but rather provide options to suit application requirements. Transactions may specify variations in the **isolation level** required for their execution. A strict 2PL paradigm is unacceptable in some cases for pragmatic reasons. An example is the running of a read-only query to determine the total amount held in the checking accounts of a bank, when the records are stored in a relational table. Holding a shared lock on the table is unacceptable for the duration of the transaction, since it will block access to short online transactions, e.g., those generated by ATM (automatic teller machine) access. One solution is for the read-only transaction to lock one page at a time and release the lock immediately after it is done with the page, which is referred to as the **cursor-stability** isolation level. The shortcoming is that the query will only provide an approximation to the total amount.

The **timestamp-ordering** concurrency control method was proposed to deal with data conflicts in distributed databases using a local algorithm, so as to minimize the overhead associated with concurrency control. There are many variations of this method, but it is generally known to provide poor performance.

The **optimistic concurrency control (OCC)** method was originally proposed to deal with locking overhead in low data contention environments. We will discuss optimistic concurrency control methods in some detail in [Section 57.4](#).

Two phase locking stipulates that transactions acquire **shared locks** on objects they read and **exclusive locks** on objects to be modified and that *no lock is released until all locks are acquired*. Transaction T_2 can access an object modified by T_1 , as soon as T_1 releases its lock, but T_2 cannot commit until T_1 commits. If T_1 aborts we might have **cascading aborts**. **Strict 2PL** eliminates cascading aborts, at the cost of a reduced concurrency level in processing transactions, by requiring locks to be held until transaction commit time. For example, T_2 cannot access an object modified by T_1 , until T_1 commits or aborts.

Most lock requests are successful, because most database objects are not locked most of the time. Otherwise, only shared locks are compatible with each other. A transaction encountering a lock conflict is blocked awaiting the release of the lock, until the transaction holding an exclusive lock or all transactions holding a shared lock commit or abort.

A **deadlock** occurs when an active transaction T_1 requests a lock held by a blocked transaction T_2 , which is in turn waiting for T_1 's completion (or abort). A deadlock may involve only one object, which occurs when two transactions holding a shared lock on an object need to upgrade their lock to exclusive mode. **Update locks**, which are not compatible with each other but are compatible with shared locks, were introduced to prevent the occurrence of such deadlocks.

So far, we have discussed **flat transactions**. The **nested transaction** paradigm offers “more decomposable execution units and finer grained control over concurrency and recovery than flat transactions” [Moss 1985]. This paradigm also supports the decomposition of a “unit of work” into subtasks and their appropriate distribution in a computer system.

Multilevel transactions are related to nested transactions, but are more specialized. Transactions hold two types of locks: (1) long-term object locks (e.g., locks on records) and (2) short-term locks are held by the subtransactions on database pages for the duration of operations on records, e.g., to increase record size by adding another field [Weikum and Vossen 2002]. Compensating operations for subtransactions are provided for rollback.

57.1.1.1 Further Reading

The reader is referred to [Chapter 56](#) in this *Handbook* on “Concurrency Control and Recovery” especially [Section 56.4.7](#) on nested transactions and [Section 56.49](#) on multilevel transactions, as well as Ramakrishnan and Gehrke [2003], Lewis et al. [2002], and Gray and Reuter [1993].

57.1.2 Transaction Processing Infrastructure

Online transaction processing (OLTP) replaced **batch processing** to handle situations where delayed updates are unacceptable (e.g., tracking cash withdrawals from ATMs). Some nonrelational DBMSs, which were mainly used for batch processing, were extended with OLTP capabilities in the 1970s. The transition to

OLTP became possible with the advent of direct access storage devices (DASD), since it became possible to access the required data records in a few milliseconds (see Chapter 86 on “Secondary Storage Filesystems”).

Transaction processing monitors (or **TP monitors**) can be considered specialized operating systems that can execute transactions concurrently using threads, although the operating systems can accomplish the same goal via multiprogramming. The advantages and disadvantages of the two approaches are beyond the scope of this discussion (see Gray and Reuter [1993]). IMS has two components — IMS/DB and IMS/DC (data communications) — where the latter is a TP monitor providing **message processing regions (MPRs)**. Transactions are classified into classes that are assigned to different MPRs to run. Smaller degrees of concurrency are required to maintain a lower level of lock contention, as discussed below.

Batch processing requires a very simple form of concurrency control, that is, the locking of complete files, allowing two applications accessing the same file need to be run serially. Concurrent execution of the two programs is possible by partitioning the files into subfiles, such that with perfect synchronization (possible in a perfect world), program one can update partition $i + 1$ while program two can read partition i . At best, the two programs can be merged to attain pipelining at the record level. This can be accomplished by global query optimization (see Chapter 55 on “Query Optimization”).

OLTP led to a flurry of research and development activities in the area of concurrency control and recovery in the late 1970s, but many refinements followed later [Gray and Reuter 1993]. This heightened activity level coincided with the advent of **relational databases** and the introduction of sophisticated locking methods, such as **intent locks** to facilitate **hierarchical locking**; for example, to detect a conflict between a shared lock on a relational table and exclusive locks on records in that table.

Application programs communicate with the TP monitors via a library of functions or a language such as the **Structured Transaction Definition Language (STDL)** [STDL 1996]. There is a STDL compiler that translates STDL statements to API (application programming interface) calls to supported TP monitors. STDL supports transaction demarcation, exception handling, interfaces to resource managers, transaction workspaces, transactional presentation messaging, calls for high-level language programs, spawning independent transactions, concurrent execution of procedures within a transaction, enqueueing and dequeueing data, data typing, and multilingual messages [STDL 1996].

Up to some point, transaction processing involved “dumb terminals” and mainframes or servers, which ran all the software required to get the job done. Things became slightly more complicated with the advent of **client/server computing** [Orfali et al. 1996]. A **three-tiered architecture** has the **clients** or users with a **graphical user interface (GUI)** on their PCs at the lowest level. The next level is an **application server** with (application) programs that are invoked by a user. The application server uses **object request brokers (ORBs)**, such as **CORBA (common ORB architecture)** or the *de facto* standard **DCOM (distributed component object model)**. Web or Internet servers are yet another category that use HTTP and XML. Finally, there is a **data server**, or simply a server.

A **two-tiered architecture** is the result of combining the client and application tiers, leading to a client/server system with **fat clients**. Clients can then communicate directly with the data server via the **SQL Structured Query Language** embedded in a client/server communication protocol such as **ODBC (Open Database Connectivity)** or **JDBC**. ODBC and JDBC use indirection to achieve SQL code portability across various levels. A two-tiered architecture may consist of a **thin client**, with the application and data-server layers at the server.

57.1.3 Distributed Transaction Processing

Centralized (with independent software components) and distributed transaction processing both require a **two-phase commit (2PC)** protocol, which is discussed in Section 57.3.

The strict 2PL protocol is also utilized in distributed transaction processing. An SQL query is subdivided into subqueries, based on the location of the relational tables being accessed. The subqueries are processed in a distributed manner at the nodes where the data resides, acquiring appropriate locks locally.

We use **waits-for-graphs (WFGs)** to represent transaction blocking, such that the nodes of the graph represent transactions and directed edges represent the waits-for relationship. **Local deadlocks** are detected by checking for cycles in local WFGs, while **distributed deadlocks** can be detected by transmitting the WFGs at various nodes to a designated node, which builds the global WFG for deadlock detection. This can be costly in the number of messages involved, and phantom deadlocks (due to out-of-date WFGs) can result in unnecessary aborts.

The **wound-wait** and **wait-die** methods proposed for distributed transaction processing are deadlock-free [Bernstein et al. 1987]. Both methods associate a **timestamp** with each transaction based on its initiation time. The timestamp is attached to lock requests and used in lock conflict resolution, as follows. The wound-wait method blocks a transaction T_A requesting a lock held by T_B , if T_A is not older than T_B ; otherwise, T_B is aborted. The wait-die method allows a younger transaction blocked by an older transaction to wait; otherwise, the transaction encountering the lock conflict is aborted.

Data access in distributed transaction processing can be accomplished according to one of the following methods [Thomasian 1996a]:

- **I/O request shipping.** An I/O request is sent to the node that holds the data on its disk or in its database buffer.
- **Data request (or call) shipping.** The query optimizer determines the location of the data by consulting the **distributed data directory** and then initiates SQL calls to appropriate sites.
- **Distributed transaction processing.** This is accomplished by **remote procedure calls (RPCs)**, which are similar to calls to (local) **stored procedures**. This approach has the advantage of minimizing the volume of the data to be transferred, because the procedure returns the answer, which may be very short.

Peer-to-peer programming allows more flexibility than RPC [Bernstein and Newcomer 1997]:

- **Flexible message sequences.** An RPC requires master-slave communication. This is a synchronous call-return model and all call-return pairs should be properly nested. Consider program A or P_A that calls P_B , that calls P_C . P_B cannot do anything until it hears from P_C , at which point it can initiate another call to P_C or return control to P_A .
- **Transaction termination.** All called programs must first announce the termination of their processing to the caller. In the above example, P_A cannot terminate until P_B terminates, and P_B cannot terminate until P_C terminates. Only then can P_A initiate commit processing. In the peer-to-peer model, any program may invoke termination via a **synchpoint** or **commit** operation. Transaction commit is delayed when some transactions are still running.
- **State of the transaction.** An RPC is **connectionless**. For the client and the server to share state, the server should return the state to the client. A **context handle** is used in some client/server systems for this purpose. In the peer-to-peer paradigm, communication programs share the transaction id and whether it is active, committed, or aborted. As far as **Web servers** are concerned the **http protocol** is stateless. Aside from maintaining the state in a middle tier, the state can be maintained via a **cookie**, which is a $(name, value)$ pair. Cookies are perceived to be invasive and browsers may disallow cookies from being saved.
- **Communication mechanism.** Connection-oriented peer-to-peer communication protocols are favored in transaction processing. IBM's **Logical Unit (LU6.2)** is a transactional peer-to-peer or RPC protocol specification, and is a *de facto* standard supported by many TP monitors.

Queued transaction processing can be used to deal with failures, so when the server or the client is down, queuing the request (from the client to the server) and the reply (from the server to the client) can be used to ensure eventual delivery. *Receiver-initiated* load balancing, where an idle server can pick up requests from a shared queue, has been shown to outperform *sender-initiated* transaction routing, because

the latter can result in an *unbalanced load* (e.g., a server is idle while other servers have a queue). IBM's MQSeries is one of the leading products in this area.

57.1.3.1 Data Replication

Data replication in a distributed system can be used to improve data availability and also performance, because data can be read from the "closest" node, which may be local. Updates are expensive if we use the **read-one write-all (ROWA)** paradigm or **synchronous replication**. When all nodes are not available, the **ROWA-A(available)** protocol updates all available nodes. The **Quorum Consensus Protocol** uses a write quorum Q_W and a read quorum Q_R , where $Q_W > N/2$ and $Q_R + Q_W > N$, and where the latter condition ensures that a read request will encounter at least one up-to-date copy of the data.

Alternatively, one of the nodes can be designated as the **primary copy**, so that all updates are first carried out at that node. Updates to the primary can be propagated to other nodes via **asynchronous update propagation** by sending the log records from the primary node to others.

To deal with network partitions, the **majority consensus** paradigm allows a subset of nodes with more than one half of the nodes to have a primary copy. The **quorum consensus** algorithm assigns different weights to nodes to deal with ties (i.e., when half of the nodes are in each partition).

57.1.3.2 Data Sharing or Shared Disk Systems

Computer systems, from the viewpoint of database applications, have been classified as:

- **Shared everything.** This is typically a **shared memory multiprocessor (SMP)**, where the processors share memory and disks. SMPs have become more powerful and can meet high-end transaction processing requirements.
- **Shared nothing.** Independent computers using message passing for communication. This configuration is most suitable for parallel database applications, such as in the case of the Teradata DBC/1012 computer or the NonStop SQL system from Tandem, which was also used for transaction processing (these are the original names of the computers and companies in the mid-1980s).
- **Shared disk or data sharing.** Data sharing can be used as a method to exceed the performance limits of a single computer, by allowing multiple computers access to data residing on a set of shared disks. **Cluster computers** with shared disk also belong to this category. Data sharing can be implemented on a shared nothing system with I/O request shipping.

A data sharing system in addition to concurrency control requires **coherency control** because more than one computer's buffer can hold the same database page. When such a page is updated by one computer, the other copies in the database buffers need to be invalidated or updated. The log is written as part of transaction commit, but the updating of disk data can wait because a NO-FORCE policy is in effect. The **broadcast invalidation** method, which is the preferred method for processor caches, will result in the purging of an updated page from the caches of other computers.

A transaction router determines the routing of transactions to the nodes of a data sharing system. The routing can be done with **load balancing** as a goal. The objective of **transaction affinity** is to reduce transaction processing requirements. This is accomplished by processing transactions in the same class or transactions that access the same datasets at the same node, so that the node buffers the pages associated with those datasets.

Primary copy locking (PCL), where each node is responsible for a database partition, is preferable to a centralized lock manager due to the following reasons [Rahm 1993]: (1) proper use of PCL results in a balanced load for processing lock requests; and (2) **affinity based routing (ABR)**, which matches transactions classes with database partitions, reduces inter-node communication. The node responsible for a part of the data is referred to as the **primary copy authority (PCA)**.

Integrated concurrency and coherency control uses **on-request-invalidation** or **check-on-access** to combine a lock request with checking the validity of a page cached locally. PCA caches at each node the current copy of recently accessed pages that belong to that partition. A node making a lock request attaches

the version number in the database buffer of the page for which the lock is being requested. The PCA returns the current copy of the page if the version number is different, along with the granting of the lock. Conversely, lock releases attach the current version of the page for caching at the primary site.

Data sharing concurrency and coherency control methods have a lot in common with client/server methods, yet there are many subtle differences [Franklin et al. 1997].

57.1.3.3 Further Information

For a more thorough discussion of the topics in this section, the reader is referred to [Chapter 58](#) on “Distributed and Parallel Database Systems,” as well as Cellary et al. [1988], Ceri and Pelagatti [1984], Gray and Reuter [1993], Bernstein and Newcomer [1997], Orfali et al. [1996], Ozsu and Valduriez [1999], and Ramakrishnan and Gehrke [2003].

57.2 Secure Distributed Transaction Processing: Cryptography

Electronic commerce is growing at a rapid pace with respect to traditional commerce, and provides major application of distributed transaction processing. This is a rapidly evolving area and our goal here is to introduce the reader to one of the more important issues, **cryptography**, and to discuss two particular protocols: iKP and NetBill.

Encryption is used to stop an intruder from reading a message that is only to be read by a certain receiver. This is accomplished by encrypting the **plaintext** ($Text_{plain}$), using a *sender key* (K_s) to produce **cyphertext** ($Text_{cipher}$), which is then decrypted by the receiver using the *receiver key* (K_r). More formally, $Text_{cipher} = K_s Text_{plain}$ and, conversely, $Text_{plain} = K_r Text_{cipher}$.

Symmetric or **secret key (SK)** cryptography uses the same key for both encryption and decryption: $K_r = K_s$, so this key should be known to each sender–receiver pair. This is the classical approach to cryptography and has been realized in countless ways.

The popular **Data Encryption Standard (DES)** uses a sequence of *transpositions* and *substitutions* on 64-bit blocks of plaintext using a 56-bit key. A successor to DES is the **Advanced Encryption Standard (AES)**, which allows 128, 192, and 256-bit key sizes. The Kerberos protocol developed at MIT also uses SK cryptography to authenticate a client to a server and create session keys on demand.

Asymmetric or **public key (PK)** cryptography assigns different public and private keys to each person (c) K_{pb}^c and K_{pr}^c , respectively. Public keys are known to everybody (e.g., by being posted on an individual’s Web page). Plaintext intended for a person with K_{pb}^c is encrypted with that key, but only that person can retrieve the original plaintext, since $T_{plain} = K_{pr}^c (K_{pb}^c T_{plain})$.

This algorithm relies on **one-way functions**, whose inverses are very expensive to compute and so the code is hard to break (this is related to computing the factors of a very large number). The most popular PK algorithm (RSA) uses modular exponentiation, so encryption, which uses a small exponent, is easy, while decryption with a large exponent is expensive. Public (resp. private) key operations were recently measured to be in tens (resp. thousands) of milliseconds as the key size is increased from 512 to 2048 bits [Menasce and Almeida 2000].

An electronic document can be signed using a **digital signature** based on PK encryption, except that K_{pr} is used for signing and P_{kp} for verification. A digital signature, similar to an ordinary signature, can be used to verify that a message received by B was indeed sent by A, rather than an imposter pretending to be A. This is accomplished by A first encrypting the message being sent using his *private key* and then encrypting it using B’s public key. After receiving a message, B first applies his private key and then A’s public key. The message received by B could only have come from A, because nobody else knows A’s private key. This allows **non-repudiation** because A cannot claim that he did not send the message.

If it is just a matter of authenticating the sender, rather than hiding the contents of the message, then the aforementioned encryptions can be applied to a **message signature** or a **message digest**, rather than the message itself. The message signature, which is obtained by a one-way function (e.g., hashing), is much smaller than the message; therefore, it is much less expensive to encrypt. There are many techniques for generating digests, such as **MD5** and **SHA-1**, that generate 128- and 160-bit digests, respectively.

The recipient A applies the hash function to the received message and compares it with the signature (after decrypting it). If they match, then the message was indeed from B and it was not corrupted in passage (perhaps by an interceptor) because the signature serves as a checksum.

A customer interested in purchasing goods from a vendor encrypts his message with the vendor's public key, so that only that particular vendor can decrypt it. There is a problem with reliably finding out a vendor's public key because, otherwise, a customer's order may go to another vendor who is impersonating the intended one.

Netscape's **Secure Sockets Layer (SSL)** protocol uses certificates to support secure communication and authentication between clients (customers) and servers (of the vendors). The Kerberos protocol developed at MIT uses SK cryptography to authenticate a customer to a server and create *session keys* on demand (see [Chapter 74](#) on "Network and Internet Security" in this *Handbook*). Kerberos is *not* suitable for the high volumes of transactions in an e-commerce environment because its server could become a bottleneck.

Vendors who want to be authenticated obtain the certificate from a **certification authority (CA)**, (e.g., Verisign); the CA issues certificates to vendors determined to be "reliable." A customer with a browser running the SSL protocol who wants to place an order with a particular vendor is first provided with the vendor's *certificate*. The browser has the public keys of all CAs, but it does not need to communicate with the CA for authentication. The **X.509 certificate**, which the vendor encrypts with its private key before sending to the customer, has the following fields: *name of the CA, vendor's name, url, public key, timestamp, and expiration time*. The browser uses the public key of the CA to decrypt the message and verifies that the URLs are the same.

The customer's browser next generates and sends to the vendor a **pre-master secret**, which is then used by the customer and the vendor, who use the same algorithm, to generate two **session keys** for communication each way during the same session. From this point on, the customer and the vendor communicate using a *symmetric* encryption protocol based on the session key. The reason for using symmetric rather than asymmetric encryption is that the latter is much more expensive.

To authenticate the customer's identity, the customer may be required to first obtain an account with the vendor, at which point the vendor verifies the customer's identity. The customer is asked to log in after the session key is established using his userid and password.

Netscape's SSL protocol, which is invoked when the browser points to a URL starting with *https*, offers authentication, confidentiality, and non-repudiation, but has been superseded by **Transport Level Security (TLS)**, which is now an IETF RFC (Internet Engineering Task Force Request for Comments). TLS running between the http and TCP layers consists of a handshake protocol and record protocol. The handshake protocol selects the DES algorithm used for bulk encryption, the **Message Authentication Code (MAC)** used for message authentication, and the compression algorithm used by the record protocol.

The **Secure Electronic Transaction (SET)** protocol can ensure that the vendor does not have access to the customer's credit card number and cannot misuse it. This can be accomplished simply by encoding credit card-related information using the public key of the credit card company. In a more elaborate scheme, each customer has a certificate that contains his credit card number and expiration date, and this information properly encrypted can only be processed by the **payment gateway**, rather than the vendor.

We next discuss two protocols for electronic commerce: the iKP family of protocols [Bellare et al. 2000] and the NetBill security and transaction protocol [Cox et al. 1995].

57.2.1 The iKP Protocol

The iKP ($i = 1, 2, 3$) family of protocols are similar in that we are dealing with customers, merchants, and a gateway between the electronic world and the payment infrastructure. The following steps are followed:

1. A customer initiates the action by sending a message to the merchant expressing interest in a product.
2. The merchant sends an invoice.
3. The customer uses his credit card for the payment.

4. The merchant asks for authorization from the gateway.
5. The gateway (also called the *acquirer*) grants authorization (most of the time).
6. The merchant sends the confirmation and the goods to the customer.

iKP protocols vary in the number of public-key pairs utilized. In 1KP, only the gateway possesses public and private keys. Payment is authenticated by sending the credit card number and the associated PIN, encrypted using the gateway public key. A weakness of this protocol is that it does not offer non-repudiation (i.e., disputes about the non-authenticity of orders, etc.). In 2KP, in addition to the gateway, the merchants hold keys, such that the customers can be sure that they are dealing with the right merchant. 3KP requires customers to have a public key, which ensures non-repudiation.

57.2.2 NetBill

NetBill extends (distributed) transaction atomicity with additional concepts to suit e-commerce as follows [Tygar 1998]:

1. **Money atomic protocols:** money is not created or destroyed in funds transfer.
2. **Goods atomic protocols:** in addition to money atomicity, ensure the exact exchange of goods for money, which is similar to the cash-on-delivery (COD) protocol.
3. **Certified delivery:** in addition to money and goods atomicity, allows both the consumer and merchant to prove that electronic goods were delivered. With COD, it is as if the contents of the delivered parcel are recorded by a trusted third party.
4. **Anonymity:** consumers do not want anybody to know their identity, for example, to preserve their privacy.

A representative anonymous electronic commerce protocol works as follows: a customer withdraws money from a bank in the form of a cryptographic token. He makes the money untraceable by cryptographically transforming the token, but the merchant can still check its validity. When spending the money, the customer applies a transformation, inserting the merchant's identity, who ensures that he has not received the token previously before sending the goods to the customer and also deposits his token at the bank. The bank checks the token for uniqueness and the customer remains anonymous, unless the token has been reused.

If the customer is not sure that the token reached the merchant, he can return the token to the bank, but if the token was, in fact, received by the merchant, then there is a problem and the identity of the customer is revealed. If the customer does not return the token and the token was not received by the merchant, then the customer will lose his money without receiving the goods.

A trusted server in NetBill acts as an ultimate authority, but security failures are possible when this server is corrupted. Appropriate log records are required to ensure recovery.

The issue of transaction size is important because it is important to ensure that the cost of processing the transaction remains a small fraction of the amount involved.

57.2.2.1 Further Information

A more in-depth treatment of this material can be found in books on cryptography and network security, such as Kaufman et al. [2002], as well as some database textbooks, such as Ramakrishnan and Gehrke [2003] and Lewis et al. [2002].

57.3 Transaction Processing on the Web: Web Services

We start with a brief introduction to **Web services (WS)**, then discuss the WS building blocks, and conclude with a discussion of **WS-transactions**.

57.3.1 Introduction to Web Services

Transaction processing is tied to WS, which is a level of abstraction like the Internet that sits above application servers like (e.g., CORBA) [WS Architecture 2003]:

A Web service is defined by a URI, whose public interfaces and bindings are defined and described using XML. Its definition can be discovered by other software systems. These systems may then interact with the Web service in a manner prescribed by its definition, using XML-based messages conveyed by Internet protocols.

The **URI (uniform resource identifier)** is better known as the **URL (uniform resource locator)**. **XML** stands for Extensible Markup Language.

Let's consider an example. A user specifies the following to a travel agent who handles vacation packages: preferences for vacation time, preferred locations ("one of the Hawaiian islands"), preferences for airlines, cars, and hotels, budget limits, etc. Some of this information may be unnecessary because the agent may be aware of the user's preferences (e.g., his participation in an airline's promotional program).

The travel agent interacts with service providers, which have posted information on the Web and can handle online reservations. Consumer payments are guaranteed by credit card companies. The user, who is *the only human in this scenario*, is, of course, interested in the best package at the lowest price. The travel agent is interested in a desirable package that will meet the user's approval and also maximize the commission. The service provider is interested in selling as many products as possible, while also minimizing cost (e.g., by routing the user via a route with excess capacity). The credit card company guarantees and makes payments for purchases.

In effect, we have a negotiation among **Web service agents** with vested interests. Before a requesting agent and a provider agent interact, there must be an agreement among the entities that own them. The travel agent uses **ontologies** (i.e., formal descriptions of a set of concepts and their relationships) to deal with the different services. Additional required technologies include: (1) trust maintenance, (2) reliability, (3) trust mechanisms, and (4) **orchestration** of services. A **choreography** is the "pattern of possible interactions between a set of services" and orchestration is a technique for realizing choreographies. [WS Architecture 2003].

This transaction can be carried out in multiple steps, with the agent getting user approval step by step. An impasse may be reached in some cases, requiring the undoing of some previous steps, as in the case where the flight is reserved but no hotel rooms are available at the destination. In case the airline reservation was made, this should be undone by canceling the reservation. Otherwise, it is possible that by the time the hotel reservation is made, the airline seat is no longer available and this step must then be repeated.

57.3.2 Components of Web Services

WS is based on XML, which is basically a markup language like **HTML (Hypertext Markup Language)**. HTML is applicable to text, while XML is also applicable to data. WS use URLs, but instead of an HTML file, an XML file is downloaded.

WSDL (Web Services Description Language) via appropriate abstractions provides an interface to WS. The two parties of a WS interaction share a common WSDL file, to generate messages at the sender end and to interpret them at the receiver.

SOAP (Simple Object Access Protocol) is a *de facto* standard for XML messaging. It provides lightweight communication capability for Web Services, but also **RPCs (remote procedure calls)**, publish and subscribe, and other communication styles. It can be utilized in conjunction with DBMSs, middleware systems, application servers, and deals with heterogeneity (e.g., J2EE and .NET) [SOAP V.1.2 P.0: Primer 2003].

UDDI (Universal Description, Discovery and Integration) is like a Yellow Pages directory and provides a repository for Web services descriptions. It is similar to Internet's DNS (domain name service) that translates host names into TCP addresses. Web services available at an Internet address are made available publicly in WSDL files.

These standards are used together in the following manner. The document submitted by a user to a Web Service is according to WSDL format. The sender's SOAP ensures that the data to be sent is appropriately converted to XML data types before being sent. The receiver's SOAP converts it to the format of the receiving computer. The receiver parses the XML message and validates it for consistency.

Distributed computing architectures, such as CORBA and DCOM, provide the same functionality as Web services. The difference is that there is a tight relationship between clients and servers, while the Web allows previously unknown connections to be made.

It is difficult to implement two-phase commit (2PC) for distributed transactions on top of HTTP, but the following connection-oriented messaging protocols for transaction coordination have been proposed: **Reliable HTTP (HTTPR)** by IBM and **Blocks Extensible Exchange Protocol (BEEP)** by IETF (Internet Engineering Task Force). The **Transaction Internet Protocol (TIP)** by IETF is then used for 2PC.

57.3.3 Web Services Transactions (WS-Transactions)

There are two categories of WS-transactions: atomic and business. WS-transactions rely on *Web services coordination* [WS Coordination 2002], whose functions are to:

1. Create a *coordination context (CC)* for a new atomic transaction at its coordinator.
2. Add interposed coordinators to existing transactions (if necessary).
3. Propagate CC in messages between WS.
4. Register for participation in coordination protocols.

An application sends a *Create Coordination Context (CCC)* message to its coordinator's *Application Service (AS)* and to register for coordination protocols to the *Registration Service (RS)*. WS coordinators allow different coordination protocols, as discussed below.

We illustrate our discussion with the coordination of two applications App1 and App2 with their own coordinators CRa and CRb, with application services ASa and ASb, and registration services RSa and RSb. The two CRs have a common protocol Y and protocol services Ya and Yb. The coordination proceeds in five steps.

1. App1 sends a CCC message for coordination type Q to ASa and gets back a *context Ca*, which consists of an *activity identifier A1*, the coordination type Q, and PortReference to RSa.
2. App1 then sends an application message to App2, including the context Ca.
3. App2 sends a CCC message to CRb's RSb with Ca as context. It gets back its context Cb with the same activity identifier and coordination type as Ca, but with its own registration service RSb.
4. App2 determines the protocol supported by coordination type Q and registers protocol Y at CRb.
5. CRb passes the registration to RSa (of CRa) registration service. It is agreed that protocol Y will be used.

The following commit protocols have been defined:

- **Completion protocol.** Completion is registered as a prelude to commit or abort.
- **PhaseZero.** This also precedes 2PC and is a notification to a transaction to FORCE outstanding cached data updates to disk.
- **Two-phase commit (2PC).** 2PC is briefly described below.
- **Outcome notification.** A transaction participant who wants to be notified about a commit-abort decision.

The WS coordinator messages first establish: (1) who are the participants, (2) the coordination protocol to be followed, and (3) the ports to be used. Web services WS-transactions use this infrastructure to carry out the commit protocol with relatively predictable message flows.

The 2PC protocol can be specified by a state transition diagram where transactions have six states: S0-active, S1-aborting, S2-preparing, S3-prepared, S4-committing, and S5-ended. We only specify a few important transitions.

The **transaction coordinator** initiates the protocol by issuing the **Prepare** message, which is a request for participants to vote. Three responses are possible:

1. **ReadOnly.** The node has not been engaged in writing any data. This is a vote to commit. The participant does not have to participate further.
2. **Aborted.** This is a vote not to commit. No further participation by the node is required.
3. **Prepared.** This is a vote to commit, and a Prepared status also indicates that the participant has logged information so that it can deal with subsequent commits or aborts.

A transaction coordinator, which receives Prepared messages from all participants, can decide to commit or abort the transaction. An appropriate message is sent after the coordinator has logged his decision. Logging is tantamount to permanently storing data onto non-volatile storage.

The **presumed commit protocol** has the following implications:

1. The coordinator need not log anything until the commit decision is made.
2. A participant can forget about a transaction after sending an Aborted or ReadOnly message.
3. When the outcome of a transaction is commit, then the coordinator has to remember it until all Committed Acks are received.

A one-phase-commit (1PC) protocol is also possible, in which the coordinator can issue a commit or abort messages, all by himself.

Detailed message flows for WS coordinations and transactions for App1 running at the Web server, App2 at the middleware server, and accessing the DBMS at the database server are given in WS Transactions [2002].

Web services security (WS-security) protocols can be used in conjunction with SOAP to ensure message integrity, confidentiality, and single message authentication. A brief review of techniques used for this purpose appear in the previous section of this chapter.

ebXML (electronic business XML) is a parallel effort to Web services and is geared toward enterprise users [Newcomer 2002].

57.3.3.1 Further Information

This is a rapidly evolving field, so that most of the more interesting and up-to-date information can be found on the Web. There are several detailed books discussing the technologies mentioned here. A book that ties everything together is Newcomer [2002]. A forthcoming book is *Web Services: Concepts, Techniques, and Examples* by S. Khoshafian, Morgan-Kaufmann Publishers, 2004. The reader is referred to <http://www.w3.org> for online material for most of the topics covered here, and to Brown and Haas [2002] for a glossary of terms.

57.4 Concurrency Control for High-Contention Environments

In this section we review concurrency control methods that have appeared in the research literature to deal with high data contention. More specifically, we are envisaging a system where data, rather than hardware resource contention, is the limiting factor for system throughput.

The standard locking method is strict 2PL (with the transaction blocking option upon a lock conflict), which limits the degree of transaction concurrency and is susceptible to thrashing, as discussed in the next section. The methods described here allow transaction aborts and restarts, which result in a reduction in the lock contention level. The “wasted” processing is expected to be toleratable with the advent of faster processors.

We first consider two classes of concurrency control methods: (1) **wait-depth limited (WDL)** methods, which limit the wait-depth of blocked transactions, while strict 2PL is the overall policy; and (2) **two-phase processing** methods, which are based on **access invariance**, that is, *a restarted transaction tends to access the same set of objects it accessed before* [Franaszek et al. 1992]. We also provide a quick overview of several methods for reducing data contention.

57.4.1 Wait-Depth Limited Methods

Before discussing the WDL method [Franaszek et al. 1992], we briefly review some other methods that also limit the wait depth.

An extreme WDL method is the **no waiting (NW)** or **immediate restart** policy, which disallows any waiting; that is, a transaction encountering a lock conflict is aborted and restarted immediately [Tay 1987]. Because an immediate restart will result in another lock conflict and abort, resulting in repeated wasted processing, **restart waiting** can be introduced to defer the restart of the aborted transaction until the transaction causing the conflict departs.

The **running priority (RP)** policy increases the degree of transaction concurrency and provides an approximation to **essential blocking**: *a transaction can be blocked only by an active transaction, which is also doing useful work*; that is, it will not be aborted in the future [Franaszek and Robinson 1985]. The approximation is due to the fact that it is not known in advance whether a transaction will commit successfully. Consider a transaction T_C that requests a lock held by T_B , which is blocked by an active transaction T_A . RP aborts T_B so that T_C can acquire its requested lock. There is a *symmetric* version of RP as well. T_C is blocked by T_B , which is initially active, but T_B is aborted when it becomes blocked by an active transaction T_A at a later time.

The **cautious waiting** aborts T_C when it becomes blocked by T_B [Hsu and Zhang 1992]. Although this policy limits the wait depth, it has the same deficiencies as the no-waiting policy.

A family of WDL methods are described in Franaszek et al. [1992]. We only consider WDL(1), which is similar to (symmetric) RP but takes into account the progress made by transactions involved in the conflict, including the active transaction, in selecting which transaction to abort. A transaction that has acquired a large number of locks and consumed a significant amount of system resources is not aborted in favor of a transaction that has made little progress, even if that transaction is active.

A simulation study of WDL methods shows that WDL(1) outperforms RP, which outperforms other methods [Thomasian 1997]. Simulation results of the WDL(1), which limits the wait depth to one, against two-phase and optimistic methods, shows that it outperforms others, unless “infinite” hardware resources are available [Franaszek et al. 1992].

Variations of the WDL are described for distributed databases in Franaszek et al. [1993]. Simulation studies show that this method outperforms strict 2PL and the wound-wait method. 2PC is the commit protocol in all cases.

57.4.2 Two-Phase Processing Methods

The first phase of transaction execution, without applying any concurrency control method, serves the role of prefetching the data required for transaction execution from disk. This phase is called **simulation** or **virtual execution** [Franaszek et al. 1992]. In the second phase, the transaction is executed according to a concurrency control method. The restarted transaction’s execution time is very short in the second phase, because the buffer is primed and it can access the blocks required for its execution from the database buffer without incurring disk I/O.

What we described is a generalization of *pipelined processing* [Gray and Reuter 1993], where transactions are executed serially in the second phase so that there is no need for a concurrency control method, but this method has a limited throughput. A generalization of this method is to execute transactions in non-interfering classes on different processors of a multiprocessor system.

Rather than wasting the execution on the first phase, some concurrency control method such as RP can be adopted. If the transaction execution is successful, it commits, and the second execution phase is not required. A transaction can be aborted according to the RP paradigm, but instead of being restarted, it continues executing in virtual execution mode. A locking method is used in the second phase, but lock requests by second phase transactions preempt locks held by first phase transactions, forcing them into virtual execution. The standard RP method (with restart waiting) is adopted when a second phase transaction is aborted (by another second phase transaction) according to the RP paradigm.

Multiphase processing methods work better with **optimistic** concurrency control methods, which execute without requesting any locks on objects they access. A transaction instead posts *access entries* to identify objects that it has accessed into an appropriate hash class. These objects are also copied into the transaction's *private workspace* and modified locally if an update is required. Upon completing its first phase, which is called the **read phase**, a transaction enters its second or **validation phase**, during which it checks whether any of the objects accessed by the transaction have been modified since they were "read." If this is true, then the transaction is aborted, otherwise it can commit. Transaction commit includes the third or **write phase**, which involves externalizing the modified objects from the private workspace into the database buffer (after appropriate logging for recovery). Note that the three optimistic steps constitute a single phase in transaction processing.

A committing transaction can invalidate others, those that had accessed objects which it has modified. Validation then just involves checking whether a transaction was conflicted (in the past) or not. In fact, a conflicted transaction can be aborted right away, which is what is done according to the **optimistic kill** policy, but two-phase processing favors the **optimistic die policy**, so that a first phase transaction executes to the end, prefetching all data, and dying a natural death.

A transaction running according to the optimistic die policy is susceptible to fail its validation according to a **quadratic effect**, that is, the probability that a transaction is conflicted is proportional to the number of objects accessed (k) and the execution time of the transaction, which is also proportional to k [Frasaszek et al. 1992]. In case a transaction with the optimistic die policy is restarted after failing its validation, its second execution phase can be very short, so that the quadratic effect is not a problem. The quadratic effect is a problem when the system is processing variable-size transactions. Larger transactions, which are more prone to conflict than shorter transactions, contribute heavily to wasted processing when they do so [Ryu and Thomasian 1987].

In fact, given that all of the objects required for the execution of a transaction have been prefetched, there is no advantage in running it to completion. The **optimistic kill** rather than the optimistic die policy should be used in the second and further phases, because doing so will reduce the wasted CPU processor and also the transaction response time.

An optimistic kill policy may result in more than two phases of execution. To minimize the number of executions, a locking method can be used in the second phase. On demand or **dynamic locking** is still susceptible to deadlocks, although we know that deadlocks tend to be rare. Because the identity of all objects required for the second phase is known, **lock preclaiming** or **static locking** can be used to ensure that the second execution phase is successful.

The optimistic die/lock preclaiming method can be utilized in a distributed system as long as the validation required for the first phase is carried out in the same order at all nodes [Thomasian 1998b]. Two-phase commit can be carried out by including lock requests as part of the *pre-commit message*. If any of the objects has been modified, its modified value is sent to the coordinator node at which the transaction executes. The transaction is reexecuted at most once because it holds lock on all required objects.

It was shown in Franaszek et al. [1992] that the performance of two-phase methods is quite similar, but with "infinite" hardware resources, they outperform WDL(1).

57.4.3 Reducing Data Contention

A short list of some interesting methods to reduce the level of lock contention is given at this point.

Ordered sharing allows a flexible lock compatibility matrix, as long as operations are executed in the same order as locks are acquired [Agrawal et al. 1994]. Thus, it introduces restrictions on the manner transactions are written. For example, a transaction T_2 can obtain a shared lock on an object locked in exclusive mode by T_1 (i.e., read the value written by T_1) but this will result in deferring T_1 's commit to after T_2 is committed. Simulation results show that there is an improvement in performance with respect to standard locking.

Altruistic locking allows transactions to *donate* previously locked objects once they are done with them, but before the objects are actually unlocked at transaction completion time [Salem et al. 1994]. Another transaction may lock a donated object, but to ensure serializability, it should remain in the “wake” of the original transaction (i.e., accesses to objects should be ordered). Cascading aborts, which are a possibility when the donated object is locked in exclusive mode, can be prevented by restricting “donations” to objects held in shared mode only. This makes the approach more suitable for read-only queries or long-running transactions with few updates.

A method for allowing interleaved execution of **random batch transactions** and short update transactions is proposed in Bayer [1986]. The random batch transaction updates database records only once and the updates can be carried out in any order (e.g., giving a 5% raise to all employees). In effect, the batch transaction converts “old” records into “new” records. Because the blocking delay is not tolerable for short transactions, the batch transaction may update the *required* old records and make them available to short transactions, after taking *intermediate commit points*.

The **escrow method** [O’Neil 1986] is a generalization of the **field calls** approach in IMS FastPath [Gray and Reuter 1993]. The minimum, current, and maximum values of an aggregate variable, such as a bank balance, are made available to other transactions.

The **proclamation-based** model for cooperating transactions is described in Jagadish and Shmueli [1992]. In addition to its original motivation of transaction cooperation, it can be used to reduce the level of lock contention. This method is different from altruistic locking in that a transaction, before releasing its lock on an object (it is not going to modify again), proclaims one or a set of possible values for it. Trivially, the two values may be the original and modified value. Transactions interested in the object can proceed with their execution according to the *proclaimed* values.

The lock holding time by long-lived transactions can be reduced using intermediate commit points according to the **sagas** paradigm [Garcia-Molina and Salem 1987]. A long-lived transaction T_1 is viewed as a set of subtransactions T_1, \dots, T_n , that are executed sequentially and can be committed individually at their completion. However, the abort of subtransaction T_j results in the undoing of the updates of all preceding subtransactions from a semantic point of view through compensating subtransactions C_1, \dots, C_{j-1} . Compensating transactions consult the log to determine the parameters to be used in compensation.

A method for **chopping** larger transactions into smaller ones to reduce the level of lock contention and increase concurrency, while preserving correctness, is presented in Shasha et al. [1995].

Semantics-based concurrency control methods rely on the semantics of transactions or the semantics of operations on database objects. The former is utilized in Garcia-Molina [1983], where transactions are classified into types and a compatibility set is associated with different types. Semantics-based concurrency control methods for objects are based on the commutativity of operations. **Recoverability of operations** is an extension of this concept that allows an operation to proceed when it is recoverable with respect to an uncommitted operation [Badrinath and Ramamritham 1992]. Various operations on stacks and tables belong to this category. Two methods based on commutativity of operations are presented in Weihl [1988]; they differ in that one method uses intention lists and the other uses undo logs. This work is extended in Lynch et al. [1994].

Checkpointing at the transaction level can be used to reduce the wasted processing due to transaction aborts. The effect of checkpointing on performance has been investigated in the context of optimistic concurrency control with kill option [Thomasian 1995]. As previously discussed, data conflicts result in transaction abort and resumption of its execution from the beginning. A reduction in checkpointing cost is to be expected due to the private workspace paradigm. There is a trade-off between checkpointing overhead and the saved processing due to partial rollbacks, which allows a transaction to resume execution from the checkpoint preceding the data item causing the data conflict.

57.4.3.1 Further Information

A more detailed discussion of these topics appears in Ramamritham and Chrisanthi [1996], Thomasian [1996a], and Thomasian [1998a] and, of course, the original papers.

57.5 Performance Analysis of Transaction Processing Systems

The performance of a **transaction processing** system is affected by **hardware resource contention** as well as **data contention**. We provide a brief introduction to **queueing theory** and especially **queueing network models (QNM)**, which provide solutions to the first problem. The description that follows is brief, yet self-complete.

The analysis of lock contention in databases is more academic in nature, but provides insight into the effect that lock contention has on system performance.

57.5.1 Hardware Resource Contention

QNM's have been used successfully in analyzing the performance of transaction processing systems. Crude QNM's can be used to roughly estimate performance, while more specialized QNM-based tools for **capacity planning** (such as BEST/1 and MAP [Lazowska et al. 1984]) can predict computer performance more accurately. Specialized tools are available to automate the extraction of QNM's input parameters.

The QNM of a computer system consists of nodes that correspond to **active resources** of the system, such as the processor and disks. The processors of a multiprocessor constitute a single node with multiple servers, which is referred to as the CPU (central processing unit). Each node in the QNM consists of a queue, which holds pending requests, and server(s). We will assume that the queueing discipline at all nodes is first-come, first serve (FCFS).

Transactions correspond to **jobs** being processed by a QNM. We consider transactions that belong to a **job class**, but multiple job classes can be defined based on their processing requirements at the resources of the computer system. Multiple transaction (or job) classes would be required if the system under consideration processed short online and long batch transactions, which definitely belong to different categories.

Transactions execute concurrently in a multiprogrammed environment to attain higher transaction throughput and resource utilization, that is, to reduce the cost per transaction per time unit. The main memory is a **passive resource** because it limits the degree of transaction concurrency or the **multiprogramming level (MPL)**, which is denoted by M . Transactions that cannot be activated due to the maximum MPL constraint (M_{max}) are held in the **memory queue**. More generally, transactions are delayed because they can only be processed by a limited number of threads.

The sharing of (active) hardware resources by concurrent transactions has an adverse effect on transaction response time. The analysis of the underlying QNM can then be used to determine the queueing delays at the active resources, as well as the maximum MPL constraint.

Transactions have multiple processing steps, where each step leads to an access to a database object. This is preceded by a lock request and acquisition. The transaction proceeds to its next step if its lock request is successful, but otherwise the transaction is blocked until the requested lock is released (this effect is discussed in the next section). The last step leads to transaction commit and the release of all locks. At this point, we assume that all lock requests are successful because we are only concerned with hardware resource contention. Lock contention is discussed in [Section 57.5.2](#).

Objects accessed by online transactions tend to be small (e.g., a database record) so they are contained in database pages or blocks (say, 8 KBytes). Most DBMSs maintain a database buffer in main memory that caches recently accessed database pages. If the required page is found in the database buffer, then the transaction can proceed to the next step in its execution; otherwise, there is a page fault. The transaction encountering a page fault remains blocked until the I/O request is completed, at which point it resumes its execution or is enqueued in the processor queue if all processors are busy. The **miss ratio** of the buffer, which is the fraction of references to missing pages, has a major effect on transaction performance. This is because of the high disk access time overhead.

A QNM with external arrivals is called an **open QNM**, while a QNM with a fixed degree of transaction concurrency, where a completed transaction is immediately replaced by a new transaction, is called a **closed QNM**. We next discuss open and closed QNM's, followed by a solution method for "closed" QNM's subject to external arrivals.

57.5.1.1 Analysis of an Open QNM

A transaction arriving at the computer system (the CPU) behaves as a token, which transitions from one node to another, acquiring service, until it is completed and leaves the system. We consider transaction execution at a special QNM known as the **central server model (CSM)**, which was introduced for modeling multiprogrammed computer systems. The central server is the CPU (node 1) and the peripheral servers are the disks (nodes 2 – N). Transactions alternate between CPU and disk processing. CPU processing ends when a transaction makes an I/O request to disk as a result of a page fault. A transaction resumes CPU processing after the disk is accessed and the page fault is resolved. Transactions leave the system after completing their last step at the CPU, which is just a matter of convention.

After completing a CPU burst, a transaction leaves the system with probability p_1 or with probability p_n , $2 \leq n \leq N$, and accesses the n th disk, so that $\sum_{n=1}^N p_n = 1$. The probability of selecting the n th disk is $q_n = p_n/(1 - p_1)$, $2 \leq n \leq N$. The probability that a transaction makes k visits to the CPU is $P_{CPU}(k) = p_1(1 - p_1)^{k-1}$, $k \geq 1$, and the mean number of visits to the CPU is then $v_{CPU} = v_1 = 1/p_1$. The total number of visits to disks is $v_{disk} = 1/p_1 - 1$, so that the mean number of visits to the n th disk is $v_n = q_n v_{disk} = p_n/p_1$, $2 \leq n \leq N$.

The **service demand** of a transaction at device n is the total service time it requires at this device: $D_n = v_n \bar{x}_n$, where \bar{x}_n is the mean service time per visit. The hardware resource requirements of a transaction can be summarized as (D_1, D_2, \dots, D_N) . In fact, detailed transition probabilities and service times are not required at all, unless one is interested in simulating the system. Data reduction applied to software measurement data can be used in estimating service demands required by QNM solvers.

An open QNM with Poisson arrivals is **product-form**; that is, an efficient solution for it is available if the service times at nodes with an FCFS queueing discipline are exponentially distributed. Poisson arrivals are random in time and transactions are generated from an “infinite” number of sources, so that the arrival rate is not affected by the number of transactions at the computer system.

The **utilization factors** of the n th node with m_n servers is given as $\rho_n = \Lambda D_n/m_n$, where $1 \leq n \leq N$. The utilization factor is the fraction of time that the servers at a node are busy and also the mean number of requests at one of the servers (provided that they have equal utilizations). Unequal server utilizations would be possible if a scheduler assigns servers in an ordered fashion, always starting with the lowest indexed server. It is intuitively clear that the condition for the stability of the system is $\rho_n < 1$ for all n . In this case, the system is *flow-balanced*, so the **system throughput** or the transaction completion rate equals the arrival rate Λ .

Little’s result states that *the mean number of requests in a queueing system equals the product of the arrival rate of requests and the mean time they spend in the system* [Trivedi 2002]. The queueing system may be the combination of the queue and the servers, the queue alone, the service facility, or one of the servers, as discussed above.

The **bottleneck** node is defined as the node with the highest service demand; but in the presence of multiple servers, it is the node with the highest D_n/m_n . The maximum throughput is given as $\Lambda_{max} = m_n/D_n$ and the system will be *saturated* if $\Lambda > \Lambda_{max}$. Faster disks and processors can be used to reduce the service demand so that a higher Λ_{max} can be attained. The load of a bottleneck disk can be reduced by reallocating its files. At best, the service demands at all disks can be made equal.

Disk arrays utilize *striping* partition files into stripe units and allocate them in a round-robin manner on disks. In this way, “hot” files with high access rates are intermixed with “cool” files. See [Chapter 21](#) on “Secondary Storage Systems” in this *Handbook* for more detail.

More efficient hardware will also result in a reduction of the service demands at the processor. Database tuning, such as implementing appropriate B-tree indices, where the higher levels of the index are held in main memory, can be used in reducing the number of disk I/Os. In effect, we have reduced the miss ratio of the database cache.

The mean residence time of a transaction at a disk is given as $R_n = D_n/(1 - \rho_n)$, $2 \leq n \leq N$; for example, D_n is expanded by a factor of two if $\rho_n = 0.5$. This formula applies to the CPU if it is a uniprocessor; but in the case of a multiprocessor with $m_1 = 2$, $R_1 = D_1/(1 - \rho^2)$, that is, $R_1 \approx 1.33$ for $\rho_1 = 0.5$.

The mean transaction response time (R) is the sum of its residence times at the nodes of the computer system: $R = \sum_{n=1}^N R_n$.

The mean number of transactions at the computer system (\bar{N}) according to Little's result is the product of the arrival rate of transactions (Λ) and the mean time transactions spend at the computer system (R); that is, $\bar{N} = \Lambda R$. This result holds for general interarrival and service time distributions and the individual nodes of a QNM: $\bar{N}_{server} = \lambda r$; for the queues: $\bar{N}_{queue} = \lambda w$; and for the servers: $\bar{N}_{servers} = \lambda \bar{x} = m\rho$, where λ is the arrival rate of requests to a node, \bar{x} , the mean service time (per visit), m the number of servers, w the mean waiting or queuing time, and $r = w + \bar{x}$, the mean residence time per visit.

Each node in an open QNM can be analyzed as an $M/M/1$ queue, where the first M implies Poisson arrivals, the second M exponential service times, and there is one server (in fact, the arrivals to nodes with feedback are not Poisson). The mean waiting time (w) can be expressed as $w = \bar{N}_q \bar{x} + \rho \bar{x}'$, which is the sum of the mean delay due to requests in the queue and the request being served (if any). The probability that the server is busy is $\rho = \lambda \bar{x}$ and \bar{x}' is the mean *residual service time* of the request being served at arrival time. This equality holds for Poisson arrivals because *Poisson arrivals see time averages (PASTA)*, due to the *memoryless property* of the exponential distribution $\bar{x}' = \bar{x}$. Noting that $\bar{N}_q = \lambda w$, we have $w = \rho \bar{x} / (1 - \rho)$. The mean response at a node per visit is $r = w + \bar{x} = \bar{x} / (1 - \rho)$ and the mean residence time at the node is then $R = vr$.

This analysis also applies to an $M/G/1$ queue with a general service, in which case $\bar{x}' = \bar{x}^2 / (2\bar{x})$, where the numerator is the second moment of service time. This leads to $W = \lambda \bar{x}^2 / (2(1 - \rho))$, which is the well-known Pollaczek-Khinchine formula for $M/G/1$ queues. Departures from an $M/G/1$ queue with FCFS are not Poisson, so that this queue cannot be included in a product-form QNM.

57.5.1.2 Analysis of a Closed QNM

A system with a maximum MPL M_{max} can be treated as an open QNM if the probability of exceeding this limit is very small. For example, the distribution of the number of jobs in $M/M/1$ queues is given by the geometric distribution [Trivedi 2002] $P(m) = (1 - \rho)\rho^m$, $m \geq 1$, so that the probability that the buffer capacity is exceeded is $P_{overflow} = \sum_{m > M_{max}} P(m)$.

The joint-distribution of the number of jobs in a product-form open QNM is

$$P(m_1, m_2, \dots, m_K) = P(m_1)P(m_2) \cdots P(m_K)$$

where each term is $P(m_k) = (1 - \rho_k)\rho_k^{m_k}$ if the node is a single server (more complicated expressions for multiserver nodes are given in Trivedi [2002]). The distribution of probability when the total number of jobs is $N = \sum_{k=1}^K n_k$ can be easily computed. The closed QNM can be considered open if the probability of exceeding M_{max} is quite small. We also need to ascertain the throughput of the system running at M_{max} : $T(M_{max}) > \Lambda$.

In a closed QNM, a completed transaction is immediately replaced by a new transaction, so that the number of transactions remains fixed at M . A closed QNM can be succinctly defined by its MPL M and transaction service demands: $(D_n, 1 \leq n \leq N)$. The **throughput characteristic** $T(M)$, $M \geq 1$ is a nondecreasing (and convex) function of M . As $M \rightarrow \infty$, $T_{max} = m_n / D_n$, where n is the index of the bottleneck resource.

The **convolution algorithm** or **mean value analysis (MVA)** can be used to determine the system throughput $T(M)$ or the mean transaction residence time $R(M)$, which are related by Little's result: $R(M) = M / T(M)$. Analysis of QNMs using MVA is specified in Lazowska et al. [1984], but at this point we provide the analysis of a **balanced QNM**, which consists of single server nodes with all service demands equal to D .

Due to symmetry there are M/N transactions at each node, on average. According to the *arrival theorem*, which is the closed system counterpart of PASTA, an arriving transaction encounters $(M - 1)/N$ transactions at each node, as if there is one transaction less in the system (the arriving transaction itself). This observation forms the basis of an iterative solution, but no iteration is required in this special case because the number of requests at each node is known. The mean residence time of transactions at node n is the sum of its service time and the queuing delay: $R_n(M) = D[1 + (M - 1)/N]$.

It follows that the mean residence time of a transaction in the system is $R(M) = NR_n(M) = (M + N - 1)D$ and that $T(M) = M/R(M) = M/[(M + N - 1)D]$, which means that as $M \rightarrow \infty$, $T_{max} = 1/D$.

Balanced job bounds, which utilize the solution to a balanced QNM, can be used to obtain upper and lower bounds to the throughput characteristic ($T(M)$, $M \geq 1$) of a computer system. Both bounds are obtained by assuming that the QNM is balanced, with the upper bound using $D_u = D_{avg} = \sum_{n=1}^N D_n/N$ and the lower bound $D_L = D = D_{max}$, where max is the index of the node with the largest service demand.

Asymptotic bounds are more robust, in that they are applicable to multiple server nodes. The maximum throughput is equal to m_{min}/D_{min} , where min is the node with the smallest such ratio. Another asymptote passes through the origin and the point $(M = 1, T(1) = 1/\sum_{n=1}^N D_n)$ of the throughput characteristic.

A rule of thumb (ROT) to determine M_{max} in a system with a single CPU and many disks (so that there is no queueing delay at the disks) is $M_{max} = D_{disk}/D_{CPU} + 1$. This ROT is based on the observation that with perfect synchronization of CPU and disk processing times, which could only be possible if they have a fixed value, M_{max} would utilize the processor 100% (with no queueing delays). If the CPU has $m_{CPU} = m_1$ processors, then $M_{max} = m_{CPU}D_{disk}/D_{CPU} + 1$.

57.5.1.3 Hierarchical Solution Method

We next consider the analysis of a transaction processing system with external arrivals, but with a constraint on the maximum MPL (M_{max}). As far as external arrivals are concerned, rather than assuming an infinite number of sources, we consider the more realistic case of a finite number of sources $I (> M_{max})$ so that queueing is possible at the memory queue. Each source has an exponentially distributed think time with mean $Z = 1/\lambda$, which is the time it takes the source to generate its next request.

A two-step **hierarchical solution method** is required, which substitutes the computer system, regardless of its complexity, with a **flow-equivalent service center (FESC)** specified by its throughput characteristic: $T(M)$, $1 \leq M \leq M_{max}$ and $T(M) = T(M_{max})$, $M \geq M_{max}$. This approximation has been shown to be very accurate by validation against simulation results.

The hierarchical solution method models the system by a one-dimensional **Markov chain**, where the state S_M designates that there are M transactions at the computer system. There are $I + 1$ states, since $0 \leq M \leq I$. The arrival rate of transactions at S_M is $(I - M)\lambda$, that is, the arrival rate decreases linearly with M . When $M \leq M_{max}$, all transactions will be activated and processed at a rate $T(M)$. Otherwise, when $M > M_{max}$, the number of transactions enqueued at the memory queue is $M - M_{max}$. The analysis, however, postulates that the FESC processes all transactions, but the maximum rate does not exceed $T(M_{max})$ even when $M > M_{max}$.

The MC is, in fact, a **birth-death process** because the transitions are only among neighboring states. The forward transitions $S_{M-1} \rightarrow S_M$ have a rate $(I - M + 1)\lambda$ and the backward transitions $S_M \rightarrow S_{M-1}$ are $T(M)$, $1 \leq M \leq I$. In equilibrium, *the rate of the forward transitions multiplied by the fraction of time the system spends in that state equals the same product for backward transitions*. Note that the fraction of time spent in a state can be expressed simply as the state probability $\pi(M)$ for S_M .

The **state equilibrium** or **steady-state** equations are given as follows:

$$(I - M + 1)\lambda\pi(M - 1) = T(M)\pi(M), \quad 1 \leq M \leq M_{max}$$

where all probabilities can be expressed as a function of $\pi(0)$, which in turn can be determined using the condition that probabilities sum to one.

Given $\pi(M)$, we can obtain the mean number of transactions at the computer system as $\bar{M} = \sum_{M=1}^I M\pi(M)$ and the system throughput as $\bar{T} = \sum_{M=1}^I T(M)\pi(M)$. The mean transaction response time, which includes the delay in the memory queue, is $R = \bar{M}/\bar{T}$; and the mean memory queue length is $\bar{M}_q = \sum_{M=M_{max}}^I (M - M_{max})\pi(M)$.

A shortcut solution is possible via **equilibrium point analysis** [Tasaka 1986], which obtains the intersection point of the throughput characteristic: $T(M)$, $M \geq 1$ vs. M and the arrival rate: $\Lambda(M) = (I - M)\lambda$ vs. M . The intersection point at coordinates (\bar{M}, \bar{T}) is the equilibrium point because the arrival rate of

requests equals the completion rate. The mean transaction response time is then $R = \bar{M}/T$. Alternatively, it follows from Little's result that $I = (R + Z)T$, so that $R = I/T - Z$.

The Transaction Processing Council's benchmarks (www.tpc.org) compare systems based on the maximum throughput (in processing one of its carefully specified benchmarks) as long as a certain percentile of transaction response time does not exceed a threshold of a few seconds.

57.5.2 Performance Degradation Due to Locking

Performance degradation due to locking is expected to be low because if it is high, steps are taken to eliminate the sources of lock contention. For example, the lock contention in a DBMS with page level locking can be reduced by introducing record level locking, that is, using a finer granularity of locking. This is at the cost of making recovery more complicated, as in the case of the ARIES recovery method [Ramakrishnan and Gehrke 2003].

There is little information about the level of lock contention in high-performance systems, although most DBMSs record the occurrence of lock conflicts. The very few studies of lock contention by analyzing lock traces (e.g., Singhal and Smith [1997]) have been carried out without a global view of the system: (1) transaction classes, their data access pattern and their frequencies; (2) the organization of the database, information about its tables and indexes, etc.; and (3) transaction scheduling, which serializes the execution of transactions in the same or conflicting classes to reduce the level of lock contention.

The solution methods provided in this section potentially can be used to predict the effect of increased arrival rates on system performance, but it should be mentioned that unlike validation studies of analytical models for hardware resource contention [Lazowska et al. 1984], we are not aware of validation studies for lock contention.

In addition to obtaining expressions for the probability of lock conflict and deadlock, we obtain the effect of locking on transaction response time. We also provide an analysis to explain the **thrashing phenomenon**, and conclude with the issue of load control and a more realistic model for lock contention.

57.5.2.1 Probability of Lock Conflict and Deadlock

A (validated) straw-man analysis of lock contention and deadlocks served as a starting point for analytic studies in this area [Gray and Reuter 1993].

We consider a closed system with M transactions that are processed according to the strict 2PL paradigm. Requested locks are uniformly distributed over the D database objects (e.g., database pages). This is, in fact, the effective database size, which can be estimated indirectly if we know (1) the probability of lock conflict, (2) that requested locks are uniformly distributed over active objects, and (3) the number of locks requested per transaction.

The effect of shared and exclusive locks and nonuniform lock distribution can be taken into account by utilizing an **effective database size**, which is larger (resp. smaller) than D from the first (resp. second) viewpoint [Tay 1987]. For example, if a fraction f_X of lock requests are exclusive, then $D_{eff} = D/[1 - (1 - f_X)^2]$, so that $D_{eff} \approx 2D$ when $f_X = 0.7$, and $D_{eff} = \infty$ when all requests are reads (i.e., no lock conflicts).

We consider fixed-size transactions of size k and variable-size transactions, where the fraction of transactions of size k is f_k , $1 \leq k \leq K_{max}$ with $\sum_{k=1}^{K_{max}} f_k = 1$. K_i denotes the i th moment of transaction size; that is, $K_i = \sum_{k=1}^{K_{max}} k^i f_k$.

A size k transaction consists of $k + 1$ steps with identically distributed execution times denoted by s , which has been characterized by a uniform and exponential distributions, but this has a secondary effect on the lock contention level. The mean step durations $s(\bar{M}_a)$ can be determined from the QNM (queueing network model) of the transaction processing, taking into account the mean number of active transactions. Different steps may have different service demands and durations, in which case we will need the mean number of active transactions in different steps, but these complications remain beyond the scope of this discussion.

The value of \bar{M}_a is initially unknown, but the analysis yields the fraction of blocked transactions (β), which can be used to obtain the mean number of active and blocked transactions as $\bar{M}_a = (1 - \beta)M$ and

$\bar{M}_b = M - \bar{M}_a = \beta M$. The mean residence time of transactions in the system, while they are not blocked due to lock conflicts, is $r(\bar{M}_a) = (K_1 + 1)s(\bar{M}_a)$.

The first k steps of a transaction lead to a lock request and the final step leads to transaction commit and the release of all locks according to the strict 2PL paradigm. Transactions are blocked upon a lock conflict awaiting the release of the requested lock. The effect of deadlocks is ignored in this analysis because deadlocks are relatively rare, even in systems with a high level of lock contention.

The probability of lock conflict for this model is the ratio of the number of locks held by transactions to the total number of locks: $P_c \approx (M - 1)\bar{L}/D$; we use $M - 1$ because the lock requested by the target transaction, may conflict with locks held by the *other* $M - 1$ transactions, and \bar{L} is the mean number of locks held by a transaction, which is the ratio of the time-space of locks (a step function, so that each acquired lock adds one unit and there is a drop to zero when all locks are released) and the execution time of the transaction. In the case of fixed-size transactions, $\bar{L} \approx k/2$ and in the case of variable size transactions, $\bar{L} \approx K_2/(2K_1)$ [Thomasian and Ryu 1991].

The probability that a transaction encounters a two-way deadlock can be approximated by $P_{D2} \approx (M - 1)k^4/(12D^2)$, which is very small because D tends to be very large [Thomasian and Ryu 1991].

57.5.2.2 Effect of Lock Contention on Response Time

The mean response time of fixed-size (of size k) and variable-size transactions is given as:

$$R_k(M) = (k + 1)s(\bar{M}_a) + kP_c W$$

$$R(M) = \sum_{k=1}^{K_{max}} R_k(M) f_k = (K_1 + 1)s(\bar{M}_a) + K_1 P_c W = r(\bar{M}_a) + K_1 P_c W$$

Note that $R(M)$ is a weighted sum of $R_k(M)$'s, based on transaction frequencies.

The fraction of blocked transactions can be expressed as the fraction of time transactions spend in the blocked state: $\beta = \bar{M}_b/M = K_1 P_c W/R(M)$ (the second ratio follows from the first by dividing both sides by $T(M)$). We have $R(M) = r(\bar{M}_a)/(1 - \beta)$, which indicates that the mean transaction residence time is expanded by the one's complement of the fraction of blocked transactions.

In a system with lower lock contention levels, most lock conflicts are with active transactions, in which case $W \approx W_1$. W_1 normalized by the mean transaction response time is $A = W_1/R \approx 1/3$; for fixed-size transactions and for variable-size transactions, we have $A \approx (K_3 - K_1)/(3K_1(K_2 + k_1))$ [Thomasian and Ryu 1991].

As far as transaction blocking is concerned, we have a forest of transactions with an active transaction at level zero (the root), transactions blocked by active transactions at level one, etc. The probability that a transaction is blocked by a level $i > 1$ transaction is $P_b(i) = \beta^i$ and, hence, $P_b(1) = 1 - \beta - \beta^2 - \dots$. Approximating the mean waiting time of transactions blocked at level $i > 1$ by $W_i = (i - 0.5)W_1$, the mean overall transaction blocking time is

$$W = \sum_{I \geq 1} P_b(i) W_i = W_1 \left[1 - \sum_{I \geq 1} \beta^i + \sum_{i > 1} (i - 1/2) \beta^{i-1} \right]$$

Multiplying both sides by $K_1 P_c / R(M)$ and defining $\alpha = K_1 P_c A$ (with $A = W_1/R(M)$), we obtain:

$$\beta = \alpha(1 + 0.5\beta + 1.5\beta^2 + 2.5\beta^3 + \dots)$$

Because $\alpha < 1$, we can obtain the following cubic equation:

$$\beta^3 - (1.5\alpha + 2)\beta^2 + (1, 5\alpha + 1)\beta - \alpha = 0$$

The cubic equation has three roots for $\alpha < 0.226$. Two of the roots are less than one and one root greater than one [Thomasian 1993]. Only the smallest root is meaningful. For $\alpha = 0.226$, we have $\beta = 0.378$; but for $\alpha > 0.226$, there is only one root, which is greater than one. In other words, the model predicts that the system is thrashing.

The simulation program used to ascertain the accuracy of the approximate analysis of strict 2PL shows the analysis to be quite accurate. The same simulation program was used to show that very long runs are required in some cases to induce thrashing, but the duration of these runs decreases as the variability of transaction sizes increases.

As we increase M , the mean number of active transactions \bar{M}_a is maximized at $\beta \approx 0.3$, or when 30% of transactions are blocked. Given that the throughput characteristic $T(M)$ increases with M , this also means that $T(0.7\bar{M})$ is the maximum system throughput.

57.5.2.3 More General Models

An analytic solution of variable-size transactions with variable step durations showed that the maximum throughput is attained at $\bar{M}_a \approx 0.7M$, as before. The analysis in this case involves a new parameter $\rho = \bar{L}_b/\bar{L}$, which is the ratio of the mean number of locks held by transactions in the blocked state to \bar{L} . In fact, ρ is related to the **conflict ratio** (c_r), which is the ratio of the total number of locks held by transactions and the total number of locks held by active transactions [Weikum et al. 1994]. It is easy to see that $\rho = 1 - 1/c_r$. Analysis of lock traces shows that the critical value for c_r is 1.3, which is in agreement with our analysis that $0.2 \leq \rho \leq 0.3$ or $1.25 \leq c_r \leq 1.33$.

A possible use of the aforementioned parameters (α and β , ρ and the conflict ratio c_r) is that they can be used as load control parameters to avoid thrashing. In fact, the fraction of blocked transactions β is the easiest to measure.

Since the above work was published, more realistic models of lock contention have been introduced. In these, the database is specified as multiple tables with different sizes and transactions are specified by the frequency of their accesses to different tables [Thomasian 1996b]. While it is not difficult to analyze these more complicated models, it is difficult to estimate the parameters.

Index locking can be a source of lock contention unless appropriate locking mechanisms are utilized. The reader is referred to Gray and Reuter [1993] and Weikum and Vossen [2002] for a description of algorithms for dealing with B+-trees. The analysis of several methods is reported in Johnson and Shasha [1993].

57.5.2.4 Further Information

Lazowska et al. [1984] is a good source for the material that we presented here on the issue of hardware resource contention. Other pertinent examples are given in Menasce and Almeida [2000]. Trivedi [2002] is an excellent textbook covering basic probability theory and random processes used in this section.

There are two monographs dealing with data contention. Tay [1987] gives an elegant analysis of the analysis of the no-waiting and blocking methods for strict 2PL. Thomasian [1996a] provides a monograph reviewing his work, while Thomasian [1998b] is a shortened version, which is much more readily available. An analysis of optimistic methods appears in Ryu and Thomasian [1987]. The analysis of locking methods with limited wait depth (WDL methods) appears in Thomasian [1998c], while simulation results are reported in Thomasian [1997].

57.6 Conclusion

Readers who have reached this point should have realized the vastness of this field. The study of transaction processing is a must in the area of Web services, where the field is evolving rapidly.

Due to space limitations, we have not discussed **workflow models**, which have some transactional properties. Business transactions discussed in [Section 57.3.3](#) belong to this category. Several advanced transaction models are described in ElMagarmid [1992].

Data mining extracts information from the data items transacted by a transaction, such as the items purchased in a single visit to a supermarket. **Association rule mining** applied to such “market basket data” has discovered association rules such as the following (at a statistically significant level): “purchases of diapers are accompanied by purchases of beer.” Transaction data is also compiled in summary tables and used for **OLAP (online analytical processing)** [Dunham 2003].

58.1 Introduction

The maturation of database management system (DBMS) technology has coincided with significant developments in distributed computing and parallel processing technologies. The end result is the emergence of **distributed database management systems** and **parallel database management systems**. These systems have become the dominant data management tools for highly data-intensive applications. With the emergence of the Internet as a major networking medium that enabled the subsequent development of the World Wide Web (WWW or Web) and grid computing, distributed and parallel database systems have started to converge.

A parallel computer, or multiprocessor, is itself a distributed system composed of a number of nodes (processors and memories) connected by a fast network within a cabinet. Distributed database technology can be naturally revised and extended to implement parallel database systems, that is, database systems on parallel computers [DeWitt and Gray 1992, Valduriez 1993]. Parallel database systems exploit the parallelism in data management in order to deliver high-performance and high-availability database servers.

This chapter presents an overview of the distributed DBMS and parallel DBMS technologies, highlights the unique characteristics of each, and indicates the similarities between them. This discussion should help establish their unique and complementary roles in data management.

58.2 Underlying Principles

A distributed database (DDB) is a collection of multiple, logically interrelated databases distributed over a computer network. A distributed database management system (distributed DBMS) is then defined as the software system that permits the management of the distributed database and makes the distribution

transparent to the users [Özsu and Valduriez 1999]. These definitions assume that each site logically consists of a single, independent computer. Therefore, each site has its own primary and secondary storage, runs its own operating system (which may be the same or different at different sites), and has the capability to execute applications on its own. The sites are interconnected by a computer network rather than a multiprocessor configuration. The important point here is the emphasis on loose interconnection between processors that have their own operating systems and operate independently.

The database is physically distributed across the data sites by **fragmenting** and **replicating** the data [Ceri et al. 1987]. Given a relational database schema, fragmentation subdivides each relation into horizontal or vertical partitions. *Horizontal fragmentation* of a relation is accomplished by a selection operation that places each tuple of the relation in a different partition based on a fragmentation predicate (e.g., an `EMPLOYEE` relation can be fragmented according to the location of the employees). *Vertical fragmentation*, divides a relation into a number of fragments by projecting over its attributes (e.g., the `EMPLOYEE` relation can be fragmented such that the `Emp_number`, `Emp_name`, and `Address` information is in one fragment, and `Emp_number`, `Salary`, and `Manager` information is in another fragment). Fragmentation is desirable because it enables the placement of data in close proximity to its place of use, thus potentially reducing transmission cost, and it reduces the size of relations that are involved in user queries.

Based on user access patterns, each of the fragments can also be replicated. This is preferable when the same data is accessed from applications that run at a number of sites. In this case, it may be more cost-effective to duplicate the data at a number of sites rather than continuously moving it between them.

In the context of the Web, the above process of defining a database schema that is then fragmented and distributed is not always possible. The data (and the databases) usually exist and one is faced with the problem of providing integrated access to this data. This process is known as *data integration* and is discussed further below.

When the architectural assumption of each site being a (logically) single, independent computer is relaxed, one gets a parallel database system. The differences between a parallel DBMS and a distributed DBMS are somewhat blurred. In particular, shared-nothing parallel DBMS architectures, which we discuss below, are quite similar to the loosely interconnected distributed systems. Parallel DBMSs exploit multiprocessor computer architectures to build high-performance and high-availability database servers at a much lower price than equivalent mainframe computers.

A parallel DBMS can be defined as a DBMS implemented on a multiprocessor computer. This includes many alternatives, ranging from the straightforward porting of an existing DBMS, which may require only rewriting the operating system interface routines, to a sophisticated combination of parallel processing and database system functions into a new hardware/software architecture. As always, we have the traditional trade-off between *portability* (to several platforms) and *efficiency*. The sophisticated approach is better able to fully exploit the opportunities offered by a multiprocessor at the expense of portability.

The solution, therefore, is to use large-scale parallelism to magnify the raw power of individual components by integrating these in a complete system along with the appropriate parallel database software. Using standard hardware components is essential in order to exploit the continuing technological improvements with minimal delay. Then, the database software can exploit the three forms of parallelism inherent in data-intensive application workloads. **Inter-query parallelism** enables the parallel execution of multiple queries generated by concurrent transactions. **Intra-query parallelism** makes the parallel execution of multiple, independent operations (e.g., select operations) possible within the same query. Both inter-query and intra-query parallelism can be obtained using *data partitioning*, which is similar to horizontal fragmentation. Finally, with **intra-operation parallelism**, the same operation can be executed as many sub-operations using *function partitioning* in addition to data partitioning. The set-oriented mode of database languages (e.g., SQL) provides many opportunities for intra-operation parallelism.

There are a number of identifying characteristics of the distributed and parallel DBMS technology:

1. *The distributed/parallel database is a database*, not some “collection” of files that can be individually stored at each node of a computer network. This is the distinction between a DDB and a collection of files managed by a distributed file system. To form a DDB, distributed data should be logically

- related, where the relationship is defined according to some structural formalism (e.g., the relational model), and access to data should be at a high level via a common interface.
2. *The system has the full functionality of a DBMS.* It is neither, as indicated above, a distributed file system, nor is it a transaction processing system. Transaction processing is only one of the functions provided by such a system, which also provides functions such as query processing, structured organization of data, and others that transaction processing systems do not necessarily deal with.
 3. *The distribution (including fragmentation and replication) of data across multiple sites/processors is not visible to the users.* This is called **transparency**. The distributed/parallel database technology extends the concept of *data independence*, which is a central notion of database management, to environments where data is distributed and replicated over a number of machines connected by a network. This is provided by several forms of transparency: *network* (and, therefore, *distribution*) *transparency*, *replication transparency*, and *fragmentation transparency*. Transparent access means that users are provided with a single logical image of the database although it may be physically distributed, enabling them to access the distributed database as if it were a centralized one. In its ideal form, full transparency would imply a query language interface to the distributed/parallel DBMS that is no different from that of a centralized DBMS.

Transparency concerns are more pronounced in the case of distributed DBMSs. There are two fundamental reasons for this. First, the multiprocessor system on which a parallel DBMS is implemented is controlled by a single operating system. Therefore, the operating system can be structured to implement some aspects of DBMS functionality, thereby providing some degree of transparency. Second, software development on parallel systems is supported by parallel programming languages, which can provide further transparency.

In a distributed DBMS, data and the applications that access that data can be localized at the same site, eliminating (or reducing) the need for remote data access that is typical of teleprocessing-based timesharing systems. Furthermore, because each site handles fewer applications and a smaller portion of the database, contention for resources and for data access can be reduced. Finally, the inherent parallelism of distributed systems provides the possibility of inter-query parallelism and intra-query parallelism.

If access to the distributed database consists only of querying (i.e., read-only access), then provision of inter-query and intra-query parallelism would imply that as much of the database as possible should be replicated. However, because most database accesses are not read-only, the mixing of read and update operations requires support for distributed transactions (as discussed in a later section).

High performance is probably the most important objective of parallel DBMSs. In these systems, higher performance can be obtained through several complementary solutions: database-oriented operating system support, parallelism, optimization, and load balancing. Having the operating system constrained and “aware” of the specific database requirements (e.g., buffer management) simplifies the implementation of low-level database functions and therefore decreases their cost. For example, the cost of a message can be significantly reduced to a few hundred instructions by specializing the communication protocol. Parallelism can increase transaction throughput (using inter-query parallelism) and decrease transaction response times (using intra-query and intra-operation parallelism).

Distributed and parallel DBMSs are intended to improve reliability because they have replicated components and thus eliminate single points of failure. The failure of a single site or processor, or the failure of a communication link that makes one or more sites unreachable, is not sufficient to bring down the entire system. Consequently, although some of the data may be unreachable, with proper system design users may be permitted to access other parts of the distributed database. The “proper system design” comes in the form of support for distributed transactions. Providing transaction support requires the implementation of distributed concurrency control and distributed reliability (commit and recovery) protocols, which are reviewed in a later section.

In a distributed or parallel environment, it should be easier to accommodate increasing database sizes or increasing performance demands. Major system overhauls are seldom necessary; expansion can usually be handled by adding more processing and storage power to the system.

Ideally, a parallel DBMS (and to a lesser degree a distributed DBMS) should demonstrate two advantages: **linear scaleup** and **linear speedup**. Linear scaleup refers to a sustained performance for a linear increase in both database size and processing and storage power. Linear speedup refers to a linear increase in performance for a constant database size, and a linear increase in processing and storage power. Furthermore, extending the system should require minimal reorganization of the existing database.

The price/performance characteristics of microprocessors and workstations make it more economical to put together a system of smaller computers with the equivalent power of a single, big machine. Many commercial distributed DBMSs operate on minicomputers and workstations to take advantage of their favorable price/performance characteristics. The current reliance on workstation technology has come about because most commercially distributed DBMSs operate within local area networks for which the workstation technology is most suitable. The emergence of distributed DBMSs that run on wide area networks may increase the importance of mainframes. On the other hand, future distributed DBMSs may support hierarchical organizations where sites consist of clusters of computers communicating over a local area network with a high-speed backbone wide area network connecting the clusters.

58.3 Distributed and Parallel Database Technology

Distributed and parallel DBMSs provide the same functionality as centralized DBMSs except in an environment where data is distributed across the sites on a computer network or across the nodes of a multiprocessor system. As discussed above, users are unaware of data distribution. Thus, these systems provide users with a *logically integrated* view of the *physically distributed* database. Maintaining this view places significant challenges on system functions. We provide an overview of these new challenges in this section. We assume familiarity with basic database management techniques.

58.3.1 Architectural Issues

There are many possible alternatives for distributing data and disseminating it to the users. We characterize the data delivery alternatives along three orthogonal dimensions: delivery modes, regularity of data delivery, and communication methods.

The alternative delivery modes are pull-only, push-only, and hybrid. In the *pull-only* mode of data delivery, the transfer of data from servers to clients is initiated by a client pull. When a client request is received at a server, the server responds by locating the requested information. The main characteristic of pull-based delivery is that the arrival of new data items or updates to existing data items are carried out at a server without notification to clients unless clients explicitly poll the server. Also, in pull-based mode, servers must be interrupted continuously to deal with requests from clients. Furthermore, the information that clients can obtain from a server is limited to when and what clients know to ask for. Conventional DBMSs (including relational and object-oriented ones) offer primarily pull-based data delivery.

In the *push-only* mode of data delivery, the transfer of data from servers to clients is initiated by a server push in the absence of any specific request from clients. The main difficulty in the push-based approach is in deciding which data would be of common interest, and when to send it to clients (periodically, irregularly, or conditionally). Thus, the usefulness of server push depends heavily on the accuracy of a server to predict the needs of clients. In push-based mode, servers disseminate information to either an unbounded set of clients (random broadcast) who can listen to a medium or a selective set of clients (multicast) who belong to some categories of recipients that may receive the data.

The *hybrid* mode of data delivery combines the client-pull and server-push mechanisms. For example, the transfer of information from servers to clients is first initiated by a client pull, and the subsequent transfer of updated information to clients is initiated by a server push [Liu et al. 1996].

There are three typical frequency measurements that can be used to classify the regularity of data delivery: *periodic*, *conditional*, and *ad-hoc* or *irregular*.

In periodic delivery, data is sent from the server to clients at regular intervals. The intervals can be defined by system default or by clients using their profiles. Both pull and push can be performed in periodic fashion.

Periodic delivery is carried out on a regular and prespecified repeating schedule. A client request for IBM's stock price every week is an example of a periodic pull. An example of periodic push is when an application can send out stock price listings on a regular basis, for example, every morning. Periodic push is particularly useful for situations in which clients might not be available at all times, or might be unable to react to what has been sent, such as in the mobile setting where clients can become disconnected.

In conditional delivery, data is sent from servers whenever certain conditions installed by clients in their profiles are satisfied. Such conditions can be as simple as a given time span or as complicated as event-condition-action rules. Conditional delivery is mostly used in the hybrid or push-only delivery systems. Using conditional push, data is sent out according to a prespecified condition, rather than any particular repeating schedule. An application that sends out stock prices only when they change is an example of conditional push. An application that sends out a balance statement only when the total balance is 5% below the predefined balance threshold is an example of hybrid conditional push. Conditional push assumes that changes are critical to the clients, and that clients are always listening and need to respond to what is being sent. Hybrid conditional push further assumes that missing some update information is not crucial to the clients.

Ad-hoc delivery is irregular and is performed mostly in a pure pull-based system. Data is pulled from servers to clients in an ad-hoc fashion whenever clients request it. In contrast, periodic pull arises when a client uses polling to obtain data from servers based on a regular period (schedule).

The third component of the design space of information delivery alternatives is the communication method. These methods determine the various ways in which servers and clients communicate for delivering information to clients. The alternatives are *unicast* and *one-to-many*. In unicast, the communication from a server to a client is one-to-one: the server sends data to one client using a particular delivery mode with some frequency. In one-to-many, as the name implies, the server sends data to a number of clients. Note that we are not referring here to a specific protocol; one-to-many communication can use a multicast or broadcast protocol.

Within this framework, we can identify a number of popular architectural approaches. The popular *client/server architecture* [Orfali et al. 1994] is a pull-only, ad hoc, and unicast data delivery system. The client/server DBMS, in which a number of client machines access a single database server, is the most straightforward one. In which can be called *multiple-client/single-server*, the database management problems are considerably simplified because the database is stored on a single server. The pertinent issues relate to the management of client buffers and the caching of data and (possibly) locks. The data management is done *centrally* at the single server.

A more distributed and more flexible architecture is the *multiple-client/multiple server architecture*, where the database is distributed across multiple servers that must communicate with each other in responding to user queries and in executing transactions. Each client machine has a "home" server to which it directs user requests. The communication of the servers among themselves is transparent to the users. Most current DBMSs implement one or the other type of client server architecture.

A truly distributed DBMS does not distinguish between client and server machines. Ideally, each site can perform the functionality of a client and a server. Such architectures, called *peer-to-peer* (P2P), require sophisticated protocols to manage the data distributed across multiple sites. P2P systems have started to become very popular with the emergence of the Internet as the primary long-haul communication medium and the development of applications such as Napster (for sharing music files) and Gnutella (for sharing general files). These first applications had a simple design with poor scaling and performance. However, newer P2P systems, using distributed hash tables to identify objects over the network, have good scaling characteristics [Balakrishnan et al. 2003]. P2P has many advantages over client server. First, there is no centralized access control. This avoids any kind of bottleneck and makes it possible to scale up to a very large number of sites. P2P systems on the Internet already claim millions of user sites. Second, by replicating data at different sites, P2P systems increase both data availability and performance through parallelism.

The primary objective of a parallel database system is to provide DBMS functions with a better cost/performance. Load balancing (i.e., the ability of the system to divide the workload evenly across all nodes) is crucial for high performance and is more or less difficult, depending on the architecture. Parallel

system architectures range between two extremes — the **shared-memory** and the **shared-nothing** architectures — and a useful intermediate point is the **shared-disk** architecture. Hybrid architectures, such as Non-Uniform Memory Architecture (NUMA) and cluster, can combine the benefits of these architectures.

In the shared-memory approach, any processor has access to any memory module or disk unit through a fast interconnect. Examples of shared-memory parallel database systems include XPRS [Hong 1992], DBS3 [Bergsten et al. 1991], and Volcano [Graefe 1990], as well as portings of major commercial DBMSs on symmetric multiprocessors. Most shared-memory commercial products today can exploit inter-query parallelism to provide high transaction throughput and intra-query parallelism to reduce response time of decision-support queries. Shared-memory makes load balancing simple. But because all data access goes through the shared memory, extensibility and availability are limited.

In the shared-disk approach, any processor has access to any disk unit through the interconnect, but exclusive (non-shared) access to its main memory. Each processor can then access database pages on the shared disk and copy them into its own cache. To avoid conflicting accesses to the same pages, global locking and protocols for the maintenance of cache coherency are needed. Shared-disk provides the advantages of shared-memory with better extensibility and availability, but maintaining cache coherency is complex.

In the shared-nothing approach, each processor has exclusive access to its main memory and disk unit(s). Thus, each node can be viewed as a local site (with its own database and software) in a distributed database system. In particular, a shared-nothing system can be designed as a P2P system [Carey et al. 1994]. The difference between shared-nothing parallel DBMSs and distributed DBMSs is basically one of implementation platform; therefore, most solutions designed for distributed databases can be reused in parallel DBMSs. Shared-nothing has three important virtues: cost, extensibility, and availability. On the other hand, data placement and load balancing are more difficult than with shared-memory or shared-disk. Examples of shared-nothing parallel database systems include the Teradata's DBC and Tandem's NonStopSQL products, as well as a number of prototypes such as BUBBA [Boral et al. 1990], GAMMA [DeWitt et al. 1990], GRACE [Fushimi et al. 1986], and PRISMA [Apers et al. 1992].

To improve extensibility, shared-memory multiprocessors have evolved toward NUMA, which provides a shared-memory programming model in a scalable shared-nothing architecture [Lenoski et al. 1992, Hagersten et al. 1992, Frank et al. 1993]. Because shared-memory and cache coherency are supported by hardware, remote memory access is very efficient, only several times (typically 4 times) the cost of local access. Database techniques designed for shared-memory DBMSs also apply to NUMA [Bouganim et al. 1999].

Cluster architectures (sometimes called hierarchical architectures) combine the flexibility and performance of shared-disk with the high extensibility of shared-nothing [Graefe 1993]. A cluster is defined as a group of servers that act like a single system and enable high availability, load balancing, and parallel processing. Because they provide a cheap alternative to tightly coupled multiprocessors, large clusters of PC servers have been used successfully by Web search engines (e.g., Google). They are also gaining much interest for managing autonomous databases [Röhm et al. 2001, Gañçarski et al. 2002]. This recent trend attests to further convergence between distributed and parallel databases.

58.3.2 Data Integration

Data integration involves the process by which information from multiple data sources can be integrated to form a single cohesive system. This problem has been studied for quite some time, and various names have been given to it over the years (e.g., heterogeneous databases, federated systems, multidatabases), currently settling on the more generic term “data integration,” which recognizes that the data sources do not all have to be databases. These systems are identified by two main characteristics of the data sources: autonomy and heterogeneity. Autonomy indicates the degree to which the individual data sources can operate independently. Each source is free to join and leave the integrated environment and is free to share some or all (or none) of its data or execute some queries but not others. This is an increasingly important issue as Web data sources become more prevalent and as Web data integration gains importance. Heterogeneity can occur in various forms in distributed systems, ranging from hardware heterogeneity and differences in networking

protocols to variations in data sources. The important ones from the perspective of this discussion relate to data sources, in particular their functionality. Not all data sources will be database managers, so they may not even provide the typical database functionality. Even when a number of database managers are considered, heterogeneity can occur in their data models, query languages, and implementation protocols. Representing data with different modeling tools creates heterogeneity because of the inherent expressive powers and limitations of individual data models. Heterogeneity in query languages not only involves the use of completely different data access paradigms in different data models (set-at-a-time access in relational systems vs. record-at-a-time access in network and hierarchical systems), but also covers differences in languages even when the individual systems use the same data model. Different query languages that use the same data model often select very different methods for expressing identical requests. Heterogeneity in implementation techniques and protocols raises issues as to what each systems can and cannot do.

In such an environment, building a system that would provide integrated access to diverse data sources raises challenging architectural, model, and system issues. The dominant architectural model is the *mediator architecture* [Wiederhold 1992], where a middleware system consisting of *mediators* is placed in between data sources and users/applications that access these data sources. Each middleware performs a particular function (provides domain knowledge, reformulates queries, etc.) and the more complex system functions may be composed using multiple mediators. An important mediator is one that reformulates a user query into a set of queries, each of which runs on one data source, with possible additional processing at the mediator to produce the final answer.

Each data source is “wrapped” by *wrappers* that are responsible for providing a common interface to the mediators. The sophistication of each wrapper varies, depending on the functionality provided by the underlying data source. For example, if the data source is not a DBMS, the wrapper may still provide a declarative query interface and perform the translation of these queries into code that is specific to the underlying data source. Wrappers, in a sense, deal with the heterogeneity issues.

To run queries over diverse data sources, a *global schema* must be defined. This can be done either in a bottom-up or top-down fashion. In the bottom-up approach, the global schema is specified in terms of the data sources. Consequently, for each data element in each data source, a data element is defined in the global schema. In the top-down approach, the global schema is defined independent of the data sources, and each data source is treated as a view defined over the global schema. These two approaches are called *global-as-view* and *local-as-view* [Lenzerini 2002]. The details of the methodologies for defining the global schema are outside the bounds of this chapter.

58.3.3 Concurrency Control

Whenever multiple users access (read and write) a shared database, these accesses must be synchronized to ensure database consistency. The synchronization is achieved by means of **concurrency control algorithms** that enforce a correctness criterion such as **serializability**. User accesses are encapsulated as **transactions** [Gray 1981], whose operations at the lowest level are a set of read and write operations to the database. Concurrency control algorithms enforce the **isolation** property of transaction execution, which states that the effects of one transaction on the database are isolated from other transactions until the first completes its execution.

The most popular concurrency control algorithms are **locking**-based. In such schemes, a lock, in either shared or exclusive mode, is placed on some unit of storage (usually a page) whenever a transaction attempts to access it. These locks are placed according to lock compatibility rules such that *read-write*, *write-read*, and *write-write* conflicts are avoided. It is a well-known theorem that if lock actions on behalf of concurrent transactions obey a simple rule, then it is possible to ensure the serializability of these transactions: “No lock on behalf of a transaction should be set once a lock previously held by the transaction is released.” This is known as **two-phase locking** [Gray 1979], because transactions go through a growing phase when they obtain locks and a shrinking phase when they release locks. In general, releasing of locks prior to the end of a transaction is problematic. Thus, most of the locking-based concurrency control algorithms are *strict*, in that they hold on to their locks until the end of the transaction.

In distributed DBMSs, the challenge is to extend both the serializability argument and the concurrency control algorithms to the distributed execution environment. In these systems, the operations of a given transaction can execute at multiple sites where they access data. In such a case, the serializability argument is more difficult to specify and enforce. The complication is due to the fact that the serialization order of the same set of transactions may be different at different sites. Therefore, the execution of a set of distributed transactions is serializable if and only if:

1. The execution of the set of transactions at each site is serializable, *and*
2. The serialization orders of these transactions at all these sites are identical.

Distributed concurrency control algorithms enforce this notion of *global serializability*. In locking-based algorithms, there are three alternative ways of enforcing global serializability: centralized locking, primary copy locking, and distributed locking.

In *centralized locking*, there is a single lock table for the entire distributed database. This lock table is placed, at one of the sites, under the control of a single lock manager. The lock manager is responsible for setting and releasing locks on behalf of transactions. Because all locks are managed at one site, this is similar to centralized concurrency control and it is straightforward to enforce the global serializability rule. These algorithms are simple to implement but suffer from two problems: (1) the central site may become a bottleneck, both because of the amount of work it is expected to perform and because of the traffic that is generated around it; and (2) the system may be less reliable because the failure or inaccessibility of the central site would cause system unavailability.

Primary copy locking is a concurrency control algorithm that is useful in replicated databases where there may be multiple copies of a data item stored at different sites. One of the copies is designated as a primary copy, and it is this copy that has to be locked in order to access that item. The set of primary copies for each data item is known to all the sites in the distributed system, and the lock requests on behalf of transactions are directed to the appropriate primary copy. If the distributed database is not replicated, copy locking degenerates into a distributed locking algorithm. Primary copy locking was proposed for the prototype distributed version of INGRES.

In *distributed* (or *decentralized*) *locking*, the lock management duty is shared by all sites in the system. The execution of a transaction involves the participation and coordination of lock managers at more than one site. Locks are obtained at each site where the transaction accesses a data item. Distributed locking algorithms do not have the overhead of centralized locking ones. However, both the communication overhead to obtain all the locks and the complexity of the algorithm are greater. Distributed locking algorithms are used in System R* and in NonStop SQL.

One side effect of all locking-based concurrency control algorithms is that they cause **deadlocks**. The detection and management of deadlocks in a distributed system is difficult. Nevertheless, the relative simplicity and better performance of locking algorithms make them more popular than alternatives such as *timestamp-based algorithms* or *optimistic concurrency control*. Timestamp-based algorithms execute the conflicting operations of transactions according to their timestamps, which are assigned when the transactions are accepted. Optimistic concurrency control algorithms work from the premise that conflicts among transactions are rare and proceed with executing the transactions up to their termination, at which point a validation is performed. If the validation indicates that serializability would be compromised by the successful completion of that particular transaction, then it is aborted and restarted.

58.3.4 Reliability

We indicated earlier that distributed DBMSs are potentially more reliable because there are multiples of each system component, which eliminates single points of failure. This requires careful system design and the implementation of a number of protocols to deal with system failures.

In a distributed DBMS, four types of failures are possible: *transaction failures*, *site (system) failures*, *media (disk) failures*, and *communication line failures*. Transactions can fail for a number of reasons. Failure can be due to an error in the transaction caused by input data, as well as the detection of a present or potential

deadlock. The usual approach to take in cases of transaction failure is to abort the transaction, resetting the database to its state prior to the start of the database.

Site (or system) failures are due to a hardware failure (e.g., processor, main memory, power supply) or a software failure (e.g., bugs in system or application code). The effect of system failures is the loss of main memory contents. Therefore, any updates to the parts of the database that are in the main memory buffers (also called **volatile database**) are lost as a result of system failures. However, the database that is stored in secondary storage (also called **stable database**) is safe and correct. To achieve this, DBMSs typically employ **logging protocols**, such as *Write-Ahead Logging*, that record changes to the database in system logs and move these log records and the volatile database pages to stable storage at appropriate times. From the perspective of distributed transaction execution, site failures are important because the failed sites cannot participate in the execution of any transaction.

Media failures refer to the failure of secondary storage devices that store the stable database. Typically, these failures are addressed by duplexing storage devices and maintaining archival copies of the database. Media failures are frequently treated as problems local to one site and therefore are not specifically addressed in the reliability mechanisms of distributed DBMSs.

The three types of failures described above are common to both centralized and distributed DBMSs. Communication failures, on the other hand, are unique to distributed systems. There are a number of types of communication failures. The most common ones are errors in the messages, improperly ordered messages, lost (or undelivered) messages, and line failures. Generally, the first two are considered the responsibility of the computer network protocols and are not addressed by the distributed DBMS. The last two, on the other hand, have an impact on the distributed DBMS protocols and therefore need to be considered in the design of these protocols. If one site is expecting a message from another site and this message never arrives, this may be because (1) the message is lost, (2) the line(s) connecting the two sites may be broken, or (3) the site that is supposed to send the message may have failed. Thus, it is not always possible to distinguish between site failures and communication failures. The waiting site simply times out and has to assume that the other site cannot communicate. Distributed DBMS protocols must deal with this uncertainty. One drastic result of line failures may be *network partitioning*, in which the sites form groups where communication within each group is possible but communication across groups is not. This is difficult to deal with in the sense that it may not be possible to make the database available for access while at the same time guaranteeing its consistency.

Two properties of transactions are maintained by reliability protocols: **atomicity** and **durability**. Atomicity requires that either all the operations of a transaction are executed or none of them are (all-or-nothing). Thus, the set of operations contained in a transaction is treated as one atomic unit. Atomicity is maintained even in the face of failures. Durability requires that the effects of successfully completed (i.e., committed) transactions endure subsequent failures.

The enforcement of atomicity and durability requires the implementation of *atomic commitment protocols* and *distributed recovery protocols*. The most popular atomic commitment protocol is **two-phase commit** (2PC). The recoverability protocols are built on top of the local recovery protocols, which are dependent upon the supported mode of interaction (of the DBMS) with the operating system.

Two-phase commit (2PC) is a very simple and elegant protocol that ensures the atomic commitment of distributed transactions. It extends the effects of local atomic commit actions to distributed transactions by insisting that all sites involved in the execution of a distributed transaction agree to commit the transaction before its effects are made permanent (i.e., all sites terminate the transaction in the same manner). If all the sites agree to commit a transaction, then all the actions of the distributed transaction take effect; if one of the sites declines to commit the operations at that site, then all the other sites are required to abort the transaction. Thus, the fundamental 2PC rule states that:

1. If even one site rejects to commit (which means it votes to abort) the transaction, the distributed transaction must be aborted at each site where it executes; *and*
2. If all the sites vote to commit the transaction, the distributed transaction is committed at each site where it executes.

The simple execution of the 2PC protocol is as follows. There is a *coordinator* process at the site where the distributed transaction originates, and *participant* processes at all the other sites where the transaction executes. Initially, the coordinator sends a “prepare” message to all the participants, each of which independently determines whether or not it can commit the transaction at that site. Those that can commit send back a “vote-commit” message, while those that are not able to commit send back a “vote-abort” message. Once a participant registers its vote, it cannot change it. The coordinator collects these messages and determines the fate of the transaction according to the 2PC rule. If the decision is to commit, the coordinator sends a “global-commit” message to all participants. If the decision is to abort, it sends a “global-abort” message to those participants that had earlier voted to commit the transaction. No message needs to be sent to those participants that had originally voted to abort because they can assume, according to the 2PC rule, that the transaction is going to be eventually globally aborted. This is known as the *unilateral abort* option of the participants.

There are two rounds of message exchanges between the coordinator and the participants; hence the name 2PC protocol. There are a number of variations of 2PC, such as linear 2PC and distributed 2PC, that have not found much favor among distributed DBMS implementations. Two important variants of 2PC are the *presumed abort 2PC* and *presumed commit 2PC* [Mohan and Lindsay 1983]. These are important because they reduce the message and I/O overhead of the protocols. Presumed abort protocol is included in the X/Open XA standard and has been adopted as part of the ISO standard for Open Distributed Processing.

An important characteristic of 2PC protocol is its *blocking* nature. Failures can occur during the commit process. As discussed above, the only way to detect these failures is by means of a timeout of the process waiting for a message. When this happens, the process (coordinator or participant) that times out follows a **termination protocol** to determine what to do with the transaction that was in the middle of the commit process. A non-blocking commit protocol is one whose termination protocol can determine what to do with a transaction in case of failures under any circumstance. In the case of 2PC, if a site failure occurs at the coordinator site and one participant site while the coordinator is collecting votes from the participants, the remaining participants cannot determine the fate of the transaction among themselves, and they have to remain blocked until the coordinator or the failed participant recovers. During this period, the locks that are held by the transaction cannot be released, which reduces the availability of the database.

Assume that a participant times out after it sends its commit vote to the coordinator, but before it receives the final decision. In this case, the participant is said to be in *READY* state. The termination protocol for the participant is as follows. First, note that the participant cannot unilaterally reach a termination decision. Because it is in the *READY* state, it must have voted to commit the transaction. Therefore, it cannot now change its vote and unilaterally abort it. On the other hand, it cannot unilaterally decide to commit the transaction because it is possible that another participant may have voted to abort it. In this case, the participant will remain blocked until it can learn from someone (either the coordinator or some other participant) the ultimate fate of the transaction. If we consider a centralized communication structure where the participants cannot communicate with one another, the participant that has timed out has to wait for the coordinator to report the final decision regarding the transaction. Because the coordinator has failed, the participant will remain blocked. In this case, no reasonable termination protocol can be designed.

If the participants can communicate with each other, a more distributed termination protocol can be developed. The participant that times out may simply ask all other participants to help it reach a decision. If during termination, all the participants realize that only the coordinator site has failed, they can elect a new coordinator that can restart the commit process. However, in the case where both a participant site and the coordinator site have failed, it is possible for the failed participant to have received the coordinator’s decision and terminated the transaction accordingly. This decision is unknown to the other participants; thus, if they elect a new coordinator and proceed, there is the danger that they may decide to terminate the transaction differently from the participant at the failed site. The above case demonstrates the blocking nature of 2PC. There have been attempts to devise non-blocking commit protocols (e.g., three-phase commit) but the high overhead of these protocols has precluded their adoption.

The inverse of termination is recovery. When the failed site recovers from the failure, what actions does it have to take to recover the database at that site to a consistent state? This is the domain of distributed

recovery protocols. Consider the recovery side of the case discussed above, in which the coordinator site recovers and the recovery protocol must now determine what to do with the distributed transaction(s) whose execution it was coordinating. The following cases are possible:

1. The coordinator failed before it initiated the commit procedure. Therefore, it will start the commit process upon recovery.
2. The coordinator failed while in the READY state. In this case, the coordinator has sent the “prepare” command. Upon recovery, the coordinator will restart the commit process for the transaction from the beginning by sending the “prepare” message one more time. If the participants had already terminated the transaction, they can inform the coordinator. If they were blocked, they can now resend their earlier votes and resume the commit process.
3. The coordinator failed after it informed the participants of its global decision and terminated the transaction. Thus, upon recovery, it does not need to do anything.

58.3.5 Replication

In replicated distributed databases,* each logical data item has a number of physical instances. For example, the salary of an employee (*logical data item*) may be stored at three sites (*physical copies*). The issue in this type of a database system is to maintain some notion of consistency among the copies. The most discussed consistency criterion is **one copy equivalence**, which asserts that the values of all copies of a logical data item should be identical when the transaction that updates it terminates.

If replication transparency is maintained, transactions will issue read and write operations on a logical data item x . The replica control protocol is responsible for mapping operations on x to operations on physical copies of x (x_1, \dots, x_n). A typical replica control protocol that enforces one copy serializability is known as the **Read-Once/Write-All** (ROWA) protocol. ROWA maps each read on x [Read(x)] to a read on one of the physical copies x_i [Read(x_i)]. The copy that is read is insignificant from the perspective of the replica control protocol and may be determined by performance considerations. On the other hand, each write on logical data item x is mapped to a set of writes on *all* copies of x .

The ROWA protocol is simple and straightforward but requires that all copies of all logical data items that are updated by a transaction be accessible for the transaction to terminate. Failure of one site may block a transaction, reducing database availability.

A number of alternative algorithms have been proposed that reduce the requirement that all copies of a logical data item be updated before the transaction can terminate. They relax ROWA by mapping each write to only a subset of the physical copies.

This idea of possibly updating only a subset of the copies, but nevertheless successfully terminating the transaction, has formed the basis of quorum-based voting for replica control protocols. Votes are assigned to each copy of a logical data item and a transaction that updates that logical data item can successfully complete as long as it has a majority of the votes. Based on this general idea, an early **quorum-based voting algorithm** [Gifford 1979] assigns a (possibly unequal) vote to each copy of a replicated data item. Each operation then has to obtain a *read quorum* (V_r) or a *write quorum* (V_w) to read or write a data item, respectively. If a given data item has a total of V votes, the quorums must obey the following rules:

1. $V_r + V_w > V$ (a data item is not read and written by two transactions concurrently, avoiding the read-write conflict).
2. $V_w > V/2$ (two write operations from two transactions cannot occur concurrently on the same data item thus avoiding write-write conflict).

*Replication is not a significant concern in parallel DBMSs because the data is normally not replicated across multiple processors. Replication may occur as a result of data shipping during query optimization, but this is not managed by the replica control protocols.

The difficulty with this approach is that transactions are required to obtain a quorum even to read data. This significantly and unnecessarily slows down read access to the database. An alternative quorum-based voting protocol that overcomes this serious performance drawback has also been proposed [Abbadi et al. 1985]. However, this protocol makes unrealistic assumptions about the underlying communication system.

Single copy equivalence replication, often called eager replication, is typically implemented using 2PC. Whenever a transaction updates one replica, all other replicas are updated inside the same transaction as a distributed transaction. Therefore, mutual consistency of replicas and strong consistency are enforced. However, it reduces availability as all the nodes must be operational. In addition, synchronous protocols may block due to network or node failures. Finally, to commit a transaction with 2PC, the number of messages exchanged to control transaction commitment is quite significant and, as a consequence, transaction response times may be extended as the number of nodes increases. A solution proposed in Kemme and Alonso [2000] reduces the number of messages exchanged to commit transactions compared to 2PC, but the protocol is still blocking and it is not clear if it scales up. For these reasons, eager replication is less and less used in practice.

Lazy replication is the most widely used form of replication in distributed databases. With lazy replication, a transaction can commit after updating one replica copy at some node. After the transaction commits, the updates are propagated to the other replicas, and these replicas are updated in separate transactions. Different from eager replication, the mutual consistency of replicas is relaxed and strong consistency is not assured. A major virtue of lazy replication is its easy deployment because it avoids all the constraints of eager replication [Gray et al. 1996]. In particular, it can scale up to large configurations such as cluster systems.

In lazy replication, a primary copy is stored at a master node and secondary copies are stored in slave nodes. A primary copy that may be stored at and updated by different master nodes is called a multi-owner copy. These are stored in multi-owner nodes and a multi-master configuration consists of a set of multi-owner nodes on a common set of multi-owner copies. Several configurations such as lazy master, multi-master, and hybrid configurations (combining lazy master and multi-master) are possible. Multi-master replication provides the highest level of data availability: a node failure does not block updates on the replicas it carries. Replication solutions that assure strong consistency for lazy master are proposed in Pacitti et al. [1999], Pacitti et al. [2001], and Pacitti and Simon [2000]. A solution to provide strong consistency for fully replicated multi-master configurations, in the context of cluster systems, is also proposed in Pacitti et al. [2003].

58.3.6 Data Placement

In a parallel database system, proper data placement is essential for load balancing. Ideally, interference between concurrent parallel operations can be avoided by having each operation work on an independent dataset. These independent datasets can be obtained by the *partitioning* of the relations based on a function (hash function or range index) applied to some placement attribute(s), and allocating each partition to a different disk. As with horizontal fragmentation in distributed databases, partitioning is useful to obtain inter-query parallelism, by having independent queries working on different partitions; and intra-query parallelism, by having a query's operations working on different partitions. Partitioning can be single-attribute or multi-attribute. In the latter case [Ghandeharizadeh et al. 1992], an exact match query requiring the equality of multi-attributes can be processed by a single node without communication. The choice between hashing or range index for partitioning is a design issue: hashing incurs less storage overhead but provides direct support for exact-match queries only, while range index can also support range queries. Initially proposed for shared-nothing systems, partitioning has been shown to be useful for shared-memory designs as well, by reducing memory access conflicts [Bergsten et al. 1991].

Full partitioning, whereby each relation is partitioned across all the nodes, causes problems for small relations or systems with large numbers of nodes. A better solution is *variable partitioning*, where each relation is stored on a certain number of nodes as a function of the relation size and access frequency

[Copeland et al. 1988]. This can be combined with multirelation clustering to avoid the communication overhead of binary operations.

When the criteria used for data placement change to the extent that load balancing degrades significantly, dynamic reorganization is required. It is important to perform such dynamic reorganization online (without stopping the incoming of transactions) and efficiently (through parallelism). By contrast, existing database systems perform static reorganization for database tuning [Shasha and Bonnet 2002]. Static reorganization takes place periodically when the system is idle to alter data placement according to changes in either database size or access patterns. In contrast, dynamic reorganization does not need to stop activities and adapts gracefully to changes. Reorganization should also remain transparent to compiled programs that run on the parallel system. In particular, programs should not be recompiled because of reorganization. Therefore, the compiled programs should remain independent of data location. This implies that the actual disk nodes where a relation is stored or where an operation will actually take place can be known only at runtime.

Data placement must also deal with data replication for high availability. A naive approach is to maintain two copies of the same data, a primary and a backup copy, on two separate nodes. However, in case of a node failure, the load of the node having the copy may double, thereby hurting load balancing. To avoid this problem, several high-availability data replication strategies have been proposed [Hsiao and DeWitt 1991]. An interesting solution is Teradata's interleaved partitioning, which partitions the backup copy on a number of nodes. In failure mode, the load of the primary copy is balanced among the backup copy nodes. However, reconstructing the primary copy from its separate backup copies may be costly. In normal mode, maintaining copy consistency may also be costly. A better solution is Gamma's chained partitioning, which stores the primary and backup copy on two adjacent nodes. In failure mode, the load of the failed node and the backup nodes are balanced among all remaining nodes using both primary and backup copy nodes. In addition, maintaining copy consistency is cheaper. Fractured mirrors [Ramamurthy et al. 2002] go one step further in storing the two copies in two different formats, each as is and the other decomposed, in order to improve access performance.

58.3.7 Query Processing and Optimization

Query processing is the process by which a declarative query is translated into low-level data manipulation operations. SQL is the standard query language that is supported in current DBMSs. **Query optimization** refers to the process by which the "best" execution strategy for a given query is found from among a set of alternatives.

In centralized DBMSs, the process typically involves two steps: *query decomposition* and *query optimization*. Query decomposition takes an SQL query and translates it into one expressed in relational algebra. For a given SQL query, there are more than one possible algebraic queries. Some of these algebraic queries are "better" than others. The quality of an algebraic query is defined in terms of expected performance. The traditional procedure is to obtain an initial algebraic query by translating the predicates and the target statement into relational operations as they appear in the query. This initial algebraic query is then transformed, using algebraic transformation rules, into other algebraic queries until the "best" one is found. The "best" algebraic query is determined according to a cost function that calculates the cost of executing the query according to that algebraic specification. This is the process of query optimization.

In distributed DBMSs, two more steps are involved between query decomposition and query optimization: *data localization* and *global query optimization*.

The input to data localization is the initial algebraic query generated by the query decomposition step. The initial algebraic query is specified on global relations irrespective of their fragmentation or distribution. The main role of data localization is to localize the query's data using data distribution information. In this step, the fragments involved in the query are determined and the query is transformed into one that operates on fragments rather than global relations. As indicated earlier, fragmentation is defined through fragmentation rules that can be expressed as relational operations (horizontal fragmentation by selection, vertical fragmentation by projection). A distributed relation can be reconstructed by applying the inverse of

the fragmentation rules. This is called a *localization program*. The localization program for a horizontally (vertically) fragmented query is the union (join) of the fragments. Thus, during the data localization step, each global relation is first replaced by its localization program, and then the resulting fragment query is simplified and restructured to produce another “good” query. Simplification and restructuring may be done according to the same rules used in the decomposition step. As in the decomposition step, the final fragment query is generally far from optimal; the process has only eliminated “bad” algebraic queries.

The input to the third step is a fragment query, that is, an algebraic query on fragments. The goal of query optimization is to find an execution plan for the query which is close to optimal. Remember that finding the optimal solution is computationally intractable. An execution plan for a distributed query can be described with *relational algebra operations* and *communication primitives* (send/receive operations) for transferring data between sites. The previous layers have already optimized the query — for example, by eliminating redundant expressions. However, this optimization is independent of fragment characteristics such as cardinalities. In addition, communication operations are not yet specified. By permuting the ordering of operations within one fragment query, many equivalent query execution plans may be found. Query optimization consists of finding the “best” one among candidate plans examined by the optimizer.* The query optimizer is usually seen as three components: a search space, a cost model, and a search strategy. The *search space* is the set of alternative execution plans to represent the input query. These plans are equivalent, in the sense that they yield the same result but they differ on the execution order of operations and the way these operations are implemented. The *cost model* predicts the cost of a given execution plan. To be accurate, the cost model must have accurate knowledge about the parallel execution environment. The *search strategy* explores the search space and selects the best plan. It defines which plans are examined and in which order.

In a distributed environment, the cost function, often defined in terms of time units, refers to computing resources such as disk space, disk I/Os, buffer space, CPU cost, communication cost, etc. Generally, it is a weighted combination of I/O, CPU, and communication costs. To select the ordering of operations, it is necessary to predict execution costs of alternative candidate orderings. Determining execution costs before query execution (i.e., static optimization) is based on fragment statistics and the formulas for estimating the cardinalities of results of relational operations. Thus, the optimization decisions depend on the available statistics on fragments. An important aspect of query optimization is *join ordering*, because permutations of the joins within the query may lead to improvements of several orders of magnitude. One basic technique for optimizing a sequence of distributed join operations is through use of the semijoin operator. The main value of the semijoin in a distributed system is to reduce the size of the join operands and thus the communication cost.

Parallel query optimization exhibits similarities with distributed query processing. It takes advantage of both intra-operation parallelism and inter-operation parallelism. Intra-operation parallelism is achieved by executing an operation on several nodes of a multiprocessor machine. This requires that the operands have been previously partitioned across the nodes. The set of nodes where a relation is stored is called its *home*. The *home of an operation* is the set of nodes where it is executed and it must be the home of its operands in order for the operation to access its operands. For binary operations such as join, this might imply repartitioning one of the operands. The optimizer might even sometimes find that repartitioning both the operands is useful. Parallel optimization to exploit intra-operation parallelism can make use of some of the techniques devised for distributed databases.

Inter-operation parallelism occurs when two or more operations are executed in parallel, either as a dataflow or independently. We designate as *dataflow* the form of parallelism induced by *pipelining*. *Independent* parallelism occurs when operations are executed at the same time or in arbitrary order. Independent parallelism is possible only when the operations do not involve the same data.

*The difference between an optimal plan and the best plan is that the optimizer does not, because of computational intractability, examine all of the possible plans.

There is a necessary trade-off between optimization cost and quality of the generated execution plans. Higher optimization costs are probably acceptable to produce “better” plans for repetitive queries, because this would reduce query execution cost and amortize the optimization cost over many executions. However, high optimization cost is unacceptable for ad hoc queries, which are executed only once. The optimization cost is mainly incurred by searching the solution space for alternative execution plans. In a parallel system, the solution space can be quite large because of the wide range of distributed execution plans. The crucial issue in terms of search strategy is the join ordering problem, which is NP-complete in the number of relations [Ibaraki and Kameda 1984]. A typical approach to solving the problem is to use dynamic programming [Selinger et al. 1979], which is a *deterministic* strategy. This strategy is almost exhaustive and assures that the best of all plans is found. It incurs an acceptable optimization cost (in terms of time and space) when the number of relations in the query is small. However, this approach becomes too expensive when the number of relations is greater than 5 or 6. For this reason, there is interest in *randomized* strategies, which reduce the optimization complexity but do not guarantee the best of all plans. Randomized strategies investigate the search space in a way that can be fully controlled such that optimization ends after a given optimization time budget has been reached. Another way to cut off optimization complexity is to adopt a heuristic approach. Unlike deterministic strategies, *randomized* strategies allow the optimizer to trade optimization time for execution time [Ioannidis and Wong 1987, Swami and Gupta 1988, Ioannidis and Kang 1990, Lanzelotte et al. 1993].

58.3.8 Load Balancing

Load balancing is distributing the amount of work the parallel system has to do between all nodes so that more work gets done in the same amount of time and, thus, all users get served faster. In a parallel database system, load balancing can be done at three levels: intra-operator, inter-operator, and inter-query.

Load balancing problems can appear with intra-operator parallelism because of the variation in partition size, namely *data skew*. The effects of skewed data distribution on parallel execution are classified in Walton et al. [1991]. *Attribute value skew (AVS)* is skew inherent in the dataset while *tuple placement skew (TPS)* is the skew introduced when the data is initially partitioned (e.g., with range partitioning). *Selectivity skew (SS)* is introduced when there is variation in the selectivity of select predicates on each node. *Redistribution skew (RS)* occurs in the redistribution step between two operators. It is similar to TPS. Finally, *join product skew (JPS)* occurs because the join selectivity may vary between nodes. Capturing these various skews in a static cost model is hard and error-prone. A more reasonable strategy is to use a dynamic approach, that is, redistribute the load dynamically in order to balance execution.

The negative impact of skew on intra-operator parallelism can be reduced with specific algorithms. A robust hash-join algorithm is proposed in Kitsuregawa and Ogawa [1990] for a shared-nothing architecture: the idea is to further partition the large hash buckets among the processors. Another solution [DeWitt et al. 1992] is to have several algorithms, each specialized for a different degree of skew, and to use a small sample of the relations to determine which algorithm is best. Distributed shared memory (implemented by software) can also help load balancing [Shatdal and Naughton 1993]. When a processor is idle, it steals work from a randomly chosen processor using distributed shared memory.

Load balancing at the inter-operator level is more involved [Wilshut et al. 1995]. First, the degree of parallelism and the allocation of processors to operators, decided in the query optimization phase, are based on a static cost model that may be inaccurate. Second, the choice of the degree of parallelism is subject to errors because both processors and operators are discrete entities. Finally, the processors associated with the latest operators in a pipeline chain may remain idle a significant time. This is called the pipeline delay problem. These problems stem from the fixed association between data, operators, and processors.

Thus, the solution is to differ the choice of these associations until runtime with more dynamic strategies. In Mehta and DeWitt [1995], the processors to run each operator are dynamically determined (just prior

to execution) based on a cost model that matches the rate at which tuples are produced and consumed. Other load balancing algorithms are proposed in Rahm and Marek [1995] and Garofalakis and Ioanidis [1996] using statistics on processor usage.

In the context of hierarchical systems (i.e., shared-nothing systems with shared-memory nodes), load balancing is exacerbated because it must be addressed at two levels, locally among the processors of each shared-memory node and globally among all nodes. The *Dynamic Processing (DP)* execution model [Bouganim et al. 1996] proposes a solution for intra- and inter-operator load balancing. The idea is to break the query into self-contained units of sequential processing, each of which can be carried out by any processor. The main advantage is to minimize the communication overhead of inter-node load balancing by maximizing intra- and inter-operator load balancing within shared-memory nodes.

Parallel database systems typically perform load balancing at the operator level (inter- and intra-operator), which is the finest way to optimize the execution of complex queries (with many operators). This is possible only because the database system has full control over the data. However, cluster systems are now being used for managing autonomous databases, for instance, in the context of an application service provider (ASP). In the ASP model, customers' applications and databases are hosted at the provider site and should work as if they were local to the customers' sites. Thus, they should remain autonomous and unchanged after migration to the provider site's cluster. Using a parallel DBMS such as Oracle Rapid Application Cluster or DB2 Parallel Edition is not acceptable because it requires heavy migration and hurts application and database autonomy [Gańczarski et al. 2002]. Given such autonomy requirements, the challenge is to fully exploit the cluster resources, in particular parallelism, in order to optimize performance. In a cluster of autonomous databases, load balancing can only be done at the coarser level of inter-query. In a shared-disk cluster architecture, load balancing is easy and can use a simple round-robin algorithm that selects, in turn, each processor to run an incoming query. The problem is more difficult in the case of a shared-nothing cluster because the queries need be routed to the nodes that hold the requested data. The typical solution is to replicate data at different nodes so that users can be served by any of the nodes, depending on the current load. This also provides high-availability because, in the event of a node failure, other nodes can still do the work. With a replicated database organization, executing update queries in parallel at different nodes can make replicas inconsistent. The solution proposed in Gańczarski et al. [2002] allows the administrator to control the trade-off between consistency and performance based on users' requirements. Load balancing is then achieved by routing queries to the nodes with the required consistency and the least load. To further improve performance of query execution, query routing can also be cache-aware [Röhm et al. 2001]. The idea is to base the routing decision on the states of the node caches in order to minimize disk accesses. In a cluster of autonomous databases (with black-box DBMS components), the main issue is to estimate the cache benefit from executing a query at a node, without any possibility of access to the directory caches. The solution proposed in Röhm et al. [2001] makes use of predicate signatures that approximate the data ranges accessed by a query.

58.4 Research Issues

Distributed and parallel DBMS technologies have matured to the point where fairly sophisticated and reliable commercial systems are now available. As expected, there are a number of issues that have yet to be satisfactorily resolved. In this section we provide an overview of some of the more important research issues.

58.4.1 Mobile Databases

Mobile computing promises to access information anywhere on the network, anytime, and from any kind of mobile appliance (digital assistant, cellular phone, smartcard, etc.). Such information ubiquity makes it possible to envision new personal and professional applications that will have a strong impact on

distributed information systems. For instance, traveling employees could access, wherever they are, their company's or co-workers' data. Distributed database technologies have been designed for fixed clients and servers connected by a wired network. The properties of mobile environments (low bandwidths of wireless networks, frequent disconnections, limited power of mobile appliances, etc.) change radically the assumptions underlying these technologies. Mobile database management (i.e., providing database functions in a mobile environment) is thus becoming a major research challenge [Helal et al. 2002]. In this section, we only mention the specific issues of distributed data management, and we ignore other important issues such as scaling down database techniques to build picoDBMS that fit in a very small device [Pucheral et al. 2001].

New distributed architectures must be designed that encompass the various levels of mobility (mobile user, mobile data, etc.) and wireless networks with handheld (lightweight) terminals, connected to much faster wire networks with database servers. Various distributed database components must be defined for the mobile environment, for example clients, data sources and wrappers, mediators, client proxies (representing mobile clients on the wire network), mediator proxies (representing the mediator on the mobile clients), etc.

Traditional client server and three-tier models are not well suited to mobile environments as servers are central points of failure and bottlenecks. Other models are better. For example, the publish-subscribe model enables clients to be notified only when an event corresponding to a subscription is published. Or a server could repeatedly broadcast information to clients who will eventually listen. These models can better optimize the bandwidth and deal with disconnections. One major issue is to scale up to very large numbers of clients.

Localizing mobile clients (e.g., cellular phones) and data accessed by the clients requires databases that deal with moving objects. Capturing moving objects efficiently is a difficult problem because it must take into account spatial and temporal dimensions, and impacts query processing.

Mobile computing suggests connected and disconnected working phases, with asynchronously replicated data. The replication model is typically symmetric (multi-master) between the mobile client and the database server, with copy divergence after disconnection. Copy synchronization is thus necessary after reconnection. Open problems are the definition of a generic synchronization model, for all kinds of objects, and the scaling up of the reconciliation algorithms.

Synchronization protocols guarantee a limited degree of copy consistency. However, there may be applications that need stronger consistency with ACID properties. In this case, transactions could be started on mobile clients and their execution distributed between clients and servers. The possible disconnection of mobile clients and the unbounded duration of disconnection suggests reconsideration of the traditional distributed algorithms to support the ACID properties.

58.4.2 Large-Scale Query Processing

Database technology is now mature enough to support all kinds of data, including complex structured documents and multimedia objects. Distributed and parallel technologies now make it possible to build very large-scale systems, for example, connecting millions of sites over the Web or thousands of nodes in shared-nothing cluster systems. These combined advances are creating the need for large-scale distributed database systems that federate very large numbers of autonomous databases. The number of potential users, some with handheld devices, is also growing exponentially. This makes query processing a very challenging problem.

Distributed query processing typically performs static query optimization, using a cost model, followed by query execution. We already discussed the problems of static query optimization in parallel database systems (skew data distributions, inaccurate estimates, etc.) that can make execution plans inefficient and some solutions. In a large-scale federated system, these problems are exacerbated by the fact that autonomous databases do not easily export cost-based information. Furthermore, workloads submitted by large communities of users are highly unpredictable. Another problem is the need to deal with data and programs in a more integrated way. In scientific applications, for example, a common

requirement [Tanaka and Valduriez 2001] is the ability to process over the network data objects that can be very large (e.g., satellite images) by scientific user programs that can be very long running (e.g., image analysis). User programs can be simply modeled as expensive user-defined predicates and included in SQL-like queries. In this context, static query optimization does not work. In particular, predicates are evaluated over program execution results that do not exist beforehand. Furthermore, program inputs (e.g., satellite images) range within an unconstrained domain, which makes statistical estimation difficult.

To adapt to runtime conditions, fully dynamic query processing techniques are needed, which requires us to completely revisit more than two decades of query optimizer technology. The technique proposed in Bouganim et al. [2001] for mediator systems adapts to the variances in estimated selectivity and cost of expensive predicates and supports nonuniform data distributions. It also exploits parallelism. Eddies [Avnur and Hellerstein 2000] have also been proposed as an adaptive query execution framework where query optimization and execution are completely mixed. Data is directed toward query operators, depending on their actual consume/produce efficiency. Eddies can also be used to dynamically process expensive predicates. More work is needed to introduce learning capabilities within dynamic query optimization.

Another area that requires much more work is load balancing. Trading consistency for performance based on user requirements is a promising approach [Gançarski et al. 2002]. It should be useful in many P2P applications where consistency is not a prime requirement.

Finally, introducing query and query processing capabilities within P2P Systems presents new challenges [Harren et al. 2002]. Current P2P systems on the Web employ a distributed hash table (DHT) to locate objects in a scalable way. However, DHT is good only for exact-match. More work is needed to extend the current techniques to support complex query capabilities.

58.5 Summary

Distributed and parallel DBMSs have become a reality. They provide the functionality of centralized DBMSs, but in an environment where data is distributed over the sites of a computer network or the nodes of a multiprocessor system. Distributed databases have enabled the natural growth and expansion of databases by the simple addition of new machines. The price-performance characteristics of these systems are favorable, in part due to the advances in computer network technology. Parallel DBMSs are perhaps the only realistic approach to meet the performance requirements of a variety of important applications that place significant throughput demands on the DBMS. To meet these requirements, distributed and parallel DBMSs need to be designed with special consideration for the protocols and strategies. In this chapter, we have provided an overview of these protocols and strategies.

One issue that we omitted is distributed object-oriented databases. The penetration of database management technology into areas (e.g., engineering databases, multimedia systems, geographic information systems, image databases) that relational database systems were not designed to serve has given rise to a search for new system models and architectures. A primary candidate for meeting the requirements of these systems is the object-oriented DBMS [Dogac et al. 1994]. The distribution of object-oriented DBMSs gives rise to a number of issues generally categorized as distributed object management [Özsu et al. 1994]. We have ignored both multidatabase system and distributed object management issues in this chapter.

Defining Terms

Atomicity: The property of transaction processing whereby either all the operations of a transaction are executed or none of them are (all-or-nothing).

Client/server architecture: A distributed/parallel DBMS architecture where a set of client machines with limited functionality access a set of servers that manage data.

Concurrency control algorithm: An algorithms that synchronizes the operations of concurrent transactions that execute on a shared database.

Data independence: The immunity of application programs and queries to changes in the physical organization (physical data independence) or logical organization (logical data independence) of the database, and vice versa.

Deadlock: An occurrence where each transaction in a set of transactions circularly waits on locks that are held by other transactions in the set.

Distributed database management system: A database management system that manages a database that is distributed across the nodes of a computer network and makes this distribution transparent to the users.

Durability: The property of transaction processing whereby the effects of successfully completed (i.e., committed) transactions endure subsequent failures.

Inter-query parallelism: The parallel execution of multiple queries generated by concurrent transactions.

Intra-operation parallelism: The execution of one relational operation as many sub-operations.

Intra-query parallelism: The parallel execution of multiple, independent operations possible within the same query.

Isolation: The property of transaction execution that states that the effects of one transaction on the database are isolated from other transactions until the first completes its execution.

Linear scaleup: Sustained performance for a linear increase in both database size and processing and storage power.

Linear speedup: Linear increase in performance for a constant database size and linear increase in processing and storage power.

Locking: A method of concurrency control where locks are placed on database units (e.g., pages) on behalf of transactions that attempt to access them.

Logging protocol: The protocol that records, in a separate location, the changes that a transaction makes to the database before the change is actually made.

One copy equivalence: Replica control policy that asserts that the values of all copies of a logical data item should be identical when the transaction that updates that item terminates.

Parallel database management system: A database management system that is implemented on a tightly coupled multiprocessor.

Query optimization: The process by which the “best” execution plan for a given query is found from among a set of alternatives.

Query processing: The process by which a declarative query is translated into low-level data manipulation operations.

Quorum-based voting algorithm: A replica control protocol where transactions collect votes to read and write copies of data items. They are permitted to read or write data items if they can collect a quorum of votes.

Read-Once/Write-All protocol: The replica control protocol that maps each logical read operation to a read on one of the physical copies and maps a logical write operation to a write on all of the physical copies.

Serializability: The concurrency control correctness criterion that requires that the concurrent execution of a set of transactions should be equivalent to the effect of some serial execution of those transactions.

Shared-disk architecture: A parallel DBMS architecture where any processor has access to any disk unit through the interconnect but exclusive (non-shared) access to its main memory.

Shared-memory architecture: A parallel DBMS architecture where any processor has access to any memory module or disk unit through a fast interconnect (e.g., a high-speed bus or a cross-bar switch).

Shared-nothing architecture: A parallel DBMS architecture where each processor has exclusive access to its main memory and disk unit(s).

Stable database: The portion of the database that is stored in secondary storage.

Termination protocol: A protocol by which individual sites can decide how to terminate a particular transaction when they cannot communicate with other sites where the transaction executes.

Transaction: A unit of consistent and atomic execution against the database.

- Transparency:** Extension of data independence to distributed systems by hiding the distribution, fragmentation, and replication of data from the users.
- Two-phase commit:** An atomic commitment protocol that ensures that a transaction is terminated the same way at every site where it executes. The name comes from the fact that two rounds of messages are exchanged during this process.
- Two-phase locking:** A locking algorithm where transactions are not allowed to request new locks once they release a previously held lock.
- Volatile database:** The portion of the database that is stored in main memory buffers.

Further Information

There are two current textbooks on distributed and parallel databases. One is our book [Özsu and Valduriez 1999] and the other book is Bell and Grimson [1992]. The first serious book on this topic was Ceri and Pelagatti [1984], which is now quite dated. Our paper [Özsu and Valduriez 1991], which is

a companion to our book, discusses many open problems in distributed databases. Two basic papers on parallel database systems are DeWitt and Gray [1992] and Valduriez [1993].

There are a number of more specific texts. On query processing, Freytag et al. [1993] provide an overview of many of the more recent research results. Elmagarmid [1992] has descriptions of a number of advanced transaction models. Gray and Reuter [1993] provide an excellent overview of building transaction managers. Another classical textbook on transaction processing is Bernstein and Newcomer [1997]. These books cover both concurrency control and reliability.

59.1 Introduction

With rapidly growing collections of images, news programs, music videos, movies, digital television programs, and training and education videos on the Internet and corporate intranets, new tools are needed to harness digital media for different applications ranging from image and video cataloging, media archival and search, multimedia authoring and synthesis, and smart browsing. In recent years, we have witnessed the growing momentum in building systems that can query and search video collections efficiently and accurately for desired video segments just in the manner text search engines on the Web have enabled easy retrieval of documents containing a required piece of text located on a server anywhere in the world. The digital video archival and management systems are also important to broadcast studios, post-production

houses, stock footage houses, and advertising agencies working with large videotape and multimedia collections, to enable integration of content in their end-to-end business processes. Further, because the digital form of videos enables rapid content editing, manipulation, and synthesis, there is burgeoning interest in building cheap, personal desktop video production tools.

An image and video content management system must allow archival, processing, editing, manipulation, browsing, and search and retrieval of image and video data for content repurposing, new program production, and other multimedia interactive services. Annotating or describing images and videos manually through a preview of the material is extremely time consuming, expensive, and unscalable with formidable data accumulation. A content management system, for example, in a digital television studio serves many sets of people, ranging from the program producer who often needs to locate material from the studio archive, to the writer who needs to write a story about the airing segment, the editor who needs to edit in the desired clip, the librarian who adds and manages new material in the archive, and the logger who actually annotates the material in terms of its metadata such as medium ID, production details, and other pertinent information about the content that enables locating it easily. Therefore, a content management tool must be scalable and highly available, ensure integrity of content, and enable easy and quick retrieval of archived material for content reuse and distribution. Automatic extraction of image and video content descriptions is highly desirable to ease the pain of manual annotation and to result in a consistent language of content description when annotating large video collections.

To answer user queries during media search, it is crucial to define a suitable representation for the media, their metadata, and the operations to be applied to them. The aim of a data model is to introduce an abstraction between the physical level (data files and indexes) and the conceptual representation, together with some operations to manipulate the data. The conceptual representation corresponds to the conceptual level in the ANSI relational database architecture [1] where algebraic optimizations and algorithm selections are performed. Optimizations at the physical level (data files and indexes) consist of defining indexes and selecting the right access methods to be used in query processing.

This chapter surveys techniques used to extract descriptions of multimedia data (mainly image, audio and video) through automated analysis and current database solutions in managing, indexing, and querying of multimedia data. The chapter is divided in two parts: multimedia data analysis and database techniques for multimedia. The multimedia data analysis part is composed of Section 59.2, which presents common features used in image databases and the techniques to extract them automatically, and Section 59.3, which discusses audio and video analysis and extraction of audiovisual descriptions. Section 59.4 then describes the problem of semantic gap in multimedia content management systems and emerging approaches to address this critical issue. The second part comprises Section 59.5, which presents some image database models; Section 59.6, which discusses video database models; Section 59.7, which describes multidimensional indexes; and Section 59.8, which discusses issues in processing multimedia queries. Section 59.9 gives an overview of the emerging multimedia content description standard. Finally, Section 59.10 concludes the chapter.

59.2 Image Content Analysis

Existing work in image content analysis can be coarsely categorized into two groups based on the features employed. The first group indexes an image based on low-level features such as color, texture, and shape, while the second group attempts to understand the image's semantic content by using mid- to high-level features and by applying more complex analysis models. Representative work in both groups is surveyed below.

59.2.1 Low-Level Image Content Analysis

Research in this area proposes to index images based on low-level features that are easy to extract and fast to implement. Some well-known content-based image retrieval (CBIR) systems such as QBIC [2], MARS [3], WebSEEK [4], and Photobook [5] have employed these features for image indexing, browsing,

and retrieval with reasonable performance achieved. However, due to the low-level nature of these features, there still exists a gap between the information revealed by these features and the real image semantics. Obviously, more high-level features are needed to truly understand the image content. Below we review some commonly used image features, including color, texture, and shape.

59.2.1.1 Color

Color is one of the most recognizable elements of image content, and is widely used as a feature for image retrieval because of its invariance to image scaling, translation, and rotation. Key issues in color feature extraction include the selection of color space and the choice of color quantization scheme.

A color space is a multidimensional space in which different dimensions represent different color components. Theoretically, any color can be represented by a linear combination of the three primary colors, the red (R), the green (G), and the blue (B). However, the RGB color space is not perceptually uniform; that is, equal distances in different areas and along different dimensions of this space do not correspond to equal perception of color dissimilarity. Therefore, some other color spaces such as the CIELAB and CIEL*u*v* have been proposed. Other widely used color spaces include YCbCr, YIQ, YUV, HSV, and Munsell spaces. The MPEG-7 standard [6], which is formally known as “Multimedia Content Description Interface,” has adopted the RGB, YCbCr, HMMMD, Monochrome, and HSV color spaces, as well as some linear transformation matrices with reference to RGB. Readers are referred to [7] for more detailed descriptions on color spaces.

Color quantization is used to reduce the color resolution of an image. Because a color space, where each color is represented by 24 bits, contains 2^{24} distinct colors, using a quantized color map can considerably decrease the computational complexity in color feature extraction. The commonly used color quantization schemes include uniform quantization, vector quantization, tree-structured vector quantization, and product quantization. MPEG-7 supports linear, nonlinear, and lookup table quantization types.

Three widely used color features (also called color descriptors in MPEG-7) for images are global color histogram, local color histogram, and dominant color. The global color histogram captures the color content of the entire image while ignoring information on the colors’ spatial layout. Specifically, a global color histogram represents an image I by an N -dimensional vector $H(I) = [H(I, j), j = 1, 2, \dots, N]$, where N is the total number of quantized colors and $H(I, j)$ is the number of pixels having color j .

In contrast, the local color histogram representation considers the position and size of each individual image region so as to describe the spatial structure of image colors. For instance, Stricker and Dimai [8] segmented each image into five non-overlapping spatial regions, from which color features were extracted and subsequently used for image matching. In [9], a scalable blob histogram was proposed, where the term *blob* denotes a group of pixels with a homogeneous color. This descriptor is able to distinguish images, which contain objects of different sizes and shapes, from each other without performing color segmentation.

The dominant color representation is considered one of the major color descriptors in MPEG-7 because of its simplicity and association with human perception. Various algorithms have been proposed to extract this feature. For instance, Ohm et al. took color clusters’ means (i.e., the cluster centroids) as the image’s dominant colors [10]. Considering that human eyes are more sensitive to the changes in smooth regions than those in detailed ones, Deng et al. proposed to extract dominant colors by hierarchically merging similar and unimportant color clusters while leaving distinct and more important clusters untouched [11].

Some other commonly used color feature representations include color moments and color sets, which have been adopted to overcome undesirable color quantization effects.

59.2.1.2 Texture

Texture refers to visual patterns with properties of homogeneity that do not result from the presence of only a single color or intensity. Tree barks, clouds, water, bricks, and fabrics are some examples. Typical texture features include contrast, uniformity, coarseness, roughness, frequency, density, and directionality, which contain important information about the structural arrangement of surfaces as well as their relationship to the surrounding environment. So far, many research efforts have been reported on texture analysis due

to its usefulness and effectiveness in applications such as pattern recognition, computer vision, and image retrieval.

There are two basic types of texture descriptors: statistical model-based and transform-based. The first approach explores the gray-level spatial dependence of textures and extracts meaningful statistics as texture representation. For instance, Haralick et al. proposed to represent textures using a co-occurrence matrix [12], where the gray-level spatial dependence of texture was explored. Moreover, they also did Line-Angle-Ratio statistics by analyzing the spatial relationships of lines as well as the properties of their surroundings. Interestingly, Tamura et al. addressed this topic from a totally different viewpoint [13]. In particular, based on psychological measurements, they claimed that the six basic textural features should be coarseness, contrast, directionality, line-likeness, regularity, and roughness. Two well-known CBIR systems namely, the QBIC and the MARS systems, have adopted this representation. Some other work has chosen to use a subset of the above six features, such as the contrast, coarseness, and directionality, for texture classification and recognition purposes.

Some commonly used transforms for transform-based texture extraction include DCT (Discrete Cosine Transform), Fourier-Mellin transform, Polar Fourier transform, Gabor, and wavelet transform. Alata et al. [14] proposed to classify rotated and scaled textures using a combination of Fourier-Mellin transform and a parametric two-dimensional spectrum estimation method (Harmonic Mean Horizontal Vertical). In [15], Wan and Kuo reported their work on texture feature extraction for JPEG images based on the analysis of DCT-AC coefficients. Chang and Kuo [16] presented a tree-structured wavelet transform that provided a natural and effective way to describe textures that have dominant middle- to high-frequency subbands. Readers are referred to [7] for detailed descriptions of texture feature extraction.

59.2.1.3 Shape

Compared to color and texture, the shape feature is less developed due to the inherent complexity of representing it. Two major steps are required to extract a shape feature: object segmentation and shape representation.

Object segmentation has been studied for decades, yet it remains a very difficult research area in computer vision. Some existing image segmentation techniques include the global threshold-based approach, the region growing approach, the split and merge approach, the edge detection-based approach, the color- and texture-based approach, and the model-based approach. Generally speaking, it is difficult to achieve perfect segmentation results due to the complexity of individual object shapes, as well as the existence of shadows and noise.

Existing shape representation approaches could be categorized into the following three classes: the boundary-based representation, the region-based representation, and their combination.

The boundary-based representation emphasizes the closed curve that surrounds the shape. Numerous models have been proposed to describe this curve, which include the chain code, polygons, circular arcs, splines, explicit and implicit polynomials, boundary Fourier descriptor, and UNL descriptor. Because digitization noise can significantly affect this approach, some robust approaches have been proposed.

The region-based representation, on the other hand, emphasizes the area within the closed boundary. Various descriptors have been proposed to model the interior regions, such as the moment invariants, Zernike moments, morphological descriptor, and pseudo-Zernike moments. Generally speaking, region-based moments are invariant to an image's affine transformations. Readers are referred to [17] for more details.

Recent work in shape representation includes the finite element method (FEM), the turning function, and the wavelet descriptor. Moreover, in addition to the above work in two-dimensional shape representation, there are also some research efforts on three-dimensional shape representation. Readers are referred to [7] for more detailed discussions on shape features.

Each descriptor, whether boundary based or region based, is intuitively appealing and corresponding to a perceptually meaningful dimension. Clearly, they could be used either independently or jointly. Although the two representations are interchangeable in the sense of information content, the issue of which aspects

of shape have been made explicit matters to the subsequent phases of the computation. Shape features represented explicitly will generally achieve more efficient retrieval when these particular features are queried [7].

59.2.2 Mid- to High-Level Image Content Analysis

Research in this area attempts to index images based on their content semantics such as salient image objects. To achieve this goal, various mid- to high-level image features, as well as more complex analysis models, have been proposed.

One good attempt was reported in [11], where a low-dimensional color indexing scheme was proposed based on homogeneous image regions. Specifically, it first applied a color segmentation approach, called JSEG, to obtain homogeneous regions; then colors within each region were quantized and grouped into a small number of clusters. Finally, color centroids as well as their percentages were used as features descriptors.

More recent work starts to understand image content by learning its semantic concepts. For instance, Minka and Picard [18] developed a system that first generated segmentations or groups of image regions using various feature combinations; then they learned from a user's input to decide which combinations best represented predetermined semantic categories. This system, however, requires supervised training for various parts of the image. In contrast, Li et al. proposed to detect salient image regions based on segmented color and orientation maps without any human intervention [19].

The Stanford SIMPLIcity system, presented in [20], applied statistical classification methods to group images into coarse semantic classes such as textured vs. non-textured and graph vs. photograph. This approach is, however, problem specific and does not extend directly to other domains. Targeting automatic linguistic indexing of pictures, Li and Wang introduced statistical modeling in their work [21]. Specifically, they first employed two-dimensional multi-resolution hidden Markov models (2-D MHMMs) to represent meaningful image concepts such as "snow," "autumn," and "people." Then, to measure the association between the image and concept, they calculated the image occurrence likelihood from its characterizing stochastic process. A high likelihood would then indicate a strong association.

Targeting a moderately large lexicon of semantic concepts, Naphade et al. proposed an SVM-based learning system for detecting 34 visual concepts, which include 15 scene concepts (e.g., outdoors, indoors, landscape, cityscape, sky, beach, mountain, and land) and 19 object concepts (e.g., face, people, road, building, tree, animal, text overlay, and train) [22]. Using TREC 2002 benchmark corpus for training and validation, this system has achieved reasonable performance with moderately large training samples.

59.3 Video Content Analysis

Video content analysis, which consists of both visual content analysis and audio content analysis, has attracted enormous interest in both academic and corporate research communities. This research appeal, in turn, further brings areas that are primarily built upon content analysis modules such as video abstraction, video browsing, and video retrieval, to be actively developed. In this section, a comprehensive survey of all these research topics is presented.

59.3.1 Visual Content Analysis

The first step in video content analysis is to extract its content structure, which could be represented by a hierarchical tree exemplified in [Figure 59.1](#) [23]. As shown, given a continuous video bitstream, we first segment it into a series of cascaded video *shots*, where a shot contains a set of contiguously recorded image frames. Because the content within a shot is always continuous, in most cases, one or more frames, which are known as *keyframes*, can be extracted to represent its underlying content. However, while the shot forms the building block of a video sequence, this low-level structure does not directly correspond to the

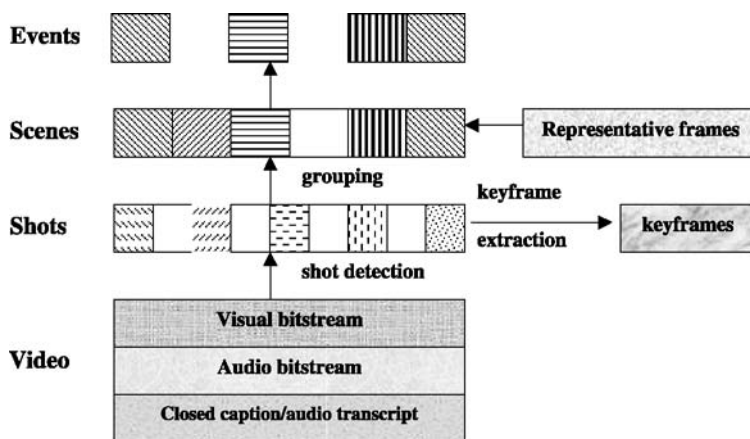

FIGURE 59.1 A hierarchical representation of video content.

video semantics. Moreover, this processing often leads to a far too fine segmentation of the video data in terms of its semantics.

Therefore, most recent work tends to understand the video semantics by extracting the underlying video scenes, where a *scene* is defined as a collection of semantically related and temporally adjacent shots that depicts and conveys a high-level concept or story. A common solution to video scene extraction is to group semantically related shots into a scene.

Nevertheless, not every scene contains a meaningful theme. For example, in feature films, there are certain scenes that are only used to establish story environment; thus, they do not contain any thematic topics. Therefore, it is necessary to find important scenes that contain specific thematic topics such as dialogs or sports highlights. Such a video unit is called an *event* in this chapter.

Previous work on the detection of video shots, scenes, and events is reviewed in this section.

59.3.1.1 Video Shot Detection

A shot can be detected by capturing camera transitions, which could be either abrupt or gradual. An abrupt transition is also called a camera break or cut, where a significant content change occurs between two consecutive frames. In contrast, a gradual transition is usually caused by some special effects such as dissolve, wipe, fade-in, and fade-out, where a smooth content change is observed over a set of consecutive frames.

Existing work in shot detection can be generally categorized into the following five classes: pixel based, histogram based, feature based, statistics based, and transform based. In particular, the pixel-based approach detects the shot change by counting the number of pixels that have changed from one frame to the next. While this approach gives the simplest way to detect the content change between two frames, it is too sensitive to object and camera motions. As a result, the histogram-based approach, which detects the content change by comparing the histogram of neighboring frames, has gained more popularity as histograms are invariant to image rotation, scaling, and transition. In fact, it has been reported that this approach can achieve good trade-off between the accuracy and speed. Many research efforts have been reported along this direction [24].

A feature-based shot detection approach was proposed in [25], where the intensity edges between two consecutive frames were analyzed. It was claimed by the authors that, during the cut and dissolve operations, new intensity edges would appear far away from the old ones; thus, by counting the new and old edge pixels, the shot transitions could be detected and classified. In [26], a visual rhythm-based approach was proposed where a visual rhythm is a special two-dimensional image reduced from a three-dimensional video such that its pixels along a vertical line are the pixels uniformly sampled along the diagonal line of

a video frame. Some other technologies such as image segmentation and object tracking have also been employed to detect the shot boundary.

Kasturi and Jain developed a statistics-based approach in which the mean and standard deviations of pixel intensities were used as features for shot boundary detection [27]. To avoid manually determining the threshold, Boreczky and Wilcox built a Hidden Markov Model (HMM) to model shot transitions where audio cepstral coefficients and color histogram differences were used as features [28].

To accommodate the trend that an increasing amount of video data is currently stored and transmitted in compressed form, transform-based approaches have been proposed where video shots are directly detected in the compressed domain. In this case, the processing could be greatly sped up because no full-frame decompression is needed. Among reported work in this domain, the DCT (Discrete Cosine Transform) and wavelet transform are the two most frequently used approaches.

Compared to the large amount of work on cut detection, little work has been directed toward the gradual transition detection due to its complex nature. A “twin-comparison” algorithm was proposed in [29] where two thresholds were utilized to capture the minor content change during the shot transition. To detect the dissolve effect, past research efforts have mainly focused on finding the relations between the dissolve formula and the statistics of interpolated MBs (Macroblocks) in P- and B-frames. Similar work was also reported for wipe detection, yet with special considerations on various wipe shapes, directions, and patterns. Clearly, in the case of gradual transition detection, algorithms developed for one type of effect may not work for another.

A detailed evaluation and comparison of several popular shot detection algorithms can be found in [30], where both abrupt and gradual transitions have been studied.

59.3.1.2 Video Scene and Event Detection

Existing scene detection approaches can be classified into the following two categories: the model-based approach and the model-free approach. In the former case, specific structure models are usually built up to model specific video applications by exploiting their scene characteristics, discernible logos, or marks. For instance, in [31], temporal and spatial structures were defined to parse TV news, where the temporal structure was modeled by a series of shots, including anchorperson shots, news shots, commercial break shots, and weather forecast shots. Meanwhile, the spatial structure was modeled by four frame templates with each containing either two anchorpersons, one anchorperson, one anchorperson with an upper-right news icon, or one anchorperson with an upper-left news icon. Some other work along this direction has tried to integrate multiple media cues such as visual, audio, and text (closed captions or audio transcripts) to extract scenes from real TV programs.

The model-based approach has also been applied to analyze sports video because a sports video can be characterized by a predictable temporal syntax, recurrent events with consistent features, and a fixed number of views. For instance, Zhong and Chang proposed to analyze tennis and baseball videos by integrating domain-specific knowledge, supervised machine learning techniques, and automatic feature analysis at multiple levels [32].

Compared to the model-based approach, which has very limited application areas, the model-free approach can be applied to very generic applications. Work in this area can be categorized into three classes according to the use of visual, audio, or both audiovisual cues. Specifically, in visual-based approaches, the color or motion information is utilized to locate the scene boundary. For instance, Yeung et al. proposed to detect scenes by grouping visually similar and temporally close shots [33]. Moreover, they also constructed a Scene Transition Graph (STG) to represent the detected scene structure. Compressed video sequences were used in their experiments. Some other work in this area has applied the cophenetic dissimilarity criterion or a set of heuristic rules to determine the scene boundary.

Pure audio-based work was reported in [34], where the original video was segmented into a sequence of audio scenes such as speech, silence, music, speech with music, song, and environmental sound based on low-level audio features. In [35], sound tracks in films and their indexical semiotic usage were studied based on an audio classification system that could detect complex sound scenes as well as the constituent

sound events in cinema. Specifically, it has studied the car chase and the violence scenes for action movies based on the detection of their characteristic sound events such as horns, sirens, car crashes, tires skidding, glass breaking, explosions, and gunshots.

However, due to the difficulty of precisely locating the scene boundaries based on pure audio cues, more recent work starts to integrate multiple media modalities for more robust results. For instance, three types of media cues, including audio, visual, and motion, were employed by [36] to extract semantic video scenes from broadcast news. Sundaram and Chang reported their work on extracting computable scenes in films by utilizing audiovisual memory models. Two types of scenes, namely, N-type and M-type, were considered, where the N-type scene was further classified into pure dialog, progressive, and hybrid [37]. A good integration of audio and visual cues was reported in [38], where audio cues, including ambient noise, background music, and speech, were cooperatively evaluated with visual features extraction in order to precisely locate the scene boundary. Special movie editing patterns were also considered in this work.

Compared to the large amount of work on scene detection, little attention has been paid to event detection. Moreover, because event is a subjectively defined concept, different work may assign it different meanings. For instance, it could be the highlight of a sports video or an interesting topic in a video document. In [39], a query-driven approach was presented to detect topics of discussion events by using image and text contents of query foils (slide) found in a lecture. While multiple media sources were integrated in their framework, identification results were mainly evaluated in the domain of classroom lectures/talks due to the special features adopted. In contrast, work on sports highlight extraction mainly focuses on detecting the announcer's speech, the audience ambient speech noise, the game-specific sounds (e.g., the baseball hits), and various background noise (e.g., the audience cheering). Targeting movie content analysis, Li et al. proposed to detect three types of events, namely, two-speaker dialogs, multi-speaker dialogs, and hybrid events, by exploiting multiple media cues and special movie production rules [40].

Contrary to all the work above on detecting interesting events, Nam and colleagues tried to detect undesired events (such as violence scenes) from movies [41]. In particular, violence-related visual cues, including spatio-temporal dynamic activity, flames in gunfire/explosion scenes, and splashed blood, were detected and integrated with the detection of violence-related audio cues such as abrupt loud sounds to help locate offensive scenes.

59.3.2 Audio Content Analysis

Existing research on content-based audio data analysis is still quite limited, and can be categorized into the following two classes.

59.3.2.1 Audio Segmentation and Classification

One basic problem in this area is the discrimination between speech and music, which are the two most important audio types. A general solution is to first extract various audio features such as the average zero-crossing rate (ZCR) and the short-time energy from the signals, and then distinguish the two sound types based on the feature values. For instance, 13 audio features calculated in time, frequency, and cepstrum domains were employed in [42] for classification purposes. It also examined and compared several popular classification schemes, including the multidimensional Gaussian maximum *a posteriori* estimator, the Gaussian mixture model, a spatial partitioning scheme based on k-d trees, and a nearest neighbor classifier. Generally speaking, a relatively high accuracy could be achieved in distinguishing speech and music because these two signals are quite different in both spectral distributions and temporal change patterns.

A more advanced classification algorithm usually takes more sound types into consideration. For instance, Wyse and Smoliar classified audio signals into three types, including "music," "speech," and "others" [43]. Specifically, music was first detected based on the average length of the interval during which peaks were within a narrow frequency band; then speech was separated out by tracking the pitches. Research in [44] was devoted to analyze the signal's amplitude, frequency, and pitch. It has also conducted simulations on human audio perception; the results were utilized to segment the audio data and recognize the music

component. More recently, Zhang and Kuo presented an extensive feature extraction and classification system for audio content segmentation and classification purposes [45]. Five audio features, including energy, average zero-crossing rate, fundamental frequency, and spectral peak tracks, were extracted to fulfill the task. A two-step audio classification scheme was proposed in [46], where in the first step, speech and non-speech were discriminated based on KNN and LSP VQ schemes. In the second step, the non-speech signals were further classified into music, environment sounds, and silence based on a feature thresholding scheme.

59.3.2.2 Audio Analysis for Video Indexing

In this section, some purely audio-based work developed for the video indexing purpose is reviewed.

Five different video classes, including news report, weather report, basketball, football, and advertisement, were distinguished in [47] using both multilayer neural networks (MNN) and the Hidden Markov Model (HMM). Features such as the silence ratio, the speech ratio, and the subband energy ratio were extracted to fulfill this task. It was shown that while MNN worked well in distinguishing among reports, games, and advertisements, it had difficulty in classifying different types of reports or games. On the contrary, the use of HMM increased the overall accuracy but it could not well classify all five video types. In [48], features such as the pitch, the short-time average energy, the band energy ratio, and the pause rate were first extracted from the coded sub-band of an MPEG audio clip; then they were integrated to characterize the clip into either silence, music, or dialog. Another approach to index videos based on music and speech detection was proposed in [49], where image processing techniques were applied to the spectrogram of the audio signals. In particular, the spectral peaks of music were recognized by applying an edge-detection operator and the speech harmonics were detected with a comb filter.

59.3.3 Video Abstraction

Video abstraction, as the name implies, generates a short summary for a long video document. Specifically, a video abstract is a sequence of still or moving images that represents the video essence in a very concise way. Video abstraction is primarily used for video browsing, and is an inseparable part of a video indexing and retrieval system.

There are two fundamentally different kinds of video abstracts: still- and moving-image abstracts. The still-image abstract, also known as static storyboard or video summary, is a small collection of keyframes extracted or generated from the underlying video source. The moving-image abstract, also known as moving storyboard or video skim, consists of a collection of image sequences, as well as the corresponding audio abstract extracted from the original sequence. Thus, it is itself a video clip but is of considerably shorter length.

59.3.3.1 Video Skimming

There are basically two types of video skim: the summary sequence and the highlight. A summary sequence is used to provide users with an impression about the entire video content, while a highlight generally only contains some interesting video segments. A good example of a video highlight is the movie trailer, which only shows some very attractive scenes without revealing the story's end.

In the VAbstract system developed in [50], the most characteristic movie segments were extracted to generate a movie trailer. Specifically, scenes that contained important objects/people, had high actions, or contained speech dialogs were selected and organized in their original temporal order to form the movie trailer. In the improved version of VAbstract, which is called MoCA, special events such as closed-up shots of leading actors, explosion, and gunfire were detected to help determine important scenes.

Defining which video segments are highlights is actually a very subjective and difficult process, and it is also difficult to map human cognition into the automated abstraction process. Therefore, most current video-skimming work focuses on the generation of the summary sequence. One of the most straightforward approaches in this case would be to compress the original video by speeding up the playback. As studied in [51], using a time compression technology, a video could be watched in a fast playback mode without distinct pitch distortion. However, according to recent research results, the maximum time compression could only reach 1.5 to 2.5, beyond which the speech will become incomprehensible.

The Informedia Project [52] at the Carnegie Mellon University aimed at creating a short synopsis of the original video by extracting significant audio and video information. In particular, an audio skim was first created by extracting audio segments with respect to preextracted text keywords; then an image skim was generated by selecting video frames that satisfied predefined visual rules. Finally, the video skim was formed based on consideration of both word relevance and structures of prioritized audio and image skims. Toklu et al. [53] also proposed to generate video skim by integrating visual, audio, and text cues. Specifically, they first grouped video shots into story units based on detected “change of speaker” and “change of subject” markers. Then, audio segments corresponding to all generated story units were extracted and aligned with closed captions. Finally, a video skim was formed by integrating the audio and text information. Similar to the Informedia Project, this work also heavily depends on the text information.

Nam and Tewfik [54] proposed to generate video skims based on a dynamic sampling scheme. Specifically, they first decomposed a video sequence into sub-shots, and then computed a motion intensity index for each of them. Next, all indices were quantized into predefined bins, where each bin was assigned a different sampling rate. Finally, keyframes were sampled from each sub-shot based on its assigned rate. Recently, a segment-based video skimming system was presented in [55]. This system was specifically developed for documentary, presentation, and educational videos, where word frequency analysis was carried out to score segments, and segments that contained frequently occurring words were selected to form the final skim. A sophisticated user study was carried out, but it did not produce satisfactory results as expected.

Some other work in this area attempts to find solutions to domain-specific video data where special features can be employed. For example, the VidSum project developed at Xerox PARC employed the presentation structure, which was particularly designed for their regular weekly forum, to assist in mapping low-level signal events onto semantically meaningful events that could be used to assemble the summary [56]. He et al. [57] reported Microsoft Research’s work on summarizing corporate informational talks. Some special knowledge of the presentation, such as the pitch and pause information, the slide transition points, as well as the information about the user access patterns, was utilized to generate the summary. Another work reported in [58] mainly focused on the summarization of home videos, which was more usage model-based than content-based. In this approach, all video shots were first clustered into five different levels based on the time and date they were taken. Then, a shot shortening process was applied to uniformly segment longer shots into 2-minute clips. Finally, clips that met certain sound pressure criteria were selected to form the final abstract.

59.3.3.2 Video Summarization

Compared to video skimming, video summarization has attracted much more research interest in recent years. Based on the way keyframes are extracted, existing work in this area can be categorized into the following three classes: sampling based, shot based, and segment based.

59.3.3.2.1 Sampling and Shot-Based Keyframe Extraction

Most of the earlier summarization work was sampling based, where keyframes were either randomly chosen or uniformly sampled from the original video. This approach gives the simplest way to extract keyframes, yet it fails to truly represent the video content.

More sophisticated work thus tends to extract keyframes by adapting to the dynamic video content. Because a shot is taken within a continuous capture period, a natural and straightforward way is to extract one or more keyframes from each shot. Based on the features used to select keyframes, we categorize the existing work into the following three classes: the color-based approach, the motion-based approach, and the mosaic-based approach.

One typical color-based approach was reported in [59], where keyframes were extracted in a sequential fashion. In particular, the first frame of each shot was always chosen as the first keyframe. Then, the next frame, which had a sufficiently large difference from the latest keyframe, was chosen as the next keyframe. Zhuang et al. [60] proposed to extract keyframes based on an unsupervised clustering scheme. Specifically, all video frames within a shot were first grouped into clusters; then the frames that were closest to cluster centroids were chosen as keyframes.

FIGURE 59.2 A mosaic image generated from a panning sequence.

Because the color histogram is invariant to image orientations and robust to background noises, color-based keyframe extraction algorithms have been widely used. However, because most of this work is heavily threshold dependent, the underlying video dynamics cannot be well captured when there are frequent camera or object motions.

The motion-based approaches are relatively better suited for controlling the number of keyframes when the video presents significant temporal dynamics. A general solution along this direction is to first measure the amount of motion contained in each frame based on calculated optical flows; then frames that have minimum motion activities are chosen as keyframes.

A domain-specific keyframe extraction method was proposed in [61], where sophisticated global motion and gesture analyses were carried out to generate a summary for videotaped presentations. Three different operation levels were suggested in [62], where at the lowest level, pixel-based frame differences were computed to generate a “temporal activity curve”; at level two, color histogram-based frame differences were computed to extract “color activity segments”; and at level three, sophisticated camera motion analysis was carried out to detect “motion activity segments.” Keyframes were then selected from each segment and the necessary elimination was applied to obtain the final result.

A limitation of the above approaches is that it is not always possible to find keyframes that can well represent the entire video content. For example, given a camera panning/tilting sequence, even if multiple keyframes are selected, the underlying dynamics still cannot be well captured. In this case, a mosaic-based approach, which generates a synthesized panoramic image to cover the video content, can provide a better solution.

Mosaic, also known as salient still, video sprite, or video layer, is usually generated in the following two steps: (1) fitting a global motion model to the motion between each pair of successive frames; (2) compositing frames into a single panoramic image by warping them using estimated camera parameters. Some commonly used motion models, such as the translational model, rotation/scaling model, affine model, planar perspective model, and quadratic model, can be found in the MPEG-7 standard [6]. Figure 59.2 shows a mosaic generated from 183 video frames using an affine model. As we can see, this single still image can provide much more information than regular keyframes can do.

To capture both foreground and background, Irani and Anandan [63] developed two types of mosaics, namely, a static background mosaic and a synopsis mosaic. While the static mosaic could capture the background scene, the synopsis mosaic was constructed to provide a visual summary of the entire foreground dynamics by detecting object trajectories. The final mosaic image was then obtained by simply combining these two mosaics. In addition, to accommodate video sources with complex camera operations and frequent object motions, Taniguchi et al. proposed to interchangeably use either a regular keyframe or mosaic image, whichever is more suitable [64].

59.3.3.2.2 Segment-Based Keyframe Extraction

One major drawback of using one or more keyframes for each shot is that it does not scale well for long video. Therefore, recently people have begun to work on a higher-level video unit, which we call “segment” here. A video segment could be a scene, an event, or even the entire sequence. Some interesting research along this direction is summarized below.

In [65], a video sequence was first partitioned into segments; then an importance measure was computed for each segment based on its length and rarity. Finally, the frame closest to the center of each qualified

FIGURE 59.3 A video summary containing variable-sized keyframes.

segment was extracted as the representative keyframe with its size proportional to the importance index. Figure 59.3 shows one of their exemplary summaries.

Yeung and Yeo reported their work on summarizing video at a scene level [66]. In particular, it first grouped shots into clusters using a proposed “time-constrained clustering” approach; then, meaningful story units or scenes were subsequently extracted. Next, an R-image was extracted from each scene to represent its component shot clusters, whose dominance value was computed based on either the frequency count of visually similar shots or the shots’ durations. Finally, all extracted R-images were organized into a predefined visual layout with their sizes being proportional to their dominance values. To allow users to freely browse the video content, a scalable video summarization scheme was proposed in [23], where the number of keyframes could be adjusted based on user preference. In particular, it first generated a set of default keyframes by distributing them among hierarchical video units, including scene, sink, and shot, based on their respective importance ranks. Then, more or less keyframes would be returned to users based on their requirements and keyframe importance indices.

Some other work in this category has attempted to treat video summarization task in a more mathematical way. For instance, some of them introduce fuzzy theory into the keyframe extraction scheme and others represent the video sequence as a curve in a high-dimensional feature space. The SVD (Singular Value Decomposition), PCA (Principle Component Analysis), mathematical morphology, and SOM (Self-Organizing Map) techniques are generally used during these processes.

59.4 Bridging the Semantic Gap in Content Management

We complete the survey by describing the problem of semantic gap in multimedia content management systems and emerging approaches to address this critical issue. Most of the approaches surveyed above for video content analysis can be broadly grouped together into two classes:

1. The first class of approaches seeks to extract as much frame-level information as possible from a video source. All further processing is carried out to merge frames and shots on the basis of various visual and aural similarity measures using low-level features. Shots that are similar in terms of the extracted features are considered semantically similar and labeled based on their common and dominant attributes.
2. The other class consist of approaches that target predefined genres of videos by describing a video in terms of its structure (e.g., news video) or events (sports). They exploit domain-specific constraints to carefully select low-level features and to analyze the patterns of their occurrences to result in higher-level descriptions of what is happening in videos. The goal is to generate descriptions from a domain-specific, finite, commonly accepted vocabulary for a specific task such as shot or scene labeling, genre discrimination, or sports events extraction.

However, it has become evident via real-world installations of content management systems that these fall far short of the expectations of users. A major problem is the gap between the descriptions that are computed by the automatic methods and those employed by users to describe an aspect of video, such as motion during their search. While users want to query in a way natural to them in terms of persons, events, topics, and emotions, actual descriptions generated by current techniques remain at a much lower level, closer to machine-speak than to the natural language. For example, in most systems, instead of being able to specify that one is looking for a clip where the U.S. President is limping to the left in a scene, one often needs to specify laboriously, “Object=human, identity=the US President, movement=left, rate of movement=x pixels per frame, etc.,” using descriptive fields amenable to the computations of algorithms provided by the annotation systems. Further, even if we allow that some systems have recently begun to address the problem of object motion-based annotation and events, what is still missing is the capability to handle high-level descriptions of, not just what the objects are and what they do in a scene, but also of emotional and visual appeal of the content seen and remembered.

The other concern is that most video annotation and search systems ignore the *fallout* rate, which measures the number of nonmatching items that were not retrieved upon a given query. This measure is extremely important for video databases, because even as a simple measure, there are more than 100,000 frames in just a single hour of video with a frame rate of 30 fps. An important design criterion would therefore emphasize deriving annotation indices and search measures that are more discriminatory, less frame-oriented, and result in high fallout rates.

59.4.1 Computational Media Aesthetics

To bridge the semantic gap between the high-level meaning sought by user queries in search for media and the low-level features that we actually compute today for media indexing and search, one promising approach [67] is founded upon an understanding of media elements and their roles in synthesizing meaning, manipulating perceptions, and crafting messages, with a systematic study of media productions. Content creators worldwide use widely accepted conventions and cinematic devices to solve problems presented when transforming a written script to an audiovisual narration, be it a movie, documentary, or a training video.

This new approach, called computational media aesthetics, is defined as the algorithmic study of a variety of image and aural elements in media, founded on their patterns of use in film grammar, and the computational analysis of the principles that have emerged underlying their manipulation, individually or jointly, in the creative art of clarifying, intensifying, and interpreting some event for the audience [68]. The core trait of this approach is that in order to create effective tools for automatically understanding video, we must be able to interpret the data with its maker’s eye.

This new research area has attracted computer scientists, content creators, and producers who seek to address the fundamental issues in spanning the data-meaning gulf by a systematic understanding and application of media production methods. Some of the issues that remain open for examination include:

- Challenges presented by semantic gap in media management
- Assessment of problems in defining and extracting high-level semantics from media
- Examination of high-level expressive elements relevant in different media domains
- New algorithms, tools, and techniques for extracting characteristics related to space, motion, lighting, color, sound, and time, and associated high-level semantic constructs
- Production principles for manipulation of affect and meaning
- Semiotics for new media
- Metrics to assess extraction techniques and representational power of expressive elements
- Case studies and working systems

Media semantics can lead to the development of shared vocabularies for structuring images and video, and serve as the foundation for media description interfaces. There is structure regardless of the

particular media context but there may not be homogeneity, and therefore it helps to be guided by production knowledge in media analysis. New software models like this will enable technologies that can emulate human perceptual capabilities on a host of difficult tasks such as parsing video into sections of interest, making inferences about semantics, and about the perceptual effectiveness of the messages contained.

Once content descriptions are extracted from the multimedia data, the main questions that follow include: (1) What is the best representation for the data? and (2) What are the basic operations needed to manipulate the data and express “all” the user queries?

59.5 Modeling and Querying Images

An image database model to organize and query images is relatively new in image databases. Usually, visual feature vectors extracted from the images are directly maintained in a multidimensional index structure to enable similarity searches. The main problems with this approach include:

- *Flexibility.* The index is the database. In traditional database systems, indexes are hidden at the physical level and are used as access methods to speed up query processing. The database system can still deliver results to queries without any index. The only problem is that the query processing will take more time as the data files will be scanned. Depending on the type of queries posed against the database, different indexes can exist at the same time, on the same set of data.
- *Expressiveness.* The only type of queries that can be handled is the query supported by the index (Query by Examples in general).
- *Portability.* Similarity queries are based on some metrics defined on the feature vectors. Once the metric has been chosen, only a limited set of applications can benefit from the index because metrics are application dependent.

To address these issues, some image models are being proposed. The image models are built on top of existing database models, mainly object relational and object oriented.

59.5.1 An Example Object-Relational Image Data Model

In [69], an image is stored in a table $T(h : Integer, x_1 : X_1, \dots, x_n : X_n)$ where h is the image identifier and x_i is an image feature attribute of domain (or type) X_i (note that classical attributes can be added to this minimal schema). The tuple corresponding to the image k is indicated by $T[k]$. Each tuple is assigned a score (ζ) which are real numbers such that $T[k].\zeta$ is a distance between the image k and the current query image. The value of ζ is assigned by a scoring operator $\Sigma_T(s)$ given a scoring function $s : (\Sigma_T(s))[k].\zeta = s(T[k].x_1, \dots, T[k].x_n)$.

Because many image queries are based on distance measures, a set of distance functions ($d : X \times X \rightarrow [0, 1]$) are defined for each feature type X . Given an element $x : X$ and a distance function d defined on X , the scoring function s assigns $d(x)$, a distance from x to every element of X . In addition, a set of score combination operators $\diamond : [0, 1] \times [0, 1] \rightarrow [0, 1]$ are defined.

New selection and join operators defined on the image table augmented with the scores allow the selection of n images with lowest scores, the images whose scores are less than a given score value ρ and the images from a table $T = T(h : Integer, x_1 : X_1, \dots, x_n : X_n)$ that match images from a Table $Q = Q(h : Integer, y_1 : Y_1, \dots, y_n : Y_n)$ based on score combination functions as follows:

- K-nearest neighbors: $\sigma_k^\#(\Sigma_T(s))$ returns the k rows of the table T with the lowest distance.
- Range query operator: $\sigma_\rho^<(\Sigma_T(s))$ returns all the rows of the table T with a distance less than ρ .
- \diamond join: $T \bowtie Q$ joins the tables T and Q on their identifiers h and returns the table $W = W(h : Integer, x_1 : X_1, \dots, x_n : X_n, y_1 : Y_1, \dots, y_n : Y_n)$. The distance in the table W is defined as $W.d = T.d \diamond Q.d$.

In [70] the same authors proposed a design model with four kind of feature dependencies that can be exploited for the design of efficient search algorithms.

59.5.2 An Example Object-Oriented Image Data Model

In the DISIMA model, an image is composed of physical salient objects (regions of the image) whose semantics are given by logical salient objects that represent real-world objects. Both images and physical salient objects can have visual properties. The DISIMA model uses an object-oriented concept and introduces three new types — *Image*, *Physical Salient Objects*, *Logical Salient Objects* — and operators to manipulate them.

Images and related data are manipulated through predicates and operators defined on images, physical and logical salient objects are used to query the images. They can be directly used in calculus-based queries to define formulas or in the definition of algebraic operators. Because the classical predicates $\{=, <, \leq, >, \geq\}$ are not sufficient for images, a new set of predicates were defined to be used on images and salient objects.

- *Contain predicate.* Let i be an image, o an object with a behavior pso that returns the associated set of physical salient objects $contains(i, o) \iff \exists p \in o.pso \wedge p \in i.pso$.
- *Shape similarity predicates.* Given a shape similarity metric d_{shape} and a similarity threshold ϵ_{shape} , two shapes s and t are similar with respect to d_{shape} if $d_{shape}(s, t) \leq \epsilon_{shape}$. In other words: $shape_similar(s, t, \epsilon_{shape}) \iff d_{shape}(s, t) \leq \epsilon_{shape}$.
- *Color similarity predicates.* Given two color representations (c_1, c_2) and a color distance metric d_{color} , the color representations c_1 and c_2 are similar with respect to d_{color} if $d_{color}(c_1, c_2) \leq \epsilon_{color}$.

Based on the above-defined predicates, some operators are defined: *contains* or *semantic join* (to check whether a salient object is found in an image), and the *similarity join* that is used to match two images or two salient objects with respect to a predefined similarity metric on some low-level features (color, texture, shape, etc.), and *spatial join* on physical salient objects:

- *Semantic join.* Let S be a set of semantic objects of the same type with a behavior pso that returns, for a semantic object, the physical salient objects it describes. The *semantic join* between an image class extent I and the semantic object class extent S , denoted by $I \bowtie_{contains} S$, defines the elements of $I \times S$ where for $i \in I$, and $s \in S$, $contains(i, s)$.
- *Similarity join.* Given a similarity predicate *similar* and a threshold ϵ , the *similarity join* between two sets R and S of images or physical salient objects, denoted by $R \bowtie_{similar(r,i,s,j,\epsilon)} S$ for $r \in R$ and $s \in S$, is the set of elements from $R \times S$ where the behaviors i defined on the elements of R and j on the elements of S return some compatible metric data type T and $similar(r,i,s,j)$ (the behaviors i and j can be the behaviors that return color, texture or shape).
- *Spatial join.* The spatial join of the extent of two sets R and S , denoted by $R \bowtie_{r,i\theta s,j} S$, is the set of elements from $R \times S$ where the behaviors i defined on the elements of R and j on the elements of S return some spatial data type, θ is a binary spatial predicate, and $R.i$ stands in relation θ to $S.j$ (θ is a spatial operator like north, west, northeast, intersect, etc.)

The predicates and the operators are the basis of the declarative query languages MOQL [71] and Visual-MOQL [72].

59.6 Modeling and Querying Videos

After obtaining video structure from the content analysis module, low- and/or high-level features can be subsequently extracted from the underlying video units to facilitate the content indexing. For instance, Zhang et al. [24] extracted four image features (color, texture, shape, and edge) and two temporal features (camera operations and temporal brightness variation) from shots and keyframes, and used them to

index and retrieve clips from a video database. Similar work was also reported in [31,73], where TV news was used to demonstrate the proposed indexing scheme. More sophisticated investigation of indexing TV broadcast news can be found in [74], where speech, speech transcript, and visual information were combined together in the proposed DANCERS system. Tsekeridou and Pitas [75] also reported their work on indexing TV news where, extracted faces, which could be talking or non-talking, and speaker identities were employed as indexing features.

A system called “PICTURESQUE” was proposed in [76], where object motions represented by its trajectory coordinates were utilized to index the video. A “VideoBook” system was presented in [77], where multiple features including motion, texture, and colorimetry cues were combined to characterize and index a video clip. A sports video indexing scheme was presented in [78], where speech understanding and image analysis were integrated to generate meaningful indexing features. A comprehensive video indexing and browsing environment (ViBE) was discussed in [79] for a compressed video database. Specifically, given a video sequence, it first represented each shot with a hierarchical structure (shot tree). Then, all shots were classified into pseudo-semantic classes according to their contents, which were finally presented to end users in an active browsing environment. A generic framework of integrating existing low- and high-level indexing features was presented in [80], where the low-level features included color, texture, motion, and shape, while the high-level features could be video scenes, events, and hyperlinks.

In general, video database models can be classified into segmentation-based models, annotation-based models, and salient object-based models.

59.6.1 Segmentation-Based Models

In segmentation-based approaches [81–83], the video data model follows the video segmentation (events, scenes, shots, and frames) and keyframes extracted from shots and scenes are used to summarize the video content. The visual features extracted from the key frames are then used to index the video.

Mahdi et al. [83] proposed a temporal cluster graph (TCG) as a data model that combines visual similarity of shots and semantic concepts such as sequence and scene. The scene construction method uses two main video features: spatial and temporal clues extracted and shot rhythms in the video. The shot rhythm is a temporal effect obtained from the duration of successive shots that is supposed to lead to a particular scene sensation. Shots are first clustered based on their color similarity. Then the clusters are grouped into sequences. A sequence is a narrative unity formed by one or several scenes. Sequences are linked to each other through an effect of gradual transition (dissolve, fade-in, or fade-out). The temporal cluster graph (TCG) is constructed to describe the clusters and their temporal relationships. A node is associated with each cluster, and the edges represent temporal relationships between clusters. Queries are directly posed against the graph.

59.6.2 Annotation-Based Models

In annotation-based approaches [84,85], the video stream is augmented with a description (annotation) layer. Each descriptor is associated with a logical video sequence and/or a physical object in the video.

Annotation-based video data models can be further classified into frame-based annotation and attribute-value pair structure. In frame-based annotation, the annotation is directly associated to the frame sequences. The annotation itself can be made of keywords [84], a description in a natural language [85], or semantic icons [86]. Smith and Davenport [84] proposed a layered annotation representation model called the stratification model that segments contextual information of the video. The stratification model divides the video sequence into a set of overlapping strata. A stratum consists of a descriptive information with the corresponding keywords and boundaries. A stratum can be contained in another stratum and may encompass multiple descriptions. The content information of a stratum is obtained by the union of all the contextual descriptions associated with it. Based on the stratification model, Weiss et al. [87] introduced a video data model called the algebraic video model. The algebraic video model is

composed of hierarchical composition of video expression with semantic description. The atomic video expression is a single window presentation from a raw video segmentation. These segments are defined by the name of the raw video data, and the starting and ending frames. Compound video expressions can be constructed from primitive video expression or other compound video expression using the algebraic operations. The video algebra operations falls into four categories: creation, composition, output and description.

An example of a natural language annotation is the VideoText model [85]. This model allows free text annotation of logical video segments. VideoText supports incremental, dynamic, and multiple creation of annotations. Basic information retrieval (IR) techniques are used to evaluate the queries and rank the results. To support interval queries based on temporal characteristics of videos, the set of classical IR operations is extended with some interval operators.

59.6.3 Salient Object-Based Models

In salient object-based approaches [88–90], salient objects (objects of interest in the video) are somehow identified and extracted, and some spatio-temporal operators are used to express events and concepts in the queries. Video data modeling based on segmentation employs image processing techniques and only deals with low-level video image features (color, shape, texture, etc). The entire modeling process can be automated. However, this solution is very limited as only query involving low-level features and shots can be posed. Chen et al. [90] proposed a model that combines segmentation and salient objects. The model extends the DISIMA model with a video block that models video following video segmentation. Each shot is represented by a set of keyframes that are treated as images following the DISIMA image data model and some new operators are defined for the videos.

59.7 Multidimensional Indexes for Image and Video Features

In the presence of a large database, a sequential scan of the database each time a query is posed is unacceptable. The aim of indexes is to filter the database and select a significantly small subset of the database that contains the result of the query. The multidimensional index structures, also known as *spatial access methods* (SAMs), are employed to index image visual features, such as average colors, color histograms, and textures, because these features are usually modeled as points in multidimensional spaces. SAMs usually organize the multidimensional points in a number of buckets, each of which corresponds to a disk block and to some subspace of the universal space. There are two categories of SAMs: tree-based methods and hashing-based methods.

Indexes are normally based on the total order of the space to be indexed and the main difficulty encountered in designing multidimensional indexing structures is that, unlike the case in one-dimensional space, there exists no total ordering among multidimensional points that preserves their proximity. In other words, there is no mapping from two- or higher-dimensional space into one-dimensional space, such that any two objects that are close in the higher-dimensional space are also close to each other in the one-dimensional sorted sequence. Multidimensional indexing structures usually employ “bucket methods” [91]. The points in the database are organized into a number of buckets, each of which corresponds to some subspace of the universal multidimensional space. The subspaces are often referred to as bucket regions, although their dimensionality may be greater than two. Through partitioning the universe into bucket regions, the multidimensional indexing structures potentially achieve clustering: separating objects that are far apart and grouping objects that are close to each other.

A typical representative for hashing-based methods is the grid file [92]. The grid file superimposes a multidimensional orthogonal grid on the universal space. One data bucket, which is stored as a disk block, is associated with one or more of these grid cells. The addresses of the data buckets are recorded in a grid directory. A common criticism of the grid file is that the directory expansion approaches an exponential rate as the data distribution becomes less uniform, and the problem is magnified by the number of dimensions of the space [93]. In [94] a multidimensional hashing method that controls the directory

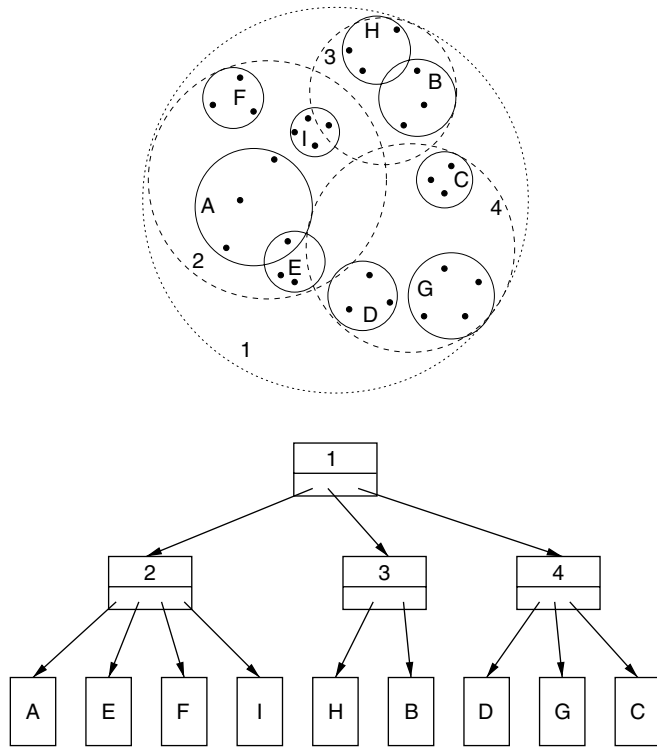

FIGURE 59.4 An SS-tree data space and the corresponding SS-tree (adapted from [97]).

expansion through a structure called mask was proposed. There has been more work on tree structures that we will summarize in the following subsection. Then we discuss the problem of dimensionality curse and the existing solutions.

59.7.1 Tree-Based Index Structures

The R-tree [95] was originally proposed to index n -dimensional rectangles but can be used to index n -dimensional points as well if points are considered as zero size rectangles. The R-tree [95] was among the first multidimensional index structures and has influenced most of work done subsequently on multidimensional indexes: R*-tree [96], SS-tree [97], and SR-tree [98] (there are others). The R-tree and the R*-tree are used for range queries and divide the universal space into multidimensional rectangles. The SS-tree is an improvement of the R*-tree by dividing the universal space into multidimensional spheres instead (better for similarity searches). The similarity search tree (SS-tree) [97] is specially designed to support similarity query in high-dimensional visual feature space. The SS-tree indexes high-dimensional vectors (points). The center of a sphere is the centroid of the underlying points. Figure 59.4 shows points in two-dimensional space followed by the corresponding SS-tree.

The SR-tree combines the use of rectangles and spheres, and it is reported that the SR-tree outperforms the R*-tree and SS-tree [98]. The SR-tree is a combination of the SS-tree and the R*-tree in that it uses both bounding spheres and bounding rectangles to group data points. Using spheres to bound data points is more suitable for similarity searches than using rectangles, because similarity search regions are usually spheres too. However, bounding spheres occupy much a larger volume than bounding rectangles when the dimensionality is high. Regions with larger volume tend to produce more overlap among themselves, which reduces similarity search efficiency. Katayama and Satoh propose the SR-tree [98] to solve this problem by integrating bounding spheres and bounding rectangles. The SR-tree specifies a region by the

FIGURE 59.5 An SR-tree data space and the corresponding SR-tree (adapted from [98]).

intersection of a bounding sphere and a bounding rectangle (Figure 59.5). The introduction of bounding rectangles permits neighborhoods to be partitioned into smaller regions than the SS-tree and improves the disjointness among regions.

59.7.2 Dimensionality Curse and Dimensionality Reduction

The multimedia feature vectors usually have a high number of dimensions. For example, color histograms typically have at least 64 dimensions. However, it is well known that current multidimensional indexing structures suffer from “dimensionality curse,” which refers to the phenomenon that the query performance of the indexing structures degrades as the data dimensionality increases. Moreover, Beyer et al. reported [99,100] a “clustering” phenomenon: as dimensionality increases, the distance to the nearest data point approaches the distance to the farthest data point. The “clustering” phenomenon can occur for as few as 10 to 15 dimensions. Under this circumstance, high-dimensional indexing is not meaningful: linear scan can outperform the R*-tree, SS-tree, and SR-tree [100]. Hence, developing more sophisticated multidimensional indexing structures is not a complete answer to the question of how to provide effective support for querying high-dimensional data. Different solutions have been proposed to address this problem: reducing the dimensionality of the data, applying a sophisticated filtering to sequential scan, and indexing the metric space.

59.7.2.1 Dimensionality Reduction

The dimensionality reduction problem is defined as: given a set of vectors in n -dimensional space, find the corresponding vectors in k -dimensional space ($k < n$) such that the distances between the points in the original space are maintained as well as possible. The following *stress* function gives the average relative error that a distance in k -dimensional space suffers from:

$$stress = \sqrt{\frac{\sum_{i,j} (d'_{ij} - d_{ij})^2}{\sum_{i,j} d_{ij}^2}},$$

where d_{ij} is the distance between objects i and j in their original n -dimensional space and d'_{ij} is their distance in the resulting k -dimensional space. Preserving distances means minimizing the stress.

There have been several techniques developed for dimensionality reduction, such as multidimensional scaling (MDS), Karhunen-Loève (K-L) transform, and fast map [101]. The basic idea of multidimensional scaling is to first assign each object to a k -dimensional point arbitrarily; and then try to move it in order to minimize the discrepancy between the distances in the original space and those in the resulting space. The above-mentioned techniques are only applicable to static databases where the set of data objects is known *a priori*. Kanth et al. propose techniques for performing SVD-based dimensionality reduction in dynamic databases [102]. When the data distribution changes considerably, due to inserts and deletes, the SVD transform is recomputed using an aggregate data set whose size is much smaller than the size of the database, in order to save computational overhead.

59.7.2.2 The Vector Approximation File (VA-File)

Another solution to the dimensionality curse problem is the VA-file. Weber et al. [103] report experiments showing little advantage of spatial indexes [96,104] over full sequential scan for feature vectors of ten or more dimensions. Hence, Weber et al. propose the VA-file, a structure performing such a scan combined with an intelligent pre-filtering of the data. They show that the VA-file achieves better performance compared to a simple sequential scan and spatial indexing structures.

The VA-file divides the data space into 2^b rectangular cells, where b denotes a user-specified number of bits to encode each dimension ($4 \leq b \leq 6$). The VA-file is a signature file containing a compressed approximation of the original data vectors. Each data vector is approximated by a bit-string encoding of the hypercube in which it lies. The hypercubes are generated by partitioning each data dimension into the number of bins representable by the number of bits used for that dimension. Typically, the compressed file is 10 to 15% of the size of the original data file. The maximum and minimum distances of a point to the hypercube provide upper and lower bounds on the distance between the query location and the original data point. In a K-nearest neighbor search, a filtering phase selects the possible K-NN points through a sequential scan of the VA-file. An approximated vector is selected if its lower bound is less than the current 5th closest upper bound. The second phase visits the candidates in ascending order of the lower bounds until the lower bound of the next candidate is greater than the actual distance to the current Kth nearest neighbor.

The pre-filtering of the VA-file requires each data point in the space to be analyzed, leading to linear complexity with a low constant.

59.7.2.3 Indexing Metric Spaces

In addition to indexing data objects in vector spaces, the indexing problem can be approached from a rather different perspective, that is, indexing in metric spaces. In metric spaces, how data objects are defined is not important (data objects may or may not be defined as vectors); what is important is the definition of the distance between data objects.

Berman proposes using triangulation tries [105] to index in metric spaces. The idea is to choose a set of *key objects* (key objects may or may not be in the datasets to be indexed), and for each object in the dataset, create a vector consisting of the ordered set of distances to the key objects. These vectors are then combined into a trie.

Space decomposition is another approach to indexing in metric spaces. An example is the *generalized hyper-plane decompositions* [106]. A generalized hyper-plane is defined by two objects o_1 and o_2 and consists of the set of objects p satisfying $d(p, o_1) = d(p, o_2)$. An object x is said to lie on the o_1 -side of the plane if $d(p, o_1) < d(p, o_2)$. The generalized hyper-plane decomposition builds a binary tree. At the root node, two arbitrary objects are picked to form a hyper-plane. The objects that are on the one side of the hyper-plane are placed in one branch of the tree, and those on the other side of the hyper-plane are placed in the other branch. The lower-level branches of the tree are constructed recursively in the same manner.

The above decomposition methods build trees by a top-down recursive process, so the trees are not guaranteed to remain balanced in case of insertions and deletions. Furthermore, these methods do not

consider secondary memory management, so they are not suitable for large databases that must be stored on disks. To address these problems, the M-tree [107,108] is proposed. The M-tree is a dynamic and balanced tree. Each node of the M-tree corresponds to a disk block. The M-tree uses sphere cuts to break up the metric space and is a multi-branch tree with a bottom-up construction. All data objects are stored in leaf nodes.

Metric space decompositions are made based on distance measures from some reference objects in data sets. The use of data set elements in defining partitions tends to permit exploitation of the distribution features of the data set itself, and thus may provide good query performance.

Indexing in metric spaces requires nothing to be known about the objects other than their pairwise distances. It only makes use of the properties of distance measures (symmetry, non-negativity, triangle inequality) to organize the objects and prune the search space. Thus, it can deal with objects whose topological relationships are unknown.

59.8 Multimedia Query Processing

The common query in multimedia is similarity search, where the object-retrieved are ordered according to some scores based on a distance function defined on a feature vector. In the presence of specialized indexes (e.g., an index for color features, an index for texture features), a similarity query involving the two or more features has to be decomposed into sub-queries and the sub-results integrated to obtain the final result. In relational database systems where sub-query results are not ordered, the integration is done using set operators (e.g., INTERSECTION, UNION, and DIFFERENCE). Because of the inherent order, a blind use of these set operators is not applicable in ordered sets (sequences).

The integration problem of N ranked lists has been studied for long time, both in IR and WWW research [109–112]. In both contexts, “integration” means find a scoring function able to aggregate the partial scores (i.e., the numbers representing the goodness of each returned object). However, all the proposed solutions make the assumption that a “sorted access” (i.e., a sequential scan) on the data has to exist based on some distance. In this way, it is possible to obtain the score for each data object accessing the sorted list and proceeding through such a list sequentially from the top. In other words, given a set of k lists, the problem, also named the “rank aggregation” problem, consists of finding a unique list that is a “good” consolidation of the given lists. In short, the problem consists of finding an aggregation function, such as *min*, *max*, or *avg*, that renders a consolidated distance.

Fagin [109,113] assumes that each multimedia object has a score for each of its attributes. Following the running example, an image object can have a color score and a texture score. For each attribute, a sorted list, which lists each object and its score under that attribute, sorted by score (highest score first) is available. For each object, an overall score is computed by combining the score attributes using a predefined monotonic aggregation function (e.g., average, min, and max). In particular, the algorithm uses upper and lower bounds on the number of objects that it is necessary to extract from a repository to meet the number of objects required in the consolidated list.

Fagin’s approach, however, works only when the sources support sorted access of the objects. The same problem has been addressed in the Web context by Gravano et al. [110,111], in which the so-called “meta-ranking” concept is defined for data sources available on the Internet that queried separately and the results merged to compose a final result to a user query. In this work also, the authors assume the existence of scores returned together with the relevant objects.

It is known that linear combinations of scores favor correlated features. When the scores do not exist, or are not available, the integration of multimedia sub-query results cannot be performed following the above-mentioned approaches. This is the case for the Boolean models and search engines, for example. In a Boolean model, the sub-queries are logical constructs [114]. Given a query, the database is divided into a set of relevant and not relevant objects. The function is analogous to a membership function on sets. Search engines usually do not disclose the scores given to the retrieved objects and the metrics used for evident commercial reasons. Instead, the objects are ranked.

59.9 Emerging MPEG-7 as Content Description Standard

MPEG-7, the Multimedia Content Description Interface, is an ISO metadata standard defined for the description of multimedia data. The MPEG-7 standard aims at helping with searching, filtering, processing, and customizing multimedia data through specifying its features in a “universal” format. MPEG-7 does not specify any applications but the format of the way the information contained within the multimedia data is represented, thereby supporting descriptions of multimedia made using many different formats. The objectives of MPEG-7 [115] include creating methods to describe multimedia content, manage data flexibly, and globalize data resources.

In creating methods to describe multimedia content, MPEG-7 aims to provide a set of tools for the various types of multimedia data. Usually there are four fundamental areas that can be addressed, depending on the data, so that the content is specified thoroughly. The first one in the basic fundamental areas is specifying the medium from which the document was created. This also includes the physical aspects of the medium such as what type of film it was originally shot on or information about the camera lenses. Another area concerns the physical aspects of the document. This type of information covers computational features that are not perceived by a person viewing the document. An example of such data includes the frequency of a sound in the document. Grouped with the perceptual area sometimes are the perceived descriptions. These descriptions specify the easily noticed features of the multimedia data such as the color or textures. Finally, the transcription descriptions control specifying the transcripts, or the textual representation of the multimedia information, within the MPEG-7.

MPEG-7 essentially provides two tools: the description definition language (MPEG-7 DDL) [116] for the definition of media schemes and an exhaustive set of media description schemes mainly for media low-level features. The predefined media description schemes are composed of visual feature descriptor schemes [117], audio feature descriptor schemes [118], and general multimedia description schemes [119]. Media description through MPEG-7 is achieved through three main elements: descriptors (Ds), description schemes (DSs), and a description definition language (DDL). The descriptors essentially describe a feature of the multimedia data, with a feature being a distinctive aspect of the multimedia data. An example of a descriptor would be a camera angle used in a video. The description scheme organizes the descriptions specifying the relationship between descriptors. Description schemes, for example, would represent how a picture or a movie would be logically ordered. The DDL is used to specify the schemes and allow modifications and extensions to the schemes.

The MPEG-7 DDL is a superset of XML Schema [120], the W3C schema definition language for XML documents. The extensions to XML Schema comprise support for array and matrix data types as well as additional temporal data types. MPEG-7 is commonly admitted as a multimedia content description tool and the number of MPEG-7 document available is increasing. With the increase of MPEG-7 documents, there will certainly be the need for suitable database support. Because MPEG-7 media descriptions are XML documents that conform to the XML Schema definition, it is natural to suggest XML database solutions for the management of MPEG-7 document as in [121]. Current XML database solutions are oriented toward text and MPEG-7 encodes nontextual data. Directly applying current XML database solutions to MPEG-7 will lower the expressive power because only textual queries will be allowed.

59.10 Conclusion

This chapter has surveyed multimedia databases from data analysis to querying and indexing. In multimedia databases, the raw multimedia is unfortunately not too useful because it is of large size and not meaningful by itself. Usually, data is coupled with descriptive data (low-level and possibly semantics) obtained from an analysis of the raw data.

The low-level features of an image are color, texture, and shape. Color is the most common feature used in images. There exist different color spaces that represent a color in three dimensions. The MPEG-7 standard has adopted the RGB, HSV, HMMD, Monochrome, and YCbCr color spaces. Texture captures the visual patterns that result from the presence of different color intensities and expresses the structural

arrangement of the surfaces in the image. Examples of texture include tree barks, clouds, water, bricks, and fabrics. The common representation classifies textures into coarseness, contrast, directionality, line-likeness, regularity, and roughness. Object shapes are usually extracted by segmenting the image into homogeneous regions. A shape can be represented by the boundary, the region (area), and a combination of the first two representations. A video can be seen as a sequences of images and is often summarized by a sequence of keyframes (images). In addition, a video has a structure (e.g., event, scene, shot), an audio component that can be analyzed and embeds some movements. Although it is relatively easier to analyze images and videos for low-level features, it is not evident to deduce semantics from the low-level features because features do not intrinsically carry any semantics. The dichotomy between low-level features and semantics is known as the “semantic gap.”

The multimedia data and the related metadata are normally stored in a database following a data model that defines the representation of the data and the operations to manipulate it. Due to the volume and the complexity of multimedia data, the analysis is performed at the acquisition of the data. Multimedia databases are commonly built on top of object or object-relational database systems. Multidimensional indexes are used to speed up query processing. The problem is that the low-level properties are represented as vectors of large size and it is well-known that beyond a certain number of dimensions, sequential scan outperforms multidimensional indexes. Current and future multimedia research is moving toward the integration of more semantics.

60.1 Introduction

With rapid advancements in computer and network technology, it is possible for an organization to collect, store, and retrieve vast amounts of data of all kinds quickly and efficiently. This, however, represents a threat to the organizations as well as individuals. Consider the following incidents of security and privacy problems:

- On November 2, 1988, Internet came under attack from a program containing a *worm*. The program affected an estimated 2000–3000 machines, bringing them to a virtual standstill.
- In 1986, a group of West German hackers broke into several military computers, searching for classified information, which was then passed to the KGB.
- According to a U.S. General Accounting Office study, authorized users (or *insiders*) were found to represent the greatest threat to the security of the Federal Bureau of Investigation's National Crime Information Center. Examples of misuse included insiders disclosing sensitive information to outsiders in exchange for money or using it for personal purposes (such as determining if a friend or a relative has a criminal record).
- Another U.S. General Accounting Office study uncovered improper accesses of taxpayer information by authorized users of the Internal Revenue Service (IRS). The report identified instances where IRS employees manipulated taxpayer records to generate unauthorized refunds and browsed tax returns that were unrelated to their work, including those of friends, relatives, neighbors, or celebrities.

The essential point of these examples is that databases of today no longer contain only data used for day-to-day data processing; they have become information systems that store everything, whether it is vital or not to an organization. Information is of strategic and operational importance to any organization; if the concerns related to security are not properly resolved, security violations may lead to losses of information that may translate into financial losses or losses whose values are obviously high by other measures (e.g., national security).

These large information systems also represent a threat to personal privacy since they contain a great amount of detail about individuals. Admittedly, the information collection function is essential for an organization to conduct its business; however, indiscriminate collection and retention of data can represent an extraordinary intrusion on the privacy of individuals.

To resolve these concerns, security or privacy issues must be carefully thought out and integrated into a system very early in its developmental life cycle. Timely attention to system security generally leads to effective measures at lower cost. A complete solution to security and privacy problems requires the following three steps:

- *Policy*: The first step consists of developing a security and privacy policy. The policy precisely defines the requirements that are to be implemented within the hardware and software of the computing system, as well as those that are external to the system such as physical, personnel, and procedural controls. The policy lays down broad goals without specifying how to achieve them. In other words, it expresses what needs to be done rather than how it is going to be accomplished.
- *Mechanism*: The security and privacy policy is made more concrete in the next step, which proposes the mechanism necessary to implement the requirements of the policy. It is important that the mechanism perform the intended functions.
- *Assurance*: The last step deals with the assurance issue. It provides guidelines for ensuring that the mechanism meets the policy requirements with a high degree of assurance. Assurance is directly related to the effort that would be required to subvert the mechanism. Low-assurance mechanisms may be easy to implement, but they are also relatively easy to subvert. On the other hand, high-assurance mechanisms can be notoriously difficult to implement.

Since most commercial database management systems (DBMSs) and database research have security rather than privacy as their main focus, we devote most of this chapter to the issues related to security. We conclude with a brief discussion of the issues related to privacy in database systems.

60.2 General Security Principles

There are three high-level objectives of security in any system:

- *Secrecy* aims to prevent unauthorized disclosure of information. The terms *confidentiality* or *nondisclosure* are synonyms for secrecy.
- *Integrity* aims to prevent unauthorized modification of information or processes.
- *Availability* aims to prevent improper denial of access to information. The term *denial of service* is often used as a synonym for denial of access.

These three objectives apply to practically every information system. For example, payroll system secrecy is concerned with preventing an employee from finding out the boss's salary; integrity is concerned with preventing an employee from changing his or her salary in the database; availability is concerned with ensuring that the paychecks are printed and distributed on time as required by law. Similarly, military command and control system secrecy is concerned with preventing the enemy from determining the target coordinates of a missile; integrity is concerned with preventing the enemy from altering the target coordinates; availability is concerned with ensuring that the missile does get launched when the order is given.

60.3 Access Controls

The purpose of access controls is to ensure that a user is permitted to perform certain operations on the database only if that user is authorized to perform them. Commercial DBMSs generally provide access controls that are often referred to as **discretionary access controls** (as opposed to the **mandatory access controls** which will be described later in the chapter).

Access controls are based on the premise that the user has been correctly identified to the system by some **authentication** procedure. Authentication typically requires the user to supply his or her claimed identity (e.g., user name, operator number, etc.) along with a password or some other authentication token. Authentication may be performed by the operating system, the DBMS, a special authentication server, or some combination thereof. Authentication is not discussed further in this chapter; we assume that a suitable mechanism is in place to ensure proper access controls.

60.3.1 Discretionary Access Controls

Most commercial DBMSs provide security by controlling modes of access by users to data. These controls are called discretionary since any user who has discretionary access to certain data can pass the data along to other users. Discretionary policies are used in commercial systems because of their flexibility; this makes them suitable for a variety of environments with different protection requirements.

There are many different administrative policies that can be applied to issue authorizations in systems that enforce discretionary protection. Some examples are *centralized* administration, where only a few privileged users may grant and revoke authorizations; *ownership-based* administration, where the creator of an object is allowed to grant and revoke accesses to the object; and *decentralized* administration, where other users, at the discretion of the owner of an object, may also be allowed to grant and revoke authorizations on the object.

60.3.1.1 Granularity and Modes of Access Control

Access controls can be imposed in a system at various degrees of granularity. In relational databases, some possibilities are the entire database, a single relation, or some rows or columns within a relation. Access controls are also differentiated by the operation to which they apply. For instance, among the basic SQL (Structured Query Language) operations, access control modes are distinguished as SELECT access, UPDATE access, INSERT access, and DELETE access. Beyond these access control modes, which apply to individual relations or parts thereof, there are also privileges which confer special authority on selected users. A common example is the DBA privilege for database administrators.

60.3.1.2 Data-Dependent Access Control

Database access controls can also be established based on the contents of the data. For example, some users may be limited to seeing salaries which are less than \$30,000. Similarly, managers may be restricted to seeing the salaries only for employees in their own departments. *Views* and *query modification* are two basic techniques for implementing data-dependent access controls in relational databases.

60.3.1.3 Granting and Revoking Access

The granting and revocation operations allow users with authorized access to certain information to selectively and dynamically grant or restrict any of those access privileges to other users. In SQL, granting of access privileges is accomplished by means of the GRANT statement, which has the following general form:

```
GRANT  privileges
[ON    relation]
TO     users
[WITH  GRANT OPTION]
```

Possible privileges users can exercise on relations are *select* (select tuples from a relation), *insert* (add tuples to a relation), *delete* (delete tuples from a relation), and *update* (modify existing tuples in a relation). These access modes apply to a relation as a whole, with the exception of the update privilege, which can be further refined to refer to specific columns inside a relation. When a privilege is given with the grant option, the recipient can in turn grant the same privilege, with or without grant option, to other users.

The GRANT command applies to base relations within the database as well as views. Note that it is not possible to grant a user the grant option on a privilege without allowing the grant option itself to be further granted.

Revocation in SQL is accomplished by means of the REVOKE statement, which has the following general format:

```

REVOKE  privileges
[ON    relation]
FROM    users
    
```

The meaning of REVOKE depends upon who executes it, as explained next.

A grant operation can be modeled as a tuple of the form $\langle s, p, t, ts, g, go \rangle$ stating that user s has been granted privilege p on relation t by user g at time ts . If $go = \text{yes}$, s has the grant option and, therefore, s is authorized to grant other users privilege p on relation t , with or without grant option. For example, tuple $\langle \text{Bob}, \text{select}, T, 10, \text{Ann}, \text{yes} \rangle$ indicates that Bob can select tuples from relation T , and grant other users authorizations to select tuples from relation T , and that this privilege was granted to Bob by Ann at time 10. Tuple $\langle C, \text{select}, T, 20, B, \text{no} \rangle$ indicates that user C can select tuples from relation T and that this privilege was granted to C by user B at time 20; this authorization, however, does not entitle user C to grant other users the select privilege on T .

The semantics of the revocation of a privilege from a user (revokee) by another user (revoker) is to consider as valid the authorizations that would have resulted had the revoker never granted the revokee the privilege. As a consequence, every time a privilege is revoked from a user, a recursive revocation may take place to delete all of the authorizations which would have not existed had the revokee never received the authorization being revoked.

To illustrate this concept, consider the sequence of grant operations for privilege p on relation t illustrated in Figure 60.1a, where every node represents a user, and an arc between node u_1 and node u_2 indicates that u_1 granted the privilege on the relation to u_2 . The label of the arc indicates the time the privilege was

FIGURE 60.1 Bob revokes the privilege from David.

granted. For the sake of simplicity, we make the assumption that all authorizations are granted with the grant option. Suppose now that Bob revokes the privilege on the relation from David at some time later than 70. According to the semantics of recursive revocation, the resulting authorization state has to be as if David had never received the authorization from Bob, and the time of the original granting is the arbiter of this recursion. That is, if David had never received the authorization from Bob, he could not have granted the privilege to Ellen (his request would have been rejected by the system at time 40). Analogously, Ellen could not have granted the authorization to Jim. Therefore, the authorizations granted by David to Ellen and by Ellen to Jim must also be deleted. Note that the authorization granted by David to Frank does not have to be deleted since David could have granted it even if he had never received the authorization from Bob (because of the authorization from Chris at time 50). The set of authorizations holding in the system after the revocation is shown in [Figure 60.1b](#).

60.3.2 Limitation of Discretionary Access Controls

Whereas discretionary access control mechanisms are adequate for preventing unauthorized disclosure of information to honest users, malicious users who are determined to seek unauthorized access to the data must be restricted by other devices. The main drawback of discretionary access controls is that although it allows an access only if it is authorized, it does not impose restrictions on further dissemination of information by a user once the user obtains it. This weakness makes discretionary controls vulnerable to **Trojan horse** attacks. A Trojan horse is a computer program with an apparent or actual useful function, but which contains additional *hidden* functions that surreptitiously exploit the access gained by legitimate authorizations of the invoking process. To understand how a Trojan horse can leak information to unauthorized users despite discretionary access control, consider the following example.

Suppose a user Burt (the bad guy) wants to access a file called **my_data** owned by Vic (the victim). To achieve this, Burt creates another file **stolen_data** and gives Vic the write authorization to **stolen_data** (Vic is not informed about this). Moreover, Burt modifies the code of an application generally used by Vic to include a Trojan horse containing two hidden operations, the first operation reads **my_data** and the second operation copies **my_data** into **stolen_data**. When Vic executes the application the next time, the application executes on behalf of Vic and, as a result, the personal information in **my_data** is copied to **stolen_data**, which can then be read by Burt.

This simple example illustrates how easily the restrictions stated by the discretionary authorizations can be bypassed and, therefore, the lack of assurance that results from the authorizations imposed by discretionary policies. For this reason discretionary policies are considered unsafe and not satisfactory for environments with stringent protection requirements.

To overcome this weakness further restrictions, beside the simple presence of the authorizations for the required operations, should be imposed on the accesses. To this end, the idea of *mandatory* (or *nondiscretionary*) access controls, together with a protection mechanism called the **reference monitor** for enforcing them, have been developed [Denning 1982].

60.3.3 Mandatory Access Controls

Mandatory access control policies provide a way to protect data against illegal accesses such as those gained through the use of the Trojan horse. These policies are mandatory in the sense that the accesses allowed are determined by the administrators rather than the owners of the data.

Mandatory access controls are usually based on the **Bell-LaPadula model** [Denning 1982], which is stated in terms of *subjects* and *objects*. An object is understood to be a data file, record, or a field within a record. A subject is an active process that can request access to an object. Every object is assigned a classification and every subject a clearance. Classifications and clearances are collectively referred to as *security* or *access* classes. A security class consists of two components: a hierarchical component (usually,

top secret, secret, confidential, and unclassified, listed in decreasing order of sensitivity) together with a set (possibly empty) of nonhierarchical categories (e.g., NATO or Nuclear).*

Security classes are partially ordered as follows: Given two security classes L_1 and L_2 , $L_1 \geq L_2$ if and only if the hierarchical component of L_1 is greater than or equal to that of L_2 and the categories in L_1 contain those in L_2 . Since the set inclusion is not a total order, neither is \geq .

The Bell–LaPadula model imposes the following restrictions on all data accesses:

The simple security property: A subject is allowed a read access to an object only if the former's clearance is identical to or higher (in the partial order) than the latter's classification.

The \star -property: A subject is allowed a write access to an object only if the former's clearance is identical to or lower than the latter's classification.

These two restrictions are intended to ensure that there is no direct flow of information from high objects to low subjects.** The Bell–LaPadula restrictions are mandatory in the sense that the reference monitor checks security classes of all reads and writes and enforces both restrictions automatically. The \star -property is specifically designed to prevent a Trojan horse operating on behalf of a user from copying information contained in a high object to another object having a lower or incomparable classification.

60.3.3.1 Covert Channels

It turns out that a system may not be secure even if it always enforces the two Bell–LaPadula restrictions correctly. A secure system must guard against not only the direct revelation of data but also violations that do not result in the direct revelation of data yet produce illegal information flows. **Covert channels** fall into the violations of the latter type. They provide indirect means by which information by subjects within high-security classes can be passed to subjects within lower security classes.

To illustrate, suppose a distributed database uses two-phase commit protocol to commit a transaction. Further, suppose that a certain transaction requires a *ready-to-commit* response from both a secret and an unclassified process to commit the transaction; otherwise, the transaction is aborted. From a purely database perspective, there does not appear to be a problem, but from a security viewpoint, this is sufficient to compromise security. Since the secret process can send one bit of information by agreeing either to commit or not to commit a transaction, both secret and unclassified processes may cooperate to compromise security as follows: The unclassified process generates a number of transactions; it always agrees to commit a transaction, but the secret process by selectively causing transaction aborts can establish a covert channel to the unclassified process.

60.3.3.2 Polyinstantiation

The application of mandatory policies in relational databases requires that all data stored in relations be classified. This can be done by associating security classes with a relation as a whole, with individual tuples (rows) in a relation, with individual attributes (columns) in a relation, or with individual elements (attribute values) in a relation. In this chapter we assume that each tuple of a relation is assigned a classification.

The assignment of security classes to tuples introduces the notion of a *multilevel* relation. An example of a multilevel relation is shown in Table 60.1. Since the security class of the first tuple is secret, any user logged in at a lower security class will not be shown this tuple.

Multilevel relations suffer from a peculiar integrity problem known as **polyinstantiation** [Abrams et al. 1995]. Suppose an unclassified user (i.e., a user who is logged in at an unclassified security class) wants to enter a tuple in a multilevel relation in which each tuple is labeled either secret or unclassified. If the same key is already occurring in a secret tuple, we cannot prevent the unclassified user from inserting the

*Although this discussion is couched within a military context, it can easily be adapted to meet nonmilitary security requirements.

**The terms *high* and *low* are used to refer to two security classes such that the former is strictly higher than the latter in the partial order.

TABLE 60.1 A Multilevel Relation

STARSHIP	DESTINATION	SECURITY_CLASS
Voyager	Rigel	Secret
Enterprise	Mars	Unclassified

TABLE 60.2 A Polyinstantiated Multilevel Relation

STARSHIP	DESTINATION	SECURITY_CLASS
Voyager	Rigel	Secret
Voyager	Mars	Unclassified

unclassified tuple without leakage of one bit of information by inference. In other words the classification of the tuple has to be treated as part of the relation key. Thus unclassified tuples and secret tuples will always have different keys, since the keys will have different security classes.

To illustrate this further, consider the multilevel relation of Table 60.2, which has the key STARSHIP, SECURITY_CLASS. Suppose a secret user inserts the first tuple in this relation. Later, an unclassified user inserts the second tuple of Table 60.2. This later insertion cannot be rejected without leaking the fact to the unclassified user that a secret tuple for the Voyager already exists. The insertion is therefore allowed, resulting in the relation of Table 60.2. Unclassified users see only one tuple for the Voyager, viz., the unclassified tuple. Secret users see two tuples. There are two different ways these two tuples might be interpreted as follows:

- There are two distinct starships named Voyager going to two distinct destinations. Unclassified users know of the existence of only one of them, viz., the one going to Mars. Secret users know about both of them.
- There is a single starship named Voyager. Its real destination is Rigel, which is known to secret users. There is an unclassified cover story alleging that the destination is Mars.

Presumably, secret users know which interpretation is intended.

The main drawback of mandatory policies is their rigidity, which makes them unsuitable for many application environments. In particular, in most environments there is a need for a decentralized form of access control to designate specific users who are allowed (or who are forbidden) access to an object. Thus, there is a need for access control mechanisms that are able to provide the flexibility of discretionary access control and, at the same time, the high assurance of mandatory access control. The development of a high-assurance discretionary access control mechanism poses several difficult challenges. Because of this difficulty, the limited research effort that has been devoted to this problem has yielded no satisfactory solutions.

60.4 Assurance

In order that a DBMS meets the U.S. Department of Defense (DoD) requirements, it must also be possible to *demonstrate* that the system is secure. To this end, designers of secure DBMSs follow the concept of a **trusted computing base*** (TCB) (also known as a *security kernel*), which is responsible for all security-relevant actions of the system. TCB mediates all database accesses and cannot be bypassed; it is small enough and simple enough so that it can be formally verified to work correctly; it is isolated from the rest of the system so that it is tamperproof.

DoD established a metric against which various computer systems can be evaluated for security. It developed a number of *levels*, A1, B3, B2, B1, C2, C1, and D, and for each level, it listed a set of requirements

*The reference monitor resides inside the trusted computing base.

that a system must have to achieve that level of security. Briefly, systems at levels C1 and C2 provide discretionary protection of data, systems at level B1 provide mandatory access controls, and systems at levels B2 or above provide increasing assurance, in particular against covert channels. The level A1, which is most rigid, requires verified protection of data. The D level consists of all systems which are not secure enough to qualify for any of levels A, B, or C.

Although these criteria were designed primarily to meet DoD requirements, they also provide a metric for the non-DoD world. Most commercial systems which implement security would fall into the C1 or D levels. The C2 level requires that decisions to grant or deny access can be made at the granularity of individual users. In principle, it is reasonably straightforward to modify existing systems to meet C2 or even B1 requirements. This has been successfully demonstrated by several operating system and DBMS vendors. It is not clear how existing C2 or B1 systems can be upgraded to B2 because B2 imposes modularity requirements on the system architectures. At B3 or A1 it is generally agreed that the system would need to be designed and built from scratch.

For obvious reasons the DoD requirements tend to focus on secrecy of information. Information integrity, on the other hand, is concerned with unauthorized or improper modification of information, such as caused by the propagation of viruses which attach themselves to executables. The commercial world also must deal with the problem of authorized users who misuse their privileges to defraud the organization. Many researchers believe that we need some notion of mandatory access controls, possibly different from the one based on the Bell-LaPadula model, in order to build high-integrity systems. Consensus on the nature of this mandatory access controls has been illusive.

60.5 General Privacy Principles

In this section, we describe the basic principles for achieving information privacy. These principles are made more concrete when specific mechanisms are proposed to support them:

- *Proper acquisition and retention* are concerned with what information is collected and after it is collected how long it is retained by an organization.
- *Integrity* is concerned with maintaining information on individuals that is correct, complete, and timely. The source of the information should be clearly stated, especially when the information is based on indirect sources.
- *Aggregation and derivation of data* are concerned with ensuring that any aggregations or derivations performed by an organization on its information are necessary to carry out its responsibilities. Aggregation is the combining of information from various sources. Derivation goes one step further; it uses different pieces of data to deduce or create new or previously unavailable information from the aggregates. Aggregation and derivation are important and desirable effects of collecting data and storing them in databases; they become a problem, however, when legitimate data are aggregated or used to derive information that is either not authorized by law or not necessary to the organizations. Aggregates and derived data pose serious problems since new information can be derived from available information in several different ways. Nonetheless, it is critical that data be analyzed for possible aggregation or derivation problems. With a good understanding of the ways problems may arise, it should be possible to take steps to eliminate them.
- *Information sharing* is concerned with authorized or proper disclosure of information to outside organizations or individuals. Information should be disclosed only when specifically authorized and used solely for the limited purpose specified. This information should be generally prohibited from being redisclosed by requiring that it be either returned or properly destroyed when no longer needed.
- *Proper access* is concerned with limiting access to information and resources to authorized individuals who have a demonstrable need for it in order to perform official duties. Thus, information should not be disclosed to those that either are not authorized or do not have a need to know (even if they are authorized).

Privacy protection is a personal and fundamental right of all individuals. Individuals have a right to expect that organizations will keep personal information confidential. One way to ensure this is to require that organizations collect, maintain, use, and disseminate identifiable personal information and data only as necessary to carry out their functions. In the U.S., Federal privacy policy is guided by two key legislations:

Freedom of Information Act of 1966: It establishes an openness in the Federal government by improving the public access to the information. Under this act, individuals may make written requests for copies of records of a department or an agency that pertain to them.

The Privacy Act of 1974: It provides safeguards against the invasion of personal privacy by the Federal government. It permits individuals to know what records pertaining to them are collected, maintained, used, and disseminated.

60.6 Relationship Between Security and Privacy Principles

Although there appears to be a large overlap in principle between security and privacy, there are significant differences between their objectives.

Consider the area of secrecy. Although both security and privacy seek to prevent unauthorized observation of data, security principles do not concern themselves with whether it is proper to gather a particular piece of information in the first place and, after it is collected, how long it should be retained. Privacy principles seek to protect individuals by limiting what is collected and, after it is collected, by controlling how it is used and disseminated. As an example, the IRS is required to collect only the information that is both necessary and relevant for tax administration and other legally mandated or authorized purposes. The IRS must dispose of personally identifiable information at the end of the retention periods required by law or regulation.

Security and privacy have different goals when new, more general information is deduced or created using available information. The objective of security controls is to determine the sensitivity of the derived data; any authorized user can access this new information. Privacy concerns, on the other hand, dictate that the system should not allow aggregation or derivation if the new information is either not authorized by law or not necessary to carry out the organization's responsibilities.

There is one misuse — denial of service — that is of concern to security but not privacy. In denial of service misuse, an adversary seeks to prevent someone from using features of the computer system by tying up the computer resources.

60.7 Research Issues

Current research efforts in the database security area are moving in three main directions. We refer the reader to Bertino et al. [1995] for a more detailed discussion and relevant citations.

60.7.1 Discretionary Access Controls

The first research direction concerns discretionary access control in relational DBMSs. Recent efforts are attempting to extend the capabilities of current authorization models so that a wide variety of application authorization policies can be directly supported. Related to these extensions is the problem of developing appropriate tools and mechanisms to support those models. Examples of these extension are models that permit negative authorizations, role-based and task-based authorization models, and temporal authorization models.

One extension introduces a new type of revoke operation. In the current authorization models, whenever an authorization is revoked from a user, a recursive revocation takes place. A problem with this approach is that it can be very disruptive. Indeed, in many organizations the authorizations users possess are related

FIGURE 60.2 Bob revokes the privilege from David without cascade.

to their particular tasks or functions within the organization. If a user changes his or her task or function (for example, if the user is promoted), it is desirable to remove only the authorizations of this user, without triggering a recursive revocation of all of the authorizations granted by this user.

To support this concept, a new type of revoke operation, called *noncascading* revoke, has been introduced. Whenever a user, say Bob, revokes a privilege from another user, say David, a noncascading revoke operation would not revoke authorizations granted by David; instead, they are respecified as if they had been granted by Bob, the user issuing revocation. The semantics of the revocation without cascade is to produce the authorization state that would have resulted if the revoker (Bob) had granted the authorizations that had been granted by revokee (David).

To illustrate how noncascading revocation works, consider the sequence of authorizations shown in Figure 60.2a. Suppose now that Bob invokes the noncascading revoke operation to the privilege granted to David. Figure 60.2b illustrates the authorization state after revocation. The authorizations given by David to Ellen and Frank are respecified with Bob as the grantor and Jim retains the authorization given him by Ellen.

Another extension of current authorization models concerns negative authorizations. Most DBMSs use a *closed world* policy. Under this policy, the lack of an authorization is interpreted as a negative authorization. Therefore, whenever a user tries to access a table, if a positive authorization (i.e., an authorization permitting access) is not found in the system catalogs, the user is denied the access.

This approach has a major problem in that the lack of a given authorization for a user does not guarantee that he or she will not acquire the authorization any time in the future. That is, anyone possessing the right to administer an object can grant any user the authorization to access that object. The use of explicit negative authorizations can overcome this drawback. An explicit negative authorization expresses a *denial* for a user to access a table under a specified mode. Conflicts between positive and negative authorizations are resolved by applying the *denials-take-precedence* policy under which negative authorizations override positive authorizations. That is, whenever a user has both a positive and a negative authorization for a given privilege on the same table, the user is prevented from using that privilege on the table. The user is denied access even if a positive authorization is granted *after* a negative authorization has been granted. There are more flexible models in which negative authorizations do not always take precedence over positive authorizations [Bertino et al. 1995].

Negative authorizations can also be used for temporarily blocking possible positive authorizations of a user and for specifying exceptions. For example, it is possible to grant an authorization to all members of a group except one specific member by granting the group the positive authorization for the privilege on the table and the given member the corresponding negative authorization.

60.7.2 Mandatory Access Controls

The second research direction deals with extending the relational model to incorporate mandatory access controls. Several results have been reported for relational DBMSs, some of which have been applied to commercial products.

When dealing with multilevel secure DBMSs, there is a need to revise not only the data models but also the transaction processing algorithms. In this section, we show that the two most popular concurrency control algorithms, *two-phase locking* and *timestamp ordering*, do not satisfy the secrecy requirements.

Consider a database that stores information at two levels: low and high. Any low-level information is made accessible to all users of the database by the DBMS; on the other hand, high-level information is available only to a selected group of users with special privileges. In accordance with the mandatory security policy, a transaction executing on behalf of a user with no special privileges would be able to access (read and write) only low-level data elements, whereas a high-level transaction (initiated by a high user) would be given full access to the high-level data elements and read-only access to the low-level elements.

It is easy to see that the previous transaction rules would prevent direct access by unauthorized users to high-level data. However, there could still be ways for an ingenious saboteur to circumvent the intent of these rules, if not the rules themselves. Imagine a conspiracy of two transactions: T_L and T_H . T_L is a transaction confined to the low-level domain; T_H is a transaction initiated by a high user and, therefore, able to read all data elements. Suppose that a two-phase locking scheduler is used and that only these two transactions are currently active. If T_H requests to read a low-level data element d , a lock will be placed on d for that purpose. Suppose that next T_L wants to write d . Since d has been locked by another transaction, T_L will be forced by the scheduler to wait. T_L can measure such a delay, for example, by going into a busy loop with a counter. Thus, by selectively issuing requests to read low-level data elements, transaction T_H could modulate delays experienced by transaction T_L , effectively sending signals to T_L . Since T_H has full access to high-level data, by transmitting such signals, it could pass on to T_L the information that the latter is not authorized to see. The information channel thus created is known as a **signaling channel**.

Note that we can avoid a signaling channel by aborting the high transactions whenever a low-transaction wants to acquire a conflicting lock on a low data item. However, the drawback with this approach is that a malicious low transaction can starve a high transaction by causing it to abort repeatedly.

The standard timestamp-ordering technique also possesses the same secrecy-related flaw. Let T_L , T_H , and d be as before. Suppose that timestamps are used instead of locks to synchronize concurrent transactions. Let $ts(T_L)$ and $ts(T_H)$ be the (unique) timestamps of transactions T_L and T_H . Let $rts(d)$ be the read timestamp of data element d . (By definition, $rts(d) = \max(rts(d), ts(T))$, where T is the last transaction that read d .) Suppose that $ts(T_L) < ts(T_H)$ and T_H reads d . If, after that, T_L attempts to write d , then T_L will be aborted. Since a high-transaction can selectively cause a (cooperating) low transaction to abort, a signaling channel can be established.

Since there does not appear to be a completely satisfactory solution for single-version multilevel databases, researchers have been looking in alternative directions for solutions. One alternative is to maintain multiple versions of data instead of a single version. Using this alternative, transaction T_H will be given older versions of low-level data, thus eliminating both the signaling channels and starvations. The other alternative is to use correctness criteria that are weaker than serializability, yet they preserve database consistency in some meaningful way.

60.7.3 Authorization for Advanced Database Management Systems

A third direction concerns the development of adequate authorization models for advanced DBMSs, like object-oriented DBMSs or active DBMSs. These DBMSs are characterized by data models that are richer than the relational model. Advanced data models often include notions such as inheritance hierarchies, composite objects, versions, and methods. Therefore, authorization models developed for relational DBMSs must be properly extended to deal with the additional modeling concepts.

Authorization models developed in the framework of relational DBMSs need substantial extensions to be suitable for object-oriented DBMSs (OODBMSs). The main requirements driving such extensions can

be summarized as follows. First, the authorization model must account for all semantic relationships which may exist among data (i.e., inheritance, versioning, or composite relationship). For example, in order to execute some operation on a given object (e.g., an instance), the user may need to have the authorization to access other objects (e.g., the class to which the instance belongs). Second, administration of authorizations becomes more complex. In particular, the ownership concept does not have a clear interpretation in the context of object-oriented databases. For example, a user can create an instance from a class owned by some other user. As a result, it is not obvious who should be considered the owner of the instance and administer authorizations to access the instance. Finally, different levels of authorization granularity must be supported. Indeed, in object-oriented database systems, objects are the units of access. Therefore, the authorization mechanism must allow users to associate authorizations with single objects. On the other hand, such fine granularity may decrease performance when accessing sets of objects, as in the case of queries. Therefore, the authorization mechanisms must allow users to associate authorizations with classes, or even class hierarchies, if needed. Different granularities of authorization objects are not required in relational DBMSs, where the tuples are always accessed in a set-oriented basis, and thus authorizations can be associated with entire relations or views.

Some of those problems have been addressed by recent research. However, work in the area of authorization models for object-oriented databases is still at a preliminary stage. Of the OODBMSs, only Orion and Iris provide authorization models comparable to the models provided by current relational DBMSs.

With respect to mandatory controls, the Bell–LaPadula model is based on the subject-object paradigm. Application of this paradigm to object-oriented systems is not straightforward. Although this paradigm has proven to be quite effective for modeling security in operating systems as well as relational databases, it appears somewhat forced when applied to object-oriented systems. The problem is that the notion of an object in the object-oriented data model does not correspond to the Bell–LaPadula notion of an object. The former combines the properties of a passive information repository, represented by attributes and their values, with the properties of an active entity, represented by methods and their invocations. Thus, the object of the object-oriented data model can be thought of as the object and the subject of the Bell–LaPadula paradigm fused into one. Moreover, as with relational databases, the problem arises of assigning security classifications to information stored inside objects. This problem is made more complex by the semantic relationships among objects which must be taken into consideration in the classification. For example, the access level of an instance cannot be lower than the access level of the class containing the instance; otherwise, it would not be possible for a user to access the instance.

Some work has been performed on applying the Bell–LaPadula principles to object-oriented systems. A common characteristic to the various models is the requirement that objects must be single level (i.e., all attributes of an object must have the same security level). A model based on single-level objects has the important advantage of making the security monitor small enough that it can be easily verified. However, entities in the real world are often multilevel: some entities may have attributes with different levels of security. Since much modeling flexibility would be lost if multilevel entities could not be represented in the database, most of the research work on applying mandatory policies to object-oriented databases has dealt with the problem of representing these entities with single-level objects.

Defining Terms

Authentication: The process of verifying the identity of users.

Bell–LaPadula model: A widely used formal model of mandatory access control. It requires that the simple security property and the \star -property be applied to all subjects and objects.

Covert channel: Any component or feature of a system that is misused to encode or represent information for unauthorized transmission, without violating access control policy of the system.

Discretionary access controls: Means of restricting access. Discretionary refers to the fact that the users at their discretion can specify to the system who can access their files.

Mandatory access controls: Means of restricting access. Mandatory refers to the fact that the security restrictions are applied to all users. Mandatory access control is usually based on the Bell–LaPadula security model.

Polyinstantiation: A multilevel relation containing two or more tuples with the same primary key values but differing in security classes.

Reference monitor: Mechanism responsible for deciding if an access request of a subject for an object should be granted or not. In the context of multilevel security, it contains security classes of all subjects and objects and enforces two Bell–LaPadula restrictions faithfully.

Signaling channel: A means of information flow inherent in the basic model, algorithm, or protocol and, therefore, implementation invariant.

Trojan horse: A malicious computer program that performs some apparently useful function but contains additional hidden functions that surreptitiously leak information by exploiting the legitimate authorizations of the invoking process.

Trusted computing base: Totality of all protection mechanisms in a computer system, including all hardware, firmware, and software that is responsible for enforcing the security policy.

Further Information

In this chapter, we have mainly focused on the security issues related to DBMSs. It is important to note, however, that the security measures discussed here constitute only a small aspect of overall security. As an increasing number of organizations become dependent on access to their data over the Internet, network security is also critical.

The most popular security measure these days is a *firewall* [Cheswick and Bellovin 1994]. A firewall sits between an organization’s internal network and the Internet. It monitors all traffic from outside to inside and blocks any traffic that is unauthorized. Although firewalls can go a long way to protect organizations against the threat of intrusion from the Internet, they should be viewed only as the first line of defense. Firewalls are not immune to penetrations; once an outsider is successful in penetrating a system, firewalls typically do not provide any protection for internal resources. Moreover, firewalls do not protect against security violations from *insiders*, who are an organization’s authorized users. Most security experts believe that insiders are responsible for a vast majority of computer crimes.

For general reference on computer security, refer to Abrams et al. [1995], Amoroso [1994], and Denning [1982]. Text by Castano et al. [1994] is specific to database security. Kaufman et al. [1995] deals with security for computer networks. Security in statistical databases is covered in Denning [1982] and in the survey by Adam and Wortmann [1989].

Intelligent Systems

The study of Intelligent Systems, often called “artificial intelligence” (AI), uses computation as a medium for simulating human perception, cognition, reasoning, learning, and action. Current theories and applications in this area are aimed at designing computational mechanisms that process visual data, understand speech and written language, control robot motion, and model physical and cognitive processes. Fundamental to all AI applications is the ability to efficiently search large and complex information structures and to utilize the tools of logic, inference, and probability to design effective approximations for various intelligent behaviors.

61.4 Research Issues and Summary

61.1 Introduction

Modern interest in artificial intelligence (AI) is coincident with the development of high-speed digital computers. Shortly after World War II, many hoped that truly intelligent machines would soon be a reality. In 1950, Turing, in his now-famous article “*Computing Machinery and Intelligence*,” which appeared in the journal *Mind*, predicted that machines would duplicate human intelligence by the end of the century. In 1956, at a workshop held at Dartmouth College, McCarthy introduced the term “*artificial intelligence*,” and the race was on. The first attempts at mechanizing reasoning included Newell and Simon’s 1956 computer program, the *Logic Theory Machine*, and a computer program developed by Wang that proved theorems in propositional logic.

Early on, it was recognized that **automated reasoning** is central to the development of machine intelligence, and central to automated reasoning is automated theorem proving, which can be thought of as mechanical techniques for determining whether a logical formula is satisfiable. The key to automated theorem proving is inference rules that can be implemented as algorithms. The first major breakthrough was Robinson’s landmark paper in 1965, in which the resolution principle and the unification algorithm were introduced [Robinson 1965]. That paper marked the beginning of a veritable explosion of research in machine-oriented logics.

The focus of this chapter is on reasoning through mechanical inference techniques. The fundamental principles underlying a number of logics are introduced, and several of the numerous theorem proving techniques that have been developed are explored.

The underlying logics can generally be classified as **classical** — roughly, the logic described by Aristotle — or as **nonstandard** — logics that were developed somewhat more recently. Most of the alternative logics that have been proposed are extensions of classical logic, and inference methods for them are typically based on classical deduction techniques. Reasoning with uncertainty through **fuzzy logic** and nonmonotonic

reasoning through **default logics**, for example, have for the most part been based on variants and extensions of classical proof techniques; see, for example, Reiter's paper in Bobrow [1980] and Lee [1972] and Lifschitz [1995].

This chapter touches on three disciplines: artificial intelligence, automated theorem proving, and symbolic logic. Many researchers have made important contributions to each of them, and it is impossible to describe all logics and inference rules that have been considered. We believe that the methodologies described are typical and should give the reader a basis for further exploration of the vast and varied literature on the subject.

61.2 Underlying Principles

We begin with a brief review of **propositional classical logic**. Propositional logic may not be adequate for many reasoning tasks, so we also examine first-order logic and consider some nonstandard logics. An excellent (and more detailed, albeit somewhat dated) exposition of the fundamentals of computational logic is the book by Chang and Lee [1973].

61.2.1 Propositional Logic

A *proposition* is a statement that is either true or false (but not both); *carbon is an element* and *Hercules is president* are both examples. A single proposition is often called an *atomic formula* or simply an *atom*. Logical formulas are built from a set \mathcal{A} of atoms, a set of connectives, and a set of logical constants in the following way: atoms and constants are formulas; if Θ is an n -ary connective and if $\mathcal{F}_1, \mathcal{F}_2, \dots, \mathcal{F}_n$ are formulas, then so is $\Theta(\mathcal{F}_1, \mathcal{F}_2, \dots, \mathcal{F}_n)$. The expression

$$(A \vee \neg B) \leftrightarrow (B \rightarrow \text{true})$$

is an example with one constant *true*, two atoms A and B , one unary connective \neg (*negation*), and three binary connectives \vee (*logical or*), \leftrightarrow (*logical if and only if*), and \rightarrow (*logical implication*). Negated atoms play a special role in most deduction techniques, and the word **literal** is used for an atom or for the negation of an atom.

The semantics (meaning) of a logical formula are characterized by truth values. In classical logic, the possible truth values are *true* and *false*; in general, the set of truth values may be any set.

Connectives can be viewed as function symbols appearing in the strings representing formulas, or, less formally, if Δ is the set of truth values, then an n -ary connective is a function from Δ^n to Δ . In classical logic, $\Delta = \{\text{true}, \text{false}\}$; there are four functions from Δ to Δ , and only one is an interesting connective: standard negation. There are 16 binary connectives (i.e., functions from $\Delta \times \Delta$ to Δ). Of particular interest are conjunction \wedge and disjunction \vee .

Most **inference rules** assume that formulas have been normalized in some manner. A formula is in **negation normal form (NNF)** if conjunction and disjunction are the only binary connectives and if all negations are at the atomic level. A formula is in **conjunctive normal form (CNF)** if it is a conjunction of clauses, where a clause is a disjunction of literals; the term "**clause form**" refers to CNF. Observe that CNF is a special case of NNF.

An **interpretation** is a function from the atom set \mathcal{A} to the set Δ of truth values. In practice, we use the word "interpretation" for a *partial interpretation* for a formula \mathcal{F} : an assignment of a truth value only to the atoms that occur in \mathcal{F} . Interpretations can be extended to complex formulas according to the functions represented by the connectives in the logic. A formula in classical logic is **satisfiable** if it evaluates to *true* under some interpretation. For other logics, where the set Δ of truth values is arbitrary, *satisfiability* is determined by a designated subset Δ^* . That is, an interpretation I satisfies a formula \mathcal{F} if I maps \mathcal{F} to a truth value in Δ^* . A formula C is said to be a **logical consequence** of \mathcal{F} if every interpretation I that satisfies \mathcal{F} also satisfies C ; in that case, we write $\mathcal{F} \models C$.

61.2.2 Inference and Deduction

To paraphrase Hayes [1977], the meaning and the implementation of a logic meet in the notion of inference. Automated inference techniques can roughly be put into one of two categories: **inference rules** and **rewrite rules**. Inference rules are applied to a formula, producing a conclusion that is conjoined to the original formula. When a rewrite rule is applied to a formula, the result is a new formula in which the original formula may not be present. The distinction is really not that clear: the rewritten formula can be interpreted as a conclusion and conjoined to the original formula. We will consider examples of both. Resolution is an inference rule, and the **tableau method** and **path dissolution** can be thought of as rewrite rules.

Inference rules can be written in the following general form:

$$\frac{\text{premise}}{\text{conclusion}} \quad (61.1)$$

where *premise* is a set of formulas* and *conclusion* is a formula. A *deduction* of a formula C from a given set of formulas \mathcal{S} is a sequence

$$C_0, C_1, \dots, C_n$$

such that $C_0 \in \mathcal{S}$, $C_n = C$, and for each i , $1 \leq i \leq n$, C_i satisfies one of the following conditions:

1. $C_i \in \mathcal{S}$
2. There is an inference rule (*premise/conclusion*) such that *premise* $\subseteq \{C_0, C_1, \dots, C_{i-1}\}$, and $C_i =$ *conclusion*

We use the notation $\mathcal{S} \vdash C$ to indicate that there is a deduction of C from \mathcal{S} .

A simple example of an inference rule is

$$\frac{\text{premise}}{\text{chocolate is good stuff}}$$

that is, *chocolate is good stuff* is inferred from any premise. We have several colleagues who can really get behind this particular rule, but it appears to lack something from the automated reasoning point of view. To avoid the possible problems inherent in this rule, there are two standards against which inference rules are judged:

1. **Soundness:** Suppose $\mathcal{F} \vdash C$. Then $\mathcal{F} \models C$.
2. **Completeness:** Suppose $\mathcal{F} \models C$. Then $\mathcal{F} \vdash C$.

Of the two properties, the first is the more important; the ability to draw valid (and only valid!) conclusions is more critical than the ability to draw all valid conclusions. In practice, many researchers are interested in *refutation* completeness, that is, the ability to verify that an unsatisfiable formula is, in fact, unsatisfiable. As we shall see when considering nonmonotonic reasoning, even soundness may not always be a desirable property.

61.2.3 First-Order Logic

Theorem proving often requires **first-order logic**. Typically, one starts with propositional inference rules and then employs some variant of Robinson's **unification algorithm** and the **lifting lemma** [Robinson 1965]. In this section we present the basics of first-order logic.

Atoms are usually called *predicates* in first-order logic, and predicates are allowed to have arguments. For example, if M is the predicate "is a man," then $M(x)$ may be interpreted as "x is a man." Thus, $M(\text{Socrates})$, $M(7)$, and (because function symbols are allowed) $M(f(x))$ are all well formed. In general, predicates can have any (finite) number of arguments, and any *term* can be substituted for any argument. Terms are

*In most settings — certainly in this chapter — a *set of formulas* is essentially the conjunction of the formulas in the set.

defined recursively as follows: variables and constant symbols are terms, and if t_1, t_2, \dots, t_n are terms and if f is an n -ary function symbol, then $f(t_1, t_2, \dots, t_n)$ is a term.

First-order formulas are essentially the same as propositional formulas, with the obvious exception that the atoms that appear are predicates. However, first-order formulas can be **quantified**. In the following example, c is a constant, x is a *universally* quantified variable, and y is *existentially* quantified; the unquantified variable z is said to be *quantifier-free* or simply *free*,

$$\forall x \exists y (P(x, y) \vee \neg Q(y, z, c))$$

Interpretations at the first-order level are different because a **domain of discourse** over which the variables may vary must be selected. If \mathcal{F} is a formula with n free variables, if I is an interpretation, and if \mathcal{D} is the corresponding domain of discourse, then I maps \mathcal{F} to a function from \mathcal{D}^n to Δ . A *valuation* is an assignment of variables to elements of \mathcal{D} . Under interpretation I and valuation V , a formula \mathcal{F} yields a truth value, and two formulas are said to be *equivalent* if they evaluate to the same truth value under all interpretations and valuations.

Of particular importance to the theoretical development of inference techniques in AI is the class of *Herbrand interpretations*. These are interpretations whose domain of discourse is the **Herbrand universe**, which is built from the variable-free terms in the given formula. It can be defined recursively as follows. Let \mathcal{F} be any formula. Then, H_0 is the set of constants that appear in \mathcal{F} . If there are no constants, let a be any constant symbol, and let $H_0 = \{a\}$. For each nonnegative integer n , H_{n+1} is the union of H_n and the set of all terms of the form $f(t_1, t_2, \dots, t_m)$, where $t_i \in H_n$ for $i = 0, 1, 2, \dots, m$. Then the Herbrand universe is $H = \bigcup_{i=0}^{\infty} H_i$. The importance of Herbrand interpretations is made clear by the following theorem: *A formula \mathcal{F} is unsatisfiable if and only if \mathcal{F} is unsatisfiable under Herbrand interpretations.*

In general, it is possible to transform any first-order formula to an equivalent (i.e., truth preserving) **prenex normal form**: all quantifiers appear in the front of the formula. A formula \mathcal{F} in prenex normal form can be further normalized to a satisfiability preserving **Skolem standard form** \mathcal{G} : All existentially quantified variables are replaced by constants or by functions of constants and the universally quantified variables. *Skolemizing* a formula in this manner preserves satisfiability: \mathcal{F} is satisfiable if and only if \mathcal{G} is.*

Because the quantifiers appearing in \mathcal{G} are all universal, we can (and typically do) write \mathcal{G} without quantifiers, it being understood that all variables are universally quantified.

A **substitution** is a function that maps variables to terms. Any substitution can be extended in a straightforward way to apply to arbitrary expressions. Given a set of expressions E_1, \dots, E_n , each of which can be a term, an atom, or a clause, a substitution θ is a **unifier** for the set $\{E_1, \dots, E_n\}$ if $\theta(E_1) = \theta(E_2) = \dots = \theta(E_n)$. A unifier θ of a set of expressions E is called *the most general unifier* (mgu) if given any unifier γ of E , $\gamma \circ \theta = \gamma$. For example, the two expressions $P(a, y), P(x, f(z))$ are unifiable via the substitution θ_1 , which maps y to $f(z)$ and x to a . They are also unifiable via the substitution θ_2 , which maps y to $f(a)$, z to a , and x to a . The substitution θ_1 is more general than θ_2 . When a substitution is applied to a formula, the resulting formula is called an *instance* of the given formula.

Robinson's unification algorithm [Robinson 1965] provides a means of finding the mgu of any set of unifiable expressions. Robinson proved the lifting lemma in the same paper, and the two together represent what may be the most important single advance in automated theorem proving.

61.3 Best Practices

61.3.1 Classical Logic

Not surprisingly, the most widely adopted logic in AI systems is classical (two-valued) logic. The truth value set Δ is $\{true, false\}$, and the designated truth value set Δ^* is $\{true\}$. Some examples of AI programs based on classical logic include problem solvers such as Green's program [Green 1969], theorem provers such

*Perhaps surprisingly, Skolemization does not, in general, preserve equivalence.

as OTTER [McCune 1992], Astrachan’s METEOR (see Wrightson [1994]), the Boyer and Moore [1979] theorem prover, the *Rewrite Rule Laboratory* [Kapur and Zhang 1989], and a number of model finding systems for propositional logic [Moskewcz et al. 2001, Zhang and Stickel 2000, Selman et al. 1992]. There are several deduction-based programming languages such as Prolog; a good source is the book by Sterling and Shapiro [1986]. In this section we describe one inference rule (**resolution**) and two rewrite rules (the **tableau method** and its generalization, **path dissolution**). These methods are *refutation* complete; that is, they verify that an unsatisfiable formula is in fact unsatisfiable. In contrast, Section 61.3.4 on “Model Finding in Propositional Logic” examines several complete and incomplete techniques for finding *models*, that is, for finding satisfying interpretations of a formula, if any exist.

61.3.2 Resolution

Perhaps the most widely applied inference rule in all of AI is the resolution principle of Robinson [1965]. It assumes that each formula is in CNF (a conjunction of clauses). To define resolution for propositional logic, suppose we have a formula in CNF containing the two clauses in the premise; then the conclusion may be inferred,

$$\frac{(A_1 \vee A_2 \vee \cdots \vee A_m \vee L) \wedge (B_1 \vee B_2 \vee \cdots \vee B_n \vee \neg L)}{(A_1 \vee A_2 \vee \cdots \vee A_m \vee B_1 \vee B_2 \vee \cdots \vee B_n)} \quad (61.2)$$

The conclusion is called the *resolvent*, and the two clauses in the premise are called the *parent clauses*.

It is easy to see why resolution is sound. If an interpretation satisfies the formula, then it must satisfy every clause. Since L and $\neg L$ cannot simultaneously evaluate to *true*, one of the other literals must be *true*. Resolution is also complete; the proof is beyond the scope of this chapter.

The lifting lemma [Robinson 1965] enables the application of resolution to formulas in first-order logic. Roughly speaking, it says that if instances of two clauses can be resolved, then the clauses can be unified and resolved. The effect is that two first-order clauses can be resolved if they contain, respectively, positive and negative unifiable occurrences of the same predicate. To state the first-order resolution inference rule, let L_1 and L_2 be two occurrences of the same predicate (one positive, one negative) and let θ be the mgu of L_1 and L_2 . Then,

$$\frac{(A_1 \vee A_2 \vee \cdots \vee A_m \vee L) \wedge (B_1 \vee B_2 \vee \cdots \vee B_n \vee \neg L)}{(\theta(A_1) \vee \theta(A_2) \vee \cdots \vee \theta(A_m) \vee \theta(B_1) \vee \theta(B_2) \vee \cdots \vee \theta(B_n))} \quad (61.3)$$

In practice, an implementation based on resolution alone has limited value because unrestricted resolution tends to produce an enormous number of inferences. There are several approaches to controlling the search space. One is the *set of support* strategy, which identifies a subset of the original set of clauses as its set of support, and then insists that at least one parent clause in every resolvent come from the set of support. Another strategy, one that is especially useful for logic programming, is the *linear restriction*, wherein one parent clause must be the most recent resolvent. These strategies may be thought of as control of the deduction process through meta-level restrictions on the search space.

As a simple example, consider the knowledge that “Tweety is a canary,” “a canary is a bird,” and “a bird flies,” encoded as the following set of clauses:

$$\begin{aligned} & \text{Canary}(I) \\ & \neg \text{Canary}(x) \vee \text{Bird}(x) \\ & \neg \text{Bird}(x) \vee \text{Flies}(x) \end{aligned}$$

A linear resolution deduction of the fact that Tweety flies can be obtained as shown in Figure 61.1. The substitutions θ_1 and θ_2 both map x to the constant *Tweety*.

Bundy et al. [1988] argue that “[logic] provides only a low-level, step-by-step understanding, whereas a high-level, strategic understanding is also required,” and there are restrictions on the search space that attempt to incorporate some kind of understanding. For example, equality and inequality have a special status in many theories. An axiom $a = b$ in a theory typically indicates that a and b can be used

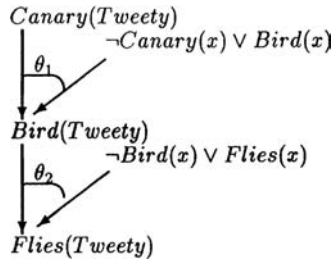

FIGURE 61.1 A deduction of $Flies(Tweety)$.

interchangeably in any context. Formally, the following equality axioms are implicitly assumed for theories requiring this property:

1. (Reflexivity) $x = x$.
2. (Symmetry) $(x = y) \rightarrow (y = x)$.
3. (Transitivity) $(x = y) \wedge (y = z) \rightarrow (x = z)$.
4. (Substitution 1) $(x_i = y) \wedge P(x_1, \dots, x_i, \dots, x_n) \rightarrow P(y_1, \dots, y, \dots, y_n)$ for $1 \leq i \leq n$, for each n -ary predicate symbol P .
5. (Substitution 2) $(x_i = y) \rightarrow f(x_1, \dots, x_i, \dots, x_n) = f(x_1, \dots, y, \dots, x_n)$ for $1 \leq i \leq n$, for each n -ary function symbol f .

The explicit incorporation of these axioms tends to drastically increase the search space, so Robinson and Wos [1969] proposed a specialized inference rule, **paramodulation**, for handling equality. Let $L[t]$ be a literal, let θ be the mgu of r and t , and let $\theta(L[s])$ be the literal obtained from $L[s]$ by replacing one occurrence of $\theta(t)$ in $L[t]$ with $\theta(s)$:

$$\frac{L[t] \vee D_1, (r = s) \vee D_2}{\theta(L[s]) \vee \theta(D_1) \vee \theta(D_2)} \quad (61.4)$$

The conclusion is called the *paramodulant* of the two clauses.

Using the Tweety example, suppose we have the additional knowledge that Tweety is known by the alias “Fred” (i.e., $Tweety = Fred$). Then the question, “Can Fred fly?” may be answered by extending the resolution proof shown in Figure 61.1 with the paramodulation inference, which substitutes the constant *Tweety* in the conclusion $Flies(Tweety)$ with *Fred* to obtain $Flies(Fred)$.

An inference rule such as paramodulation is semantically based because its definition comes from unique properties of the predicate and function symbols. Paramodulation treats the equality symbol $=$ with a special status that enables it to perform larger inference steps. Other semantically based inference rules can be found in Slagle [1972], Manna and Waldinger [1986], Stickel [1985], and Bledsoe et al. [1985].

Controlling paramodulation in an implementation is difficult. One system designed to handle equality is the RUE* system of Digricoli and Harrison [1986]. Its goal-directed nature tends to produce better computational behavior than paramodulation. The essential idea, illustrated in the following example, is to build the two substitution axioms into resolution. Let \mathcal{S} be the set of clauses

$$\{P(f(a)), \neg P(f(b)), (a = b)\}$$

and let \mathcal{E} be the equality axioms; that is, \mathcal{E} consists of the rules for reflexivity, transitivity, symmetry, and the following two substitution axioms:

$$\begin{aligned} (x = y) \wedge \neg P(x) &\rightarrow P(y) \\ (x = y) &\rightarrow (f(x) = f(y)) \end{aligned}$$

*Resolution with Unification and Equality.

As an equality theory, the set is unsatisfiable. That is, $\mathcal{S} \cup \mathcal{E}$ is not satisfiable; a straightforward resolution proof can be obtained as follows. Apply resolution to the first substitution axiom and the clause $\neg P(f(b))$ from \mathcal{S} ; the resolvent is

$$x \neq f(b) \vee P(x)$$

Resolving now with the clause $P(f(a))$ yields the resolvent

$$f(a) \neq f(b)$$

Finally, this clause can be resolved with the second substitution axiom to produce the clause $a \neq b$. This resolves with $a = b$ from the set \mathcal{S} to complete the proof.

RUE builds into the resolution inference the substitution axioms by observing that the two substitution axioms can be expressed equivalently as

$$\begin{aligned} P(y) \wedge \neg P(x) &\rightarrow x \neq y \\ f(x) \neq f(y) &\rightarrow x \neq y \end{aligned}$$

The inference rule

$$\frac{P(y), \neg P(x)}{x \neq y}$$

is introduced from the first axiom, and from the second, we obtain the inference rule

$$\frac{f(x) \neq f(y)}{x \neq y}$$

RUE further optimizes its computation by allowing the application of both inference rules in a single step. Thus, from the clauses $P(f(a))$ and $\neg P(f(b))$, the RUE resolvent $a \neq b$ can be obtained in a single step. Note that if only the first inference rule is applied, then the RUE resolvent of $P(f(a))$ and $\neg P(f(b))$ would be $f(a) \neq f(b)$.

61.3.3 The Method of Analytic Tableaux and Path Dissolution

Most theorem proving techniques employ clause form; the tableau method and the more general path dissolution do not. Tableau methods were originally developed and studied by a number of logicians, among them Beth [1955], Hintikka [1955], and Smullyan [1995], who built on the work of Gentzen [1969]. It is probably Smullyan who is most responsible for popularizing these methods; his particularly elegant variation on these techniques is known as the *method of analytic tableaux*. More recently, tableau methods have been receiving considerable attention from researchers investigating both automated deduction and logics for artificial intelligence; this includes serious implementors and those whose focus is primarily theoretical. See Beckert and Posegga [1995] for a compact (eight lines of Prolog code!) implementation of the tableau method. *Path dissolution* operates on a complementary pair of literals within a formula by restructuring the formula in such a way that all paths through the link vanish. The tableau method restructures the formula so that the paths through the link are immediately accessible and then marks them closed, in effect deleting them. It does this by selectively expanding the formula toward disjunctive normal form. The sense in which path dissolution generalizes the tableau method is that dissolution need not distinguish between the restructuring and the closure operations.

61.3.3.1 Negation Normal Form

One way to classify deduction systems is by what normalization they require of the formulas upon which they operate. As we have seen, resolution uses conjunctive normal form. Path dissolution and the tableau method cannot be restricted to clause form; both restructure a formula in such a way that clause form may not be preserved. In essence, both methods work with formulas in negation normal form (NNF). It turns

$$((\overline{C} \wedge A) \vee D \vee E) \wedge (\overline{A} \vee (B \wedge C)) \quad \equiv \quad \begin{array}{c} \overline{C} \\ \wedge \vee D \vee E \\ A \\ \wedge \\ \overline{A} \vee \begin{array}{c} B \\ \wedge \\ C \end{array} \end{array}$$

FIGURE 61.2 Graphical representation of a formula.

out that NNF formulas can be far more complex than formulas in clause form, and a careful analysis of NNF will facilitate the introduction of these proof techniques.

Recall that a formula is in NNF if conjunction and disjunction are the only binary connectives and if all negations are at the atomic level. Propositional formulas in NNF can be described recursively as follows:

1. The constants t and f are NNF formulas.
2. The literals A and $\neg A$ are NNF formulas.
3. If \mathcal{F} and \mathcal{G} are formulas, then so are $\mathcal{F} \wedge \mathcal{G}$ and $\mathcal{F} \vee \mathcal{G}$.

Each formula used in the construction of an NNF formula is called an *explicit subformula*. When a formula contains occurrences of *true* and *false*, the obvious truth-functional reductions apply. For example, if \mathcal{F} is any formula, then $t \wedge \mathcal{F} = \mathcal{F}$. Unless otherwise stated, we will assume that formulas are automatically so reduced.

It is often convenient to write formulas as two-dimensional graphs in a manner that can easily be understood by considering a simple example. In Figure 61.2, the formula on the left is displayed graphically on the right. For a more detailed exposition, see Murray and Rosenthal [1993].

Naturally, a literal A can occur more than once in a formula. As a result, we use the term “node” for a literal occurrence in a formula. If A and B are nodes in a formula \mathcal{F} , and if \mathcal{F} contains the subformula $X \wedge Y$ with A in X and B in Y , then we say that A and B are *c-connected*; *d-connected* nodes are similarly defined. In Figure 61.2, C is *c-connected* to each of B , A , \overline{C} , D , and E is *d-connected* to \overline{A} .

Let \mathcal{F} be a formula. A *partial c-path through \mathcal{F}* is a set of nodes such that any two are *c-connected*, and a *c-path through \mathcal{F}* is a partial *c-path* that is not properly contained in any partial *c-path*. The *c-paths* of the formula of Figure 61.2 are $\{\overline{C}, A, \overline{A}\}$, $\{\overline{C}, A, B, C\}$, $\{D, \overline{A}\}$, $\{D, B, C\}$, $\{E, \overline{A}\}$, and $\{E, B, C\}$. A *d-path* is similarly defined using *d-connected* nodes in place of *c-connected* nodes.

The *c-paths* of a formula are the clauses of one of its disjunctive normal form equivalents. Similarly, the *d-paths* correspond to the clauses of a CNF equivalent. It is easy to see that a formula is unsatisfiable if and only if every *c-path* in it is unsatisfiable, and a *c-path* is unsatisfiable if and only if it contains a *link* (i.e., a complementary pair of literals [an atom and its negative]). Most inference mechanisms operate on links; several are path based. The idea of the method of analytic tableaux is to isolate paths containing a link and then to eliminate them. Path dissolution accomplishes this without first isolating the paths in question. Other path-based methods include Andrews’s work on matings [Andrews 1976] and Bibel’s connection and connection graph methods (see Bibel [1987]).

61.3.3.2 The Tableau Method

The reader should be forewarned that there is a potentially misleading difference in emphasis between the typical descriptions of the tableau method and the one presented here. Tableau proofs are usually cast as tree structures in which paths can grow through the addition of new *lines* in the tree; the number of paths can increase due to a *splitting* or *branching* operation. The lines and branch points of a tableau proof tree are meta-linguistic representations of conjunction and disjunction, respectively. Here we strip them of their special status; a tableau proof tree then becomes merely a single formula. This simplifies the presentation, which is an advantage because of space limitations, and makes the relationship to path dissolution easier to see. Smullyan’s [1995] book is an excellent source for the traditional description of the tableau method.

Defining the tableau method in terms of formulas requires three rules: *separation*, *dispersion*, and *closure*. It is also convenient to designate certain subformulas as *primary*; they form a tree that corresponds precisely to the proof tree maintained by the more traditional approach to the tableau method. Initially, the entire formula is the only primary subformula. A separation is performed on any primary subformula whose highest-level connective is a conjunction by removing the primary designation from it and bestowing that designation on its conjuncts. There is essentially no cost to this operation, and it can be regarded as automatic whenever a conjunction becomes primary.

A separation can also be performed on a disjunction that is a leaf in the primary tree. (Separating an interior disjunction is not allowed because such an operation would destroy the tree structure.) Separations of such disjunctions should not be regarded as automatic; this operation increases the number of paths in the tree (we call such paths *tree* paths to distinguish them from *c*-paths); thus, although there is no cost to the operation itself, there is a potential penalty from the extra paths.

The process of dispersing a primary subformula whose highest-level connective is a disjunction can now be defined precisely: a copy of the subformula is placed at the end of one path descending from it and separated. For example, suppose that $X = X_1 \vee X_2$ is a primary subformula, and that the leaf Y is a descendant of X . On the left, we show the original tree path from X to Y ; on the right is the extension of that path produced by dispersing X :

The subformulas X and Y remain primary, and X_1 and X_2 are now designated as primary. Note that if a subformula is eventually dispersed to the ends of every path descending from it, the original copy is no longer required.

The key operations in a tableau deduction are the closures, which close tree paths. Marking a tree path closed is equivalent to deleting it. In terms of the tree of primaries, a tree path can be closed when a separation or a dispersion makes primary a literal that forms a link with one of its ancestors. The literal and all of its descendants are deleted, and any leaves that result are, in turn, deleted. Because the tree path through the link is removed, the effect is to delete all *c*-paths through the link.

Consider, for example, the unsatisfiable formula $((A \wedge B) \vee \overline{C}) \wedge C \wedge (\overline{A} \vee \overline{B})$, pictured in [Figure 61.3a](#). Boxes are used to designate primary subformulas; initially, the entire formula is the only one. Because it is a conjunction, this primary subformula is automatically separated; the result is [Figure 61.3b](#).

Note that there is yet only one path in the tree. As a result, a dispersion can be performed by moving (without a duplicate copy) any primary to the leaf position and then separating. For simplicity, we separate the primary that is already a leaf ([Figure 61.3c](#)). The formula, as a formula, is unchanged. But by designating \overline{A} and \overline{B} as primary, the proof tree has split and now contains two tree paths. Only one operation can follow: dispersion of the upper primary. It can be dispersed twice, once for each tree path, allowing the deletion of the original copy at the root; the result is pictured in [Figure 61.4](#).

The remainder of the proof is straightforward. Each of the primary subformulas $(A \wedge B)$ is separated into two primaries, and each of the four paths in the tree can be closed; two paths contain a $\{C, \overline{C}\}$ link, another contains $\{\overline{A}, A\}$, and the fourth contains $\{\overline{B}, B\}$.

A tree path is the conjunction of its nodes, that is, of its primary subformulas. We can also view a tree path as a collection of *c*-paths. For example, the single tree path in [Figure 61.3c](#) that contains \overline{A} is a conjunction of three primaries and contains the *c*-paths $\{A, B, C, \overline{A}\}$, $\{\overline{C}, C, \overline{A}\}$. Note also that dispersion is the source

FIGURE 61.3 Separation of primary subformulas.

FIGURE 61.4 Duplication produced by dispersion.

of all literal duplication (the expensive part) with the tableau method. In Figure 61.4, for example, an extra copy (in this case only one) of $((A \wedge B) \vee \bar{C})$ has been created for all but the last descendant leaf to which it has been dispersed.

61.3.3.3 Path Dissolution

Path dissolution operates on a *link* — a complementary pair of literals — within a formula by restructuring the formula in such a way that all paths through the link vanish. The tableau method restructures a formula so that the paths through the link are immediately accessible and then marks them closed, in effect deleting them. It does this by selectively expanding the formula toward disjunctive normal form. The sense in which dissolution generalizes the tableau method is that dissolution need not distinguish between the restructuring and closure operations.

Path dissolution is, in general, applicable to collections of links; here we restrict attention to single links. Suppose then that we have complementary literals A and \bar{A} residing in conjoined subformulas X and Y , respectively. Consider, for example, the link $\{A, \bar{A}\}$ on the left in Figure 61.5. Then the formula can be written $\mathcal{D} = (X \wedge Y)$, where

$$X = \begin{matrix} \bar{C} \\ \wedge \\ A \end{matrix} \vee D \vee E \quad \text{and} \quad Y = \begin{matrix} B \\ \wedge \\ C \end{matrix}$$

The *c-path complement* of a node A with respect to X , written $CC(A, X)$, is defined to be the subformula of X consisting of all literals in X that lie on c -paths that do not contain A ; the *c-path extension* of A with respect to X , written $CPE(A, X)$, is the subformula containing all literals in X that lie on paths that *do* contain A .

FIGURE 61.5 The right side is the path-dissolvent of $\{A, \overline{A}\}$ on the left.

In Figure 61.5, $CC(A, X) = (D \vee E)$; $CPE(A, X) = (\overline{C} \wedge A)$.

It is intuitively clear that the paths through $(X \wedge Y)$ that do not contain the link are those through $CPE(A, X) \wedge CC(\overline{A}, Y)$ plus those through $(CC(A, X) \wedge CPE(\overline{A}, Y))$ plus those through $(CC(A, X) \wedge CC(\overline{A}, Y))$. The reader is referred to Murray and Rosenthal [1993] for the formal definitions of CC and of CPE and for the appropriate theorems.

The *dissolvent* of the link $H = \{A, \overline{A}\}$ in $M = X \wedge Y$ is defined by

$$DV(H, M) = \begin{array}{ccc} CPE(A, X) & & CC(A, X) \\ \wedge & \vee & \wedge \\ CC(\overline{A}, Y) & & CPE(\overline{A}, Y) \end{array} \vee \begin{array}{ccc} CC(A, X) & & \\ \wedge & & \\ CC(\overline{A}, Y) & & \end{array}$$

The c -paths of $DV(H, M)$ are exactly the c -paths of M that *do not* contain the link. Thus, M and $DV(H, M)$ are equivalent. In general, M need not be the entire formula; without being precise, M is the smallest part of the formula that contains the link. If \mathcal{F} is the entire formula, then the *dissolvent of \mathcal{F} with respect to H* , denoted $Diss(\mathcal{F}, H)$, is the formula produced by replacing M in \mathcal{F} by $DV(H, M)$. If \mathcal{F} is a propositional formula, then $Diss(\mathcal{F}, H)$ is equivalent. Because the paths of the new formula are all that appeared in \mathcal{F} except those that contained the link, this formula has strictly fewer c -paths than \mathcal{F} . As a result, finitely many dissolutions (bounded above by the number of c -paths in the original formula) will yield a linkless equivalent formula. We can therefore say that path dissolution is a *strongly complete* rule of inference for propositional logic; that is, if a formula is unsatisfiable, any sequence of dissolution steps will eventually produce the empty clause.

A useful special case of dissolution arises when X consists of A alone; then $CC(A, X)$ is empty, and the dissolvent of the link $\{A, \overline{A}\}$ in the subformula $X \wedge Y$ is $X \wedge CC(\overline{A}, Y)$; that is, dissolving has the effect of replacing Y by $CC(\overline{A}, Y)$, which is formed by deleting \overline{A} and anything directly conjoined to it. Hence, no duplications whatsoever are required. A tableau closure is essentially a dissolution step of this type. Observe that a separation in a tableau proof does not really affect the structure of the formula; it is a bookkeeping device employed to keep track of the primaries in the tree. A dispersion is essentially an application of the distributive laws, which of course can be used by any logical system. As a result, every tableau proof is a dissolution proof, but certainly not vice versa.

61.3.4 Model Finding in Propositional Logic

Model finding is the counterpart of determining unsatisfiability; it is the process of searching for an interpretation that satisfies a given formula. A number of high-performance model finding systems have been developed in recent years. They are able to handle formulas with thousands of variables and millions of clauses. These systems generally fall into one of two categories: *systematic* or *stochastic*. Roughly speaking, systematic methods explore the space of interpretations through variations of backtracking techniques. Given sufficient time and space, these methods are guaranteed to find a satisfying interpretation, if one exists. Systematic methods are thus complete. Stochastic methods are, in contrast, incomplete. They apply heuristic search techniques to prune large portions of the search space and often find satisfying interpretations much more quickly than systematic methods. The basis for most systematic systems is the Davis-Putnam procedure. The **GSAT** algorithm introduced by Selman, Levesque, and Mitchell [1992] is an example of a simple yet rather ingenious stochastic system.

61.3.4.1 The Davis-Putnam Procedure

The *Davis-Putnam* procedure consists of four inference rules: tautology removal, unit propagation, pure-literal removal, and splitting. These rules can be applied independently in any order but are often combined and ordered to reduce the search space. The following algorithm forms the basis of the system **SATO** by Zhang and Stickle [2000] and is typical of the technique.

```

bool DP-sat(clause set S) {
    repeat
        for each unit clause L in S do
            /* unit propagation */
            delete from S every clause containing L
            delete ¬L from every clause of S
        if S is empty return true
        else if S contains the empty clause return false
    until no changes occur in S
    /* splitting */
    choose a literal L in S
    if DP-sat(S ∪ {L})
        return true
    else if DP-sat(S ∪ {¬L})
        return true
    else
        return false
}

```

For example, consider the unsatisfiable input clause set,

$$\{A \vee B \vee \neg C, A \vee \neg B, \neg A, C, D\}$$

The algorithm repeatedly applies unit propagation until the empty clause is derived. Suppose A is selected first; then unit propagation produces

$$\{B \vee \neg C, \neg B, C, D\}$$

Selecting C next yields

$$\{B, \neg B, D\}$$

Finally, unit propagation on B produces a set that contains the empty clause (represented by \square):

$$\{\square, D\}$$

The presence of \square signals that the original clause set is unsatisfiable.

Note that if the clause set is satisfiable, then the literals selected during the computation of the algorithm produce a model of the set, as the next example illustrates. Consider the input set

$$\{A \vee B, \neg B, \neg A \vee B \vee \neg C\}$$

Selecting $\neg B$ and applying unit propagation yields the clause set

$$\{A, \neg A \vee \neg C\}$$

Applying unit propagation on A then produces the set

$$\{\neg C\}$$

Finally, unit propagation on $\neg C$ results in the empty set. The model thus obtained for the initial clause set is $\{\neg B, A, \neg C\}$.

Literals selected for splitting can also contribute to the model. For example, no unit propagation is possible with the input set

$$\{A \vee \neg B, \neg A \vee B, B \vee \neg C, \neg B \vee \neg C\}$$

If A is selected for splitting, then the clause set passed to the recursive call of the algorithm is

$$\{A \vee \neg B, \neg A \vee B, B \vee \neg C, \neg B \vee \neg C, A\}$$

The only literal on which unit propagation is possible is A . Hence, if the clause set is satisfiable, the model produced will contain A . It is easy to verify that the model for this example is $\{A, B, \neg C\}$.

Different implementations of the basic Davis-Putnam procedure have been developed. These include the use of sophisticated heuristics for literal selection, complex data structures, and efficient conflict detection methods.

61.3.4.2 GSAT

The GSAT algorithm employs a hill-climbing heuristic to find models of propositional clauses. Given a set of clauses, the algorithm first randomly assigns a truth value to each propositional variable and records the number of satisfied clauses. The main loop of the algorithm then repeatedly toggles the truth value of variables to increase the number of satisfied clauses. The algorithm continues until either all clauses are satisfied, or a preset amount of time has elapsed. The latter can occur either with an unsatisfiable clause set or if a model for a satisfiable clause set has not been found. That is to say, GSAT is incomplete. Figure 61.6 outlines the GSAT algorithm in more detail.

61.3.5 Nonclassical Logics

Many departures from classical logic that have been formalized in the AI research program have been aimed at common-sense reasoning. Perhaps the two most widely addressed limits of classical logic are its inability to model either reasoning with uncertain knowledge or reasoning with incomplete information. A number of nonclassical logics have been proposed; here we consider **multiple-valued logics**, fuzzy logic, and default logic. Alternatives to uncertain reasoning include probabilistic reasoning — see [Chapter 70](#)

Input: A set of clauses C , MAX-FLIPS, MAX-TRIES

Output: An interpretation that satisfies C or “don’t know”

1. for $i = 1$ to MAX-TRIES
 - $T =$ randomly generate a truth assignment for the variables of C
 - for $j = 1$ to MAX-FLIPS
 - (a) if T satisfies C return T
 - (b) find a variable p such that a change in its truth value gives the largest increase in the total number of clauses of C satisfied by T
 - (c) $T = T$ modified by the changing the truth assignment of p
2. return “don’t know”

FIGURE 61.6 The GSAT algorithm.

TABLE 61.1 Truth Table

G	H	$G \wedge H$	$G \vee H$	$G \rightarrow H$	$\neg G$
0	0	0	0	1	1
0	1/2	0	1/2	1	1
0	1	0	1	1	1
1/2	0	0	1/2	1/2	1/2
1/2	1/2	1/2	1/2	1	1/2
1/2	1	1/2	1	1	1/2
1	0	0	1	0	0
1	1/2	1/2	1	1/2	0
1	1	1	1	1	0

and nonmonotonic formalisms for knowledge representation. Inference techniques in nonclassical logics remain important; a common approach is to designate a set of satisfying truth values and then to adapt classical inference techniques.

61.3.5.1 Multiple-Valued Logics

One of the drawbacks of classical logic is its restricted set Δ of truth values. A logic that generalizes Δ to be an arbitrary set is commonly referred to as a *multiple-valued* (or *many-valued*) logic (MVL). Although the precise boundary of what can be classified as a multiple-valued logic is not all that clear [Urquhart 1986], logics that are generally agreed to fit that description have been applied to reasoning with uncertainty, to reasoning with inconsistency, to natural language processing, and, to some extent, to nonmonotonic reasoning.

We examine extensions of classical inference techniques to MVLs based on the framework of **signs**: sets of truth values. The discussion of MVLs leads naturally to the examination of fuzzy logic, which, from a deduction point of view, can be viewed as an MVL.

An MVL Λ is more general than classical logic in one respect: the set Δ of truth values can be arbitrary. As with classical logic, an interpretation for Λ is a function from its atom set \mathcal{A} to Δ ; that is, an assignment of truth values to every atom in Λ . A connective Θ of arity n denotes a function $\Theta : \Delta^n \rightarrow \Delta$. Interpretations are extended in the usual way to mappings from the set of formulas to Δ .

Consider, for example, Łukasiewicz's [1970] three-valued logic. The set of truth values is $\Delta = \{0, 1/2, 1\}$; the binary connectives are \wedge , \vee , and \rightarrow ; and the only unary connective is \neg . The connectives are defined by the truth table, Table 61.1.

The designated set of truth values of Łukasiewicz's logic is $\{1\}$. Thus, the consequence relation means that $\mathcal{F} \models C$ if whenever an interpretation I assigns the value 1 to \mathcal{F} , then I also assigns 1 to C .

Intuitively, the truth value $1/2$ in Łukasiewicz's logic denotes possible. A variant of this three-valued logic is Kleene's, in which the truth value $1/2$ corresponds to undefined [Kleene 1952]. In a more recent three-valued logic proposed by Priest, the value $1/2$ may be thought of as denoting inconsistency.

A good reference for deduction techniques for MVLs is Hähnle's monograph, *Automated Deduction in Multiple-Valued Logics* [Hähnle 1994]. The key to the approach described there is the use of signs — subsets of the set Δ of truth values. If \mathcal{F} is any formula and if S is any sign, the expression $S : \mathcal{F}$ can be interpreted as the assertion " \mathcal{F} evaluates to a truth value in S ." For each interpretation over the MVL Λ , this assertion is either true or false, so $S : \mathcal{F}$ can be treated as a proposition in classical logic. For example, let \mathcal{F} be a formula in Łukasiewicz's logic, and suppose we are interested in determining whether a formula C is a logical consequence of \mathcal{F} . One strategy is to determine whether the following disjunction of signed formulas must evaluate to *true* under all interpretations over Λ :

$$\{0, 1/2\} : \mathcal{F} \vee \{1\} : C$$

The connective \vee is classical. Thus, given any interpretation, for the disjunction to evaluate to 1, either \mathcal{F} evaluates to 0 or to $1/2$, or C evaluates to 1. In particular, if \mathcal{F} evaluates to 1, then so must C , which is to say that C is a logical consequence of \mathcal{F} .

For example, let \mathcal{F} be the formula $(p \wedge r) \wedge (p \rightarrow q)$. To show that q is a logical consequence of \mathcal{F} , we must determine whether the formula

$$\{0, 1/2\} : \mathcal{F} \vee \{1\} : q \quad (61.5)$$

is a tautology. Using the tableau method, we attempt to find a closed tableau for the negation of Equation 61.5. It is useful to first drive the signs inward; thus, from the truth table:

$$\begin{aligned} \{1\} : ((p \wedge r) \wedge (p \rightarrow q)) \wedge \{0, 1/2\} : q &= \{1\} : p \wedge \{1\} : r \wedge \{1\} : (\neg p \vee q) \wedge \{0, 1/2\} : q \\ &= \{1\} : p \wedge \{1\} : r \wedge (\{1\} : \neg p \vee \{1\} : q) \wedge \{0, 1/2\} : q \\ &= \{1\} : p \wedge \{1\} : r \wedge (\{0, 1/2\} : p \vee \{1\} : q) \wedge \{0, 1/2\} : q \end{aligned}$$

The last formula is the initial tableau tree; if the disjunction is dispersed, the tableau becomes

$$\begin{array}{c} \boxed{\{1\} : p} \\ \wedge \\ \boxed{\{1\} : r} \\ \wedge \\ \boxed{\{0, 1/2\} : q} \\ \wedge \\ \boxed{\{0, 1/2\} : p} \vee \boxed{\{1\} : q} \end{array}$$

To close a tree path, the path must contain a *generalized link*: signed atoms $S_1 : A$ and $S_2 : A$, where S_1 and S_2 are disjoint. There are two tree paths in this tableau; the left path contains the link $\{\{1\} : p, \{0, 1/2\} : p\}$, and the right contains the link $\{\{0, 1/2\} : q, \{1\} : q\}$. Thus, the tableau can be closed and the proof is complete.

Most other classical inference techniques — for example, resolution and path dissolution — can similarly be generalized to MVLs using signed formulas, which can be thought of as formalizing metalevel reasoning about an arbitrary MVL Δ . In Lu et al. [1998], signed formulas provide a framework for adapting most classical inference techniques. The idea is to treat each signed formula $S : \mathcal{F}$ as a proposition in classical logic. Then, classical inferences made by restricting attention to the Δ -consistent interpretations — those interpretations that assign true to a proposition $S : \mathcal{F}$ if and only if there is a corresponding interpretation over Δ that assigns some truth value in S to \mathcal{F} — yield an inference about the MVL Δ .

The language of signed formulas is closely related to the system of annotated logic studied in Kifer and Lozinskii [1992] and in Blair and Subrahmanian [1989]. Those authors had the goal of developing reasoning systems capable of dealing with inconsistent information. An examination of the relationship between logic programming based on signs and annotations can be found in Lu [1996]. Automated reasoning systems that implement reasoning in MVLs based on signed formulas include the 3TAP program of Beckert et al. [1992].

61.3.5.2 Fuzzy Logic

In recent years, fuzzy logic, which was introduced by Zadeh in 1965, has received considerable attention, largely for engineering applications such as heuristic control theory. There are at least two other views of fuzzy logic — see Dubois and Prade [1995] and Gaines [1977] — both closer to mainstream AI. One is that fuzzy logic can be regarded as an extension of classical logic for handling *uncertain* propositions — propositions whose truth values are derived from the unit interval $[0, 1]$. But relatively little attention has been paid to inference techniques for fuzzy logic; examples of deduction-based systems for fuzzy logic include Baldwin [1986], Lee [1972], Mukaidono [1982], and Weigert et al. [1993].

In fuzzy logic, the set of truth values is $\Delta = [0, 1]$, and so interpretations assign each proposition a value in the interval $[0, 1]$. As usual, n -ary connectives are functions from $[0, 1]^n$ to $[0, 1]$. Conjunction \wedge is

usually the function min, disjunction \vee is usually the function max, and \neg is usually defined by $\neg\phi = 1 - \phi$. There are several possibilities for the function \rightarrow ; perhaps the most obvious is $A \rightarrow B \equiv \neg A \vee B$.

The designated set of truth values Δ^* in fuzzy logic is a subinterval of $[0, 1]$ of the form $[\alpha, 1]$ for some $\alpha \geq 0.5$. We call such an interval positive, and correspondingly call an interval of the form $[0, \alpha]$, where $\alpha \leq 0.5$, negative. For example, Weigert et al. [1993] defined a threshold of acceptability, $\tau \geq 0.5$, which in effect specifies Δ^* to be $[\tau, 1]$. On the other hand, Lee and Mukaidono do not explicitly define Δ^* . However, their systems implicitly adopt $\Delta^* = [0.5, 1]$. We begin this section by considering the fuzzy logic developed by Lee [1972] and extended by Mukaidono [1982], and then examine the more recent work of Weigert et al. [1993].

If we restrict attention to fuzzy formulas that use \wedge and \vee interpreted as min and max, respectively, as the only binary connectives and \neg as defined as the only unary connective, then, as in the classical case, a formula can be put into an equivalent CNF. The keys are the observations

$$\neg(\mathcal{F} \wedge \mathcal{G}) = \neg\mathcal{F} \vee \neg\mathcal{G} \quad \text{and} \quad \neg(\mathcal{F} \vee \mathcal{G}) = \neg\mathcal{F} \wedge \neg\mathcal{G} \quad (61.6)$$

The resolution inference rule introduced by Lee is the obvious generalization of classical resolution. Let C_1 and C_2 be clauses (i.e., disjunctions of literals), and let L be an atom. Then the resolvent is defined by

$$\frac{L \vee C_1, \neg L \vee C_2}{C_1 \vee C_2} \quad (61.7)$$

Lee proved the following: Let C_1 and C_2 be two clauses, and let $R(C_1, C_2)$ be a resolvent of C_1 and C_2 . If I is any interpretation, let $\max\{I(C_1), I(C_2)\} = b$ and $\min\{I(C_1), I(C_2)\} = a > 0.5$. Then $a \leq I(R(C_1, C_2)) \leq b$.

Mukaidono defines an inference to be *significant* if for any interpretation, the truth value of the conclusion is greater than or equal to the truth value of the minimum of the clauses in the premise. Lee's theorem can thus be interpreted to say that an inference using resolution is significant.

Weigert et al. [1993] built on the work of Lee and Mukaidono. They augmented the language by allowing infinitely many negation symbols that they call *fuzzy operators*. A formula is defined as follows: Let A be an atom, let \mathcal{F} and \mathcal{G} be fuzzy formulas, and let $\phi \in [0, 1]$.^{*} Then:

1. ϕA is a fuzzy formula (also called a *fuzzy literal*)
2. $\phi(\mathcal{F} \wedge \mathcal{G})$ is a fuzzy formula
3. $\phi(\mathcal{F} \vee \mathcal{G})$ is a fuzzy formula

A simple example of a fuzzy formula is

$$\mathcal{F} = A \wedge 0.3(0.9B \vee 0.2C)$$

Several observations are in order. First, fuzzy operators are represented by real numbers in the unit interval. (That there are uncountably many fuzzy operators should not cause alarm. In practice, considering only rational fuzzy operators is not likely to be a problem. Indeed, with a computer implementation, we are restricted to a finite set of terminating decimals of at most n digits for some not very large n .) In particular, real numbers in the unit interval denote both truth values and fuzzy operators. Second, every formula and subformula is prefixed by a fuzzy operator; any subformula that does not have an explicit fuzzy operator prefix is understood to have 1 as its fuzzy operator.

The semantics of fuzzy operators are given via a kind of fuzzy product.

Definition 61.1 If $\phi, \delta \in [0, 1]$, then $\phi \otimes \delta = (2\phi - 1) \cdot \delta - \phi + 1$.

Observe that \otimes is commutative and associative. Also observe that

$$\phi \otimes \delta = \phi \cdot \delta + (1 - \phi) \cdot (1 - \delta)$$

^{*}Weigert et al. [1993] use λ for the fuzzy operator and Λ for the threshold of acceptability. We use ϕ and τ to avoid confusion with notation used in other parts of the chapter.

This last observation provides the intuition behind the fuzzy product \otimes : Were ϕ the probability that A_1 is true and were δ the probability that A_2 is true, then $\phi \otimes \delta$ would be the probability that A_1 and A_2 are both true or both false. (This probabilistic analogy is for intuition only; fuzzy logic is not based on probability.)

It turns out that the following generalization of Equation 61.6 holds: Let \mathcal{F} and \mathcal{G} be fuzzy formulas, and let ϕ be a fuzzy operator. If $\phi > 0.5$, then

$$\phi(\mathcal{F} \wedge \mathcal{G}) = \phi\mathcal{F} \wedge \phi\mathcal{G} \quad \text{and} \quad \phi(\mathcal{F} \vee \mathcal{G}) = \phi\mathcal{F} \vee \phi\mathcal{G}$$

If $\phi < 0.5$, then

$$\phi(\mathcal{F} \wedge \mathcal{G}) = \phi\mathcal{F} \vee \phi\mathcal{G} \quad \text{and} \quad \phi(\mathcal{F} \vee \mathcal{G}) = \phi\mathcal{F} \wedge \phi\mathcal{G}$$

In particular, every fuzzy formula is equivalent to one in which 1 is the only fuzzy operator applied to nonatomic arguments.

In addition to introducing fuzzy operators, Weigert et al. extended Lee and Mukaidono's work with the *threshold of acceptability*: a real number $\tau \in [0.5, 1]$. Then an interpretation I is said to τ -satisfy the formula \mathcal{F} if $I(\mathcal{F}) \geq \tau$. Observe that the threshold of acceptability is essentially a redefinition of Δ^* to $[\tau, 1]$. That is, the threshold of acceptability provides a variable for the definition of the designated set of truth values.

The significance of the threshold can be made clear by looking at some simple examples. Let $\tau = 0.7$ and consider each of the following three formulas: $0.8A$, $0.2A$, and $0.6A$. Suppose A is 1; that is, $I(A) = 1$ for some interpretation I . Then $I(0.8A) = 0.8 \geq \tau$, so that the first formula is satisfied. The latter two evaluate to 0.2 and to 0.6, and so neither is satisfied. Now suppose A is 0. The first formula evaluates to $0.8 \otimes 0 = 0.2$, and the second evaluates to $0.2 \otimes 0 = 0.8$, so that the second formula is τ -satisfied. In effect, because the fuzzy operator 0.2 is less than $1 - \tau$, $0.2A$ is a negative literal and is τ -satisfied by assigning false to the atom A . The value of the third formula is now $0.6 \otimes 0 = 0.4$. Thus, in either case, the third formula is τ -unsatisfiable. Weigert et al., in fact, define a clause to be τ -empty if every fuzzy operator of every literal in the clause lies between $1 - \tau$ and τ ; it is straightforward to prove that every τ -empty clause is τ -unsatisfiable.

The fuzzy resolution rule relies upon complementary pairs of literals. However, complementarity is a relative notion depending on the threshold τ . Two literals $\phi_1 A$ and $\phi_2 A$ are said to be τ -complementary if $\phi_1 \leq 1 - \tau$ and $\phi_2 \geq \tau$. Resolution for fuzzy logic, which Weigert et al. proved is sound and complete, can now be defined with respect to the threshold τ : Let $\phi_1 A$ and $\phi_2 A$ be τ -complementary, and let C_1 and C_2 be fuzzy clauses. Then,

$$\frac{\phi_1 A \vee C_1, \phi_2 A \vee C_2}{C_1 \vee C_2} \quad (61.8)$$

Suppose we now reconsider the example from the Resolution section, which encoded the knowledge that "Tweety is a canary," "A canary is a bird," and "A bird flies." In reality, not all birds fly. A perhaps more realistic representation of this knowledge is:

$$\begin{aligned} &1 \text{ Canary}(\text{Tweety}) \\ &0 \text{ Canary}(x) \vee 1 \text{ Bird}(x) \\ &0 \text{ Bird}(x) \vee 0.8 \text{ Flies}(x) \end{aligned}$$

The first two clauses represent the facts that Tweety is a canary and that all canaries are birds. In other words, the fuzzy operator 1 represents true, and the fuzzy operator 0 represents false. The fuzzy operator 0.8 can be interpreted as *highly likely*; thus, the third clause expresses the notion that most birds fly. Using the threshold 0.7 again and applying the same resolution steps as in Figure 61.1, we can infer $0.8 \text{ flies}(\text{Tweety})$. Observe that this means that the truth value of $\text{flies}(\text{Tweety})$ must be at least $5/6$ because $0.8 \otimes 5/6 = 0.7$.

61.3.5.3 Nonmonotonic Logics

Common-sense reasoning requires the ability to draw conclusions in the presence of incomplete information. Indeed, very few conclusions in our everyday thinking are based on knowledge of every piece of relevant information. Typically, numerous assumptions are required. Even a simple inference such as, *if x is a bird, then x flies*, is based on a host of assumptions regarding x; for instance, that x is not an unusual bird such as an ostrich or a penguin. It follows that logics for common-sense reasoning must be capable of modeling reasoning processes that permit incorrect (and reversible) conclusions based on false assumptions. This observation has motivated the development of nonmonotonic logics, whose origins can be traced to foundational works by Clark, McCarthy, McDermott and Doyle, and Reiter; see Gallaire and Minker [1978] and Bobrow [1980].

The term **nonmonotonic logic** highlights the fundamental technical difference from classical logic, which is monotonic in the sense that

$$\mathcal{F}_1 \vdash \gamma \quad \text{and} \quad \mathcal{F}_1 \subseteq \mathcal{F}_2 \quad \text{implies} \quad \mathcal{F}_2 \vdash \gamma \quad (61.9)$$

That is, classical entailment dictates that the set of conclusions from a knowledge base is inviolable; the addition of new knowledge never invalidates previously inferred conclusions. A classically based reasoning agent will therefore never be able to retract a conclusion in light of new, possibly contradictory information. Nonmonotonic logics, on the other hand, need not obey Equation 61.9.

The investigation of inference techniques for nonmonotonic logics has been limited, but there have been several interesting attempts. Comprehensive studies of nonmonotonic reasoning and default logic include Etherington [1988], Marek and Truszczyński [1993], Besnard [1989], and Moore's autoepistemic logic [Moore 1985]. We will focus on the nonmonotonic formalism of Reiter known as *default logic*; see his paper in Bobrow [1980]. Some of the other proposed systems contain technical differences, but the essence of *nonmonotonicity* — the failure to obey Equation 61.9 — is adhered to by all.

A *default* is an inference (scheme) of the form

$$\frac{\alpha : M\beta_1, \dots, M\beta_m}{\gamma} \quad (61.10)$$

where $\alpha, \beta_1, \dots, \beta_m$, and γ are formulas. The formula α is the *prerequisite* of the default, $\{M\beta_1, \dots, M\beta_m\}$ is the *justification*, and γ is the *consequent*; the M in the justification serve merely to demark the justification. A *default theory* is a pair (D, W) , where W is a set of formulas and D is a set of defaults. Intuitively, W can be thought of as the set of knowledge that is known to be true. A default theory (D, W) then enables a reasoner to draw additional conclusions through the defaults in D .

As a motivating example, consider the default rule

$$\frac{Bird(x) : MFly(x)}{Fly(x)} \quad (61.11)$$

The prerequisite specifies *if an individual x is a bird*, and the justification specifies, *if it is consistent to assume that x flies*, then we may infer by default that x flies. Suppose we have a theory consisting of the clause set $W = \{Canary(Tweety), \neg Canary(x) \vee Bird(x)\}$. Using classical logic, one logical consequence of W is the fact $Bird(Tweety)$. If $S = \{\alpha \mid W \vdash \alpha\}$ represents the reasoner's knowledge, then $S \cup \{Fly(Tweety)\}$ is consistent. That is, $S \cup \{Fly(Tweety)\}$ has a satisfying interpretation in classical logic. The default rule Equation 61.11 then warrants the inference $Fly(Tweety)$.

It is important to note that formulas and consequences in default logics are classical in the sense that a formula is either true or false. The difference from classical logic lies in the manner in which consequences are derived from a given set of formulas. From W we can conclude $Fly(Tweety)$. However, suppose we add to W the additional knowledge set A consisting of the clauses:

$$\begin{aligned} & Broken_Wings(Tweety) \\ & Broken_Wings(x) \rightarrow \neg Fly(x) \end{aligned}$$

Then $S = \{\alpha \mid W \vdash \alpha\}$ contains, among other things, the fact $\neg \text{Fly}(\text{Tweety})$. In this case, $\text{Fly}(\text{Tweety})$ is inconsistent with S ; that is, $S \cup \{\text{Fly}(\text{Tweety})\}$ is not satisfiable. Thus, the condition for the justification part of the default rule (Equation 61.11) is not met, and hence the conclusion $\text{Fly}(\text{Tweety})$ cannot be drawn. This provides a clear illustration of the nonmonotonic nature of default inference rules such as the default rule in Equation 61.11:

$$W \vdash_D \text{Fly}(\text{Tweety}), \quad \text{but} \quad W \cup A \not\vdash_D \text{Fly}(\text{Tweety})$$

where \vdash_D means deduction based on classical inference or the default rules in D .

In the initial version of the example, the conclusion $\text{Fly}(\text{Tweety})$ was obtained starting with the set S (which is the set of all classical consequences of W), and then applying the default rule according to the condition that $\text{Bird}(\text{Tweety})$ is a consequence of S , and that $\{\text{Fly}(\text{Tweety})\} \cup S$ is satisfiable. Now suppose a reasoner holds the following initial set of beliefs:

$$S_0 = \{\text{Bird}(\text{Tweety}), \text{Fly}(\text{Tweety}), \text{Canary}(\text{Tweety}), \text{Canary}(x) \rightarrow \text{Bird}(x)\}$$

This set contains S , and applications of the default rule (Equation 61.11) with respect to S_0 yield no additional conclusions. That is, because $\text{Bird}(\text{Tweety})$ is a classical consequence of S_0 , and $\text{Fly}(\text{Tweety}) \in S_0$, so that $\{\text{Fly}(\text{Tweety})\} \cup S_0$ is consistent, adding the conclusion $\text{Fly}(\text{Tweety})$ from the consequent of the default rule produces no changes in the beliefs S_0 . A set that has such a property holds special status in default logic and is called an *extension*. Intuitively, an extension E can be thought of as a set of formulas that *agree* with all the default rules in the logic; that is, every default whose prerequisites are in E and whose justification is consistent with E must have its consequence in E . Still another way to look at an extension E of W is as a superset of W that is closed under both classical and default inference.

To formally define extension, given a set of formulas E , let $th(E)$ denote the set of all classical consequence of E ; that is, $th(E) = \{\alpha \mid E \vdash \alpha\}$. If (D, W) is a default theory, let $\Gamma(E)$ be the smallest set of formulas that satisfies the following conditions:

1. $W \subseteq \Gamma(E)$.
2. $\Gamma(E) = th(\Gamma(E))$.
3. Suppose $(\alpha : M\beta_1, \dots, M\beta_m / \gamma) \in D$, $\alpha \in \Gamma(E)$, and $\neg\beta_1, \dots, \neg\beta_m \notin E$. Then $\gamma \in \Gamma(E)$.

Then, E is an extension of (D, W) if $E = \Gamma(E)$.

Observe that the third part of the definition requires $\neg\beta_i \notin E$ for each i . This is, in general, a weaker notion than the requirement that β_i be consistent with E . That is, were E not deductively closed under inference in classical logic, it is possible that one $\neg\beta_i$ is not a member of but is a logical consequence of E ; $E \cup \{\beta_i\}$ would then be inconsistent. However, in the case of an extension, which is closed under classical deduction, the two notions coincide.

The simple example just illustrated suggests a natural way of computing extensions; namely, begin with the formulas in W and repeatedly apply each default inference rule until no new inferences are possible. Of course, because default rules can be interdependent, the choice of which default rule to apply first can affect the extension that is obtained. For example, with the following two simple rules, the application of one prevents the application of the other by making the justification of the other inconsistent with the inferred fact:

$$\frac{\text{true} : MB}{\neg A} \quad \frac{\text{true} : MA}{\neg B}$$

Marek and Truszczyński introduced the operator R^D to compute extensions of a default logic. Let U be a set of formulas; then

$$R^D(U) = th\left(U \cup \left\{ \gamma \mid \frac{\alpha}{\gamma} \in D \text{ and } \alpha \in U \right\}\right)$$

Observe that α/γ is justification-free. Thus, R^D amounts to the closure of U under classical and justification-free default inference.

Repeated applications of the operator R^D is merely function composition and can be written as follows:

$$\begin{aligned} R^D \uparrow 0(U) &= U \\ R^D \uparrow (\alpha + 1)(U) &= R^D(R^D \uparrow \alpha(U)) \\ R^D \uparrow \lambda(U) &= \bigcup \{R^D \uparrow \alpha(U) \mid \alpha < \lambda\} \quad \text{for a limit ordinal } \lambda \end{aligned}$$

Given a default theory (D, W) and a set of formulas S , the *reduct* of D with respect to S (D_S) is defined to be the set of justification-free inference rules of the form α/γ , where $(\alpha : M\beta_1, \dots, M\beta_m/\gamma)$ is a default in D , and $\neg\beta_i \notin S$ for each i . The point is, once we know that a justification is satisfiable, then the corresponding justification-free rule is essentially equivalent.

Marek and Truszczyński showed that from the knowledge base W of a default theory, it is possible to use the operator R^D to determine whether a set of formulas is an extension.* More precisely, a set of formulas E is an extension of a default theory (D, W) if and only if $E = R^{D_E} \uparrow \omega(W)$.

Default logic is intimately connected with nonmonotonic logic programming. Analogs of the many results regarding extensions can be found in nonmonotonic logic programming. The problem of determining whether a formula is contained in some extension of a default theory is called the *extension membership problem*; in general, it is quite difficult because it is not semidecidable (as compared, for example, with first-order classical logic). This makes implementation of nonmonotonic reasoning much harder than the already-difficult task of implementing monotonic reasoning. Reiter speculated that a reasonable computational approach to default logic will necessarily allow for incorrect (unsound) inferences [Bobrow 1980]. This issue was also considered in Etherington [1988]. Some recent work on proof procedures for default logic can be found in Barback and Lobo [1995] (resolution based), in the work of Thielscher and Schaub (see Lifschitz [1995]), and in the tableau-based work of Risch and Schwind (see Wrightson [1994]). Work on general nonmonotonic deduction systems include Kraus et al. [1990].

61.4 Research Issues and Summary

Logic-based deductive reasoning has played a central role in the development of artificial intelligence. The scope of AI research has expanded to include, for example, vision and speech [Russell and Norvig 1995], but the importance of logical reasoning remains. At the heart of logic-based deductive reasoning is the ability to perform inference. In this chapter we have discussed but a few of the numerous inference rules that have been widely applied.

There are several directions that researchers commonly pursue in automated reasoning. One is the exploration of new logics. This line of research is more theoretical and intimately tied to the philosophical foundation of the reasoning processes of intelligent agents. Typically, the motivation behind newly proposed logics lies with some aspect of reasoning for which classical two-valued logic may not be adequate. Among the many examples are temporal logic, which attempts to deal with time-oriented reasoning [Allen 1991]; modal logics, which address questions of knowledge and beliefs [Fagin et al. 1992], and alternative MVLs [Ginsberg 1988].

Another area of ongoing research is the development of new inference techniques for existing logics, both classical and nonclassical; for example, Henschen [1979] and McRobbie [1991]. Such techniques might produce better general purpose inference engines or might be especially well-suited for some narrowly defined reasoning process.

Inference also plays an important role in *complexity theory*, which is, more or less, the analysis of the running time of algorithms; it is carefully described in other chapters. A fundamental question in complexity theory — indeed, a famous open question in all of computer science — is, “Does the class \mathcal{NP} equal the class \mathcal{P} ?” It has been shown [Cook 1971] that this question is equivalent to the question,

*Even for propositional default theory, this checking process is computationally very expensive because it is necessary to choose the set E non-deterministically.

“Is there a fast algorithm for determining whether a formula in classical propositional logic is satisfiable?” (Roughly speaking, *fast* means a running time that is polynomial in the size of the input.)

Implementation of deduction techniques continues to receive a great deal of attention from researchers. Considerable effort has gone into controlling the search space. In recent years, many authors have chosen to replace domain-independent, general-purpose control strategies with domain-specific strategies, for example, the work of Bundy, van Harmelen, Hesketh and Smaill, Smith, and Wos. Other implementation techniques for theorem provers include the use of discrimination trees by McCune, flatterms by Christian, and parallel representation by Fishman and Minker.

Defining Terms

Artificial intelligence: The field of study that attempts to capture aspects of human intelligence in machines.

Automated deduction, automated reasoning: Deduction techniques that can be mechanized.

Classical logic: The standard logic that employs the usual connectives and the truth values $\{true, false\}$.

Clause: A disjunction of literals.

Completeness: An inference or rewrite rule is complete if the rule can verify that an unsatisfiable formula is unsatisfiable.

Conjunctive normal form (CNF): A conjunction of clauses.

Davis-Putnam procedure: A systematic, backtracking procedure for propositional model finding.

Default logic: A nonmonotonic logic.

Domain of discourse: The set of values to which a first-order variable can be assigned.

First-order logic: Logic in which predicates can have arguments and formulas can be quantified.

Fuzzy logic: An extension of classical logic for handling uncertain propositions.

GSAT: A stochastic procedure for propositional model finding.

Herbrand universe: A domain of discourse constructed from the constants and function symbols that appear in a logical formula.

Inference rule: A rule that, when applied to a formula, produces another formula.

Interpretation: A function from the atom set to the set of truth values.

Lifting lemma: A lemma for proving completeness at the first-order level from completeness at the propositional level.

Literal: An atom or the negation of an atom.

Logical consequence: A formula C is a logical consequence of \mathcal{F} if every interpretation that satisfies \mathcal{F} also satisfies C .

Multiple-valued logic: Any logic whose set of truth values is *not* restricted to $\{true, false\}$.

Negation normal form (NNF): A form for logical formulas in which conjunction and disjunction are the only binary connectives and in which all negations are at the atomic level.

Nonmonotonic logic: A logic in which the addition of new knowledge may invalidate previously inferrable conclusions.

Paramodulation: A specialized inference rule for handling equality.

Path dissolution: An inference mechanism that operates on formulas in NNF.

Prenex normal form: A form for first-order logical formulas in which all quantifiers appear in the front of the formula.

Propositional logic: Logic in which predicates cannot have variables as arguments.

Quantifier: A restriction on variables in a first-order formula.

Resolution: An inference rule that operates on sets of clauses.

Rewrite rule: A rule that modifies formulas.

Satisfiable: A formula in classical logic is satisfiable if it evaluates to *true* under some interpretation.

Sign: Any subset of the set of truth values.

Skolem standard form: A form for first-order logical formulas in which all existentially quantified variables are replaced by constants or by functions of constants and the universally quantified variables.

Soundness: An inference (or rewrite rule) is sound if every inferred formula is a logical consequence of the original formula.

Substitution: A function that maps variables to terms.

Tableau method: An inference mechanism that operates on formulas in NNF.

Unification algorithm: An algorithm that finds the most general unifier of a set of terms.

Unifier: A substitution that unifies — makes identical — terms in different predicate occurrences.

Further Information

The *Journal of Automated Reasoning* is an excellent reference for current research and advances in logic-based automated deduction techniques for both classical and nonclassical logics. The International Conference on Automated Deduction (CADE) is the major forum for researchers focusing on logic-based deduction techniques; its proceedings are published by Springer-Verlag. Other conferences with an emphasis on computational logic and logic-based reasoning include the International Logic Programming Conference (ICLP), Logics in Computer Science (LICS), Logic Programming and Nonmonotonic Reasoning Conference (LPNMR), International Symposium on Multiple-Valued Logics (ISMVL), the International Symposium on Methodologies for Intelligent Systems (ISMIS), and the IEEE International Conference on Fuzzy Systems.

More general conferences on AI include two major annual meetings: the conference of the AAAI and the International Joint Conference on AI. Each of these conferences regularly publishes logic-based deduction papers. The *Artificial Intelligence* journal is an important source for readings on logics for common-sense reasoning and related deduction techniques.

Other journals of relevance include the *Journal of Logic and Computation*, the *Journal of Computational Intelligence*, the *Journal of Logic Programming*, the *Journal of Symbolic Computation*, *IEEE Transactions on Fuzzy Systems*, *Theoretical Computer Science*, and the *Journal of the Association of Computing Machinery*.

Most of the texts referenced in this chapter provide a more detailed introduction to the field of computational logic. They include Bibel [1987], Chang and Lee [1973], Fitting [1990], Loveland [1978], Robinson [1979], and Wos et al. [1992]. Good introductory texts for mathematical logic are Mendelson [1979] and Smullyan [1995].

Model finding and propositional deduction is an active area of research with special issues of journals and workshops dedicated to the topic. See Gent and Walsh [2000] and Kautz and Selman [2001] for recent advances in the field. Improvements on implementation techniques continue to be reported at a rapid rate. A useful source of information on the latest developments in the field can be found at <http://www.satlive.org>

62.1 Introduction

Qualitative reasoning is the area of artificial intelligence (AI) that creates representations for continuous aspects of the world, such as space, time, and quantity, which support reasoning with very little information. Typically, it has focused on scientific and engineering domains, hence its other name, qualitative physics. It is motivated by two observations. First, people draw useful and subtle conclusions about the physical world without equations. In our daily lives we figure out what is happening around us and how we can affect it, working with far less data, and less precise data, than would be required to use traditional, purely quantitative methods. Creating software for robots that operate in unconstrained environments and modeling human cognition require understanding how this can be done. Second, scientists and engineers appear to use qualitative reasoning when initially understanding a problem, when setting up more formal methods to solve particular problems, and when interpreting the results of quantitative simulations, calculations, or measurements. Thus, advances in qualitative physics should lead to the creation of more flexible software that can help engineers and scientists.

Qualitative physics began with de Kleer's investigation on how qualitative and quantitative knowledge interacted in solving a subset of simple textbook mechanics problems [de Kleer, 1977]. After roughly a decade of initial explorations, the potential for important industrial applications led to a surge of interest in the mid-1980s, and the area grew steadily, with rapid progress. Qualitative representations have made their way into commercial supervisory control software for curing composite materials, design, and FMEA (Failure Modes and Effects Analysis). The first product known to have been designed using qualitative physics techniques appeared on the market in 1994 [Shimomura et al., 1995]. Given its demonstrated utility in industrial applications and its importance in understanding human cognition, work in qualitative modeling is likely to remain an important area in artificial intelligence.

This chapter first surveys the state of the art in qualitative representations and in qualitative reasoning techniques. The application of these techniques to various problems is discussed subsequently.

62.2 Qualitative Representations

As with many other representation issues, there is no single, universal right or best qualitative representation. Instead, there exists a spectrum of choices, each with its own advantages and disadvantages for particular tasks. What all of them have in common is that they provide notations for describing and reasoning about continuous properties of the physical world. Two key issues in qualitative representation are resolution and **compositionality**. We discuss each in turn.

Resolution concerns the level of information detail in a representation. Resolution is an issue because one goal of qualitative reasoning is to understand how little information suffices to draw useful conclusions. Low-resolution information is available more often than precise information (“the car heading toward us is slowing down” vs. “the derivative of the car’s velocity along the line connecting us is -28 km/hr/sec”), but conclusions drawn with low-resolution information are often ambiguous. The role of ambiguity is important: the prediction of alternative futures (i.e., “the car will hit us” vs. “the car won’t hit us”) suggests that we may need to gather more information, analyze the matter more deeply, or take action, depending on what alternatives our qualitative reasoning uncovers. High-resolution information is often needed to draw particular conclusions (i.e., a finite element analysis of heat flow within a notebook computer design to ensure that the CPU will not cook the battery), but qualitative reasoning with low-resolution representations reveals what the interesting questions are. Qualitative representations comprise one form of tacit knowledge that people, ranging from the person on the street to scientists and engineers, use to make sense of the world.

Compositionality concerns the ability to combine representations for different aspects of a phenomenon or system to create a representation of the phenomenon or system as a whole. Compositionality is an issue because one goal of qualitative reasoning is to formalize the modeling process itself. Many of today’s AI systems are based on handcrafted knowledge bases that express information about a specific artifact or system needed to carry out a particular narrow range of tasks involving it. By contrast, a substantial component of the knowledge of scientists and engineers consists of principles and laws that are broadly applicable, both with respect to the number of systems they explain and the kinds of tasks they are relevant for. Qualitative physics is developing the ideas and organizing techniques for knowledge bases with similar expressive and inferential power, called **domain theories**.

The remainder of this section surveys the fundamental representations used in qualitative reasoning for quantity, mathematical relationships, **modeling assumptions**, causality, space, and time.

62.2.1 Representing Quantity

Qualitative reasoning has explored trade-offs in representations for continuous parameters ranging in resolution from sign algebras to the hyperreals. Most of the research effort has gone into understanding the properties of low-resolution representations because the properties of high-resolution representations tend to already be well understood due to work in mathematics.

The lowest resolution representation for continuous parameters is the status abstraction, which represents a quantity by whether or not it is *normal* [Abbott et al., 1987]. It is a useful representation for certain diagnosis and monitoring tasks because it is the weakest representation that can express the difference between something working and not working. The next step in resolution is the sign algebra, which represents continuous parameters as either $-$, $+$, or 0 , according to whether the sign of the underlying continuous parameter is negative, positive, or zero. The sign algebra is surprisingly powerful: because a parameter’s derivatives are themselves parameters whose values can be represented as signs, some of the main results of the differential calculus (e.g., the mean value theorem) can be applied to reasoning about sign values [de Kleer and Brown, 1984]. This allows sign algebras to be used for qualitative reasoning about dynamics, including expressing properties such as oscillation and stability. The sign algebra is the weakest representation that supports such reasoning.

Representing continuous values via sets of ordinal relations (also known as the **quantity space** representation) is the next step up in resolution [Forbus, 1984]. For example, the temperature of a fluid might be represented in terms of its relationship between the freezing point and boiling point of the material that comprises it. Like the sign algebra, quantity spaces are expressive enough to support qualitative reasoning about dynamics. (The sign algebra can be modeled by a quantity space with only a single comparison point, zero.) Unlike the sign algebra, which draws values from a fixed finite algebraic structure, quantity spaces provide variable resolution because new points of comparison can be added to refine values. The temperature of water in a kettle on a stove, for instance, will likely be defined in terms of its relationship with the temperature of the stove as well as its freezing and boiling points. There are two kinds of comparison points used in defining quantity spaces. **Limit points** are derived from general properties of a domain as applicable to a specific situation. Continuing with the kettle example, the particular ordinal relationships used were chosen because they determine whether or not the **physical processes** of freezing, boiling, and heat flow occur in that situation. The precise numerical value of limit points can change over time (e.g., the boiling point of a fluid is a function of its pressure). **Landmark** values are constant points of comparison introduced during reasoning to provide additional resolution [Kuipers, 1986]. To ascertain whether an oscillating system is overdamped, underdamped, or critically damped, for instance, requires comparing successive peak values. Noting the peak value of a particular cycle as a landmark value, and comparing it to the landmarks generated for successive cycles in the behavior, provides a way of making this inference.

Intervals are a well-known variable-resolution representation for numerical values and have been heavily used in qualitative reasoning. A quantity space can be thought of as partial information about a set of intervals. If we have complete information about the ordinal relationships between limit points and landmark values, these comparison points define a set of intervals that partition a parameter's value. This natural mapping between quantity spaces and intervals has been exploited by a variety of systems that use intervals whose endpoints are known numerical values to refine predictions produced by purely qualitative reasoning. Fuzzy intervals have also been used in similar ways, for example, in reasoning about control systems.

Order of magnitude representations stratify values according to some notion of scale. They can be important in resolving ambiguities and in simplifying models because they enable reasoning about what phenomena and effects can safely be ignored in a given situation. For instance, heat losses from turbines are generally ignored in the early stages of power plant design, because the energy lost is very small relative to the energy being produced. Several stratification techniques have been used in the literature, including hyperreal numbers, numerical thresholds, and logarithmic scales. Three issues faced by all these formalisms are (1) the conditions under which many small effects can combine to produce a significant effect, (2) the soundness of the reasoning supported by the formalism, and (3) the efficiency of using them.

Although many qualitative representations of number use the reals as their basis, another important basis for qualitative representations of number is finite algebras. One motivation for using finite algebras is that observations are often naturally categorized into a finite set of labels (i.e., very small, small, normal, large, very large). Research on such algebras is aimed at solving problems such as how to increase the compositionality of such representations (e.g., how to propagate information across different resolution scales).

62.2.2 Representing Mathematical Relationships

Like number, a variety of qualitative representations of mathematical relationships have been developed, often by adopting and adapting systems developed in mathematics. Abstractions of the analytic functions are commonly used to provide the lower resolution and compositionality desired. For example, **confluences** are differential equations over the sign algebra [de Kleer and Brown, 1984]. An equation such as $V = IR$ can be expressed as the confluence

$$[V] = [I] + [R]$$

where $[Q]$ denotes taking the sign of Q . Differential equations can also be expressed in this manner, for instance,

$$[F] = \partial_V$$

which is a qualitative version of $F = MA$ (assuming M is always positive). Thus, any system of algebraic and differential equations with respect to time can be described as a set of confluences.

Many of the algebraic operations taken for granted in manipulating analytic functions over the reals are not valid in weak algebras [Struss, 1988]. Because qualitative relationships most often are used to propagate information, this is not a serious limitation. In situations where algebraic solutions themselves are desirable, mixed representations that combine algebraic operations over the reals and move to qualitative abstractions when appropriate provide a useful approach [Williams, 1991].

Another low-resolution representation of equations uses monotonic functions over particular ranges; that is,

$$M + (\text{acceleration, force})$$

states that acceleration depends only on the force, and the function relating them is increasing monotonic [Kuipers, 1986]. Compositionality is achieved using qualitative proportionalities [Forbus, 1984] to express partial information about functional dependency; for example,

$$\text{acceleration} \propto_{Q+} \text{force}$$

states that acceleration depends on force and is increasing monotonic in its dependence on force, but may depend on other factors as well. Additional constraints on the function that determines force can be added by additional **qualitative proportionalities**; for example,

$$\text{acceleration} \propto_{Q-} \text{mass}$$

states that acceleration also depends on mass, and is decreasing monotonic in this dependence. Qualitative proportionalities must be combined via closed-world assumptions to ascertain all the effects on a quantity. Similar primitives can be defined for expressing relationships involving derivatives, to define a complete language of compositional qualitative mathematics for ordinary differential equations. As with confluences, few algebraic operations are valid for combining monotonic functions, mainly composition of functions of identical sign; that is,

$$M + (f, g) \wedge M + (g, h) \Rightarrow M + (f, h)$$

In addition to resolution and compositionality, another issue arising in qualitative representations of mathematical relationships is causality. There are three common views on how mathematical relationships interact with the causal relationships people use in common-sense reasoning. One view is that there is no relationship between them. The second view is that mathematical relationships should be expressed with primitives that also make causal implications. For example, qualitative proportionalities include a causal interpretation, that is, a change in force causes a change in acceleration, but not the other way around. The third view is that acausal mathematical relationships give rise to causal relationships via the particular process of using them. For example, confluences have no built-in causal direction, but are used in causal reasoning by identifying the flow of information through them while reasoning with a presumed flow of causality in the physical system they model. One method for imposing causality on a set of acausal constraint equations is by computing a causal ordering [Iwasaki and Simon, 1986] that imposes directionality on a set of equations, starting from variables considered to be exogenous within the system.

Each view of causality has its merits. For tasks where causality is truly irrelevant, ignoring causality can be a reasonable approach. To create software that can span the range of human common-sense reasoning, something like a combination of the second and third views appears necessary because the appropriate notion of causality varies [Forbus and Gentner, 1986]. In reasoning about chemical phenomena, for instance, changes in concentration are always caused by changes in the amounts of the constituent parts and never the other way around. In electronics, on the other hand, it is often convenient to consider voltage

changes as being caused by changes in current in one part of a circuit and to consider current changes as being caused by changes in voltage in another part of the same circuit.

62.2.3 Ontology

Ontology concerns how to carve up the world, that is, what kinds of things there are and what sorts of relationships can hold between them. Ontology is central to qualitative modeling because one of its main goals is formalizing the art of building models of physical systems. A key choice in any act of modeling is figuring out how to construe the situation or system to be modeled in terms of the available models for classes of entities and phenomena. No single ontology will suffice for the span of reasoning about physical systems that people do. What is being developed instead is a catalog of ontologies, describing their properties and interrelationships and specifying conditions under which each is appropriate. While several ontologies are currently well understood, the catalog still contains gaps.

An example of ontologies will make this point clearer. Consider the representation of liquids. Broadly speaking, the major distinction in reasoning about fluids is whether one individuates fluid according to a particular collection of particles or by location [Hayes, 1985]. The former are called Eulerian, or piece of stuff, ontologies. The latter are called Lagrangian, or contained stuff, ontologies. It is the contained stuff view of liquids we are using when we treat a river as a stable entity, although the particular set of molecules that comprises it is changing constantly. It is the piece of stuff view of liquids we are using when we think about the changes in a fluid as it flows through a steady-state system, such as a working refrigerator. Ontologies multiply as we try to capture more of human reasoning. For instance, the piece of stuff ontology can be further divided into three cases, each with its own rules of inference: (1) molecular collections, which describe the progress of an arbitrary piece of fluid that is small enough to never split apart but large enough to have extensive properties; (2) slices which, like molecular collections, never subdivide but unlike them are large enough to interact directly with their surroundings; and (3) pieces of stuff large enough to be split into several pieces (e.g., an oil slick). Similarly, the contained stuff ontology can be further specialized according to whether or not individuation occurs simply by container (abstract contained stuffs) or by a particular set of containing surfaces (bounded stuffs). Abstract contained stuffs provide a low-resolution ontology appropriate for reasoning about system-level properties in complex systems (e.g., the changes over time in a lubricating oil subsystem in a propulsion plant), whereas bounded stuffs contain the geometric information needed to reason about the interactions of fluids and shape in systems such as pumps and internal combustion engines.

Cutting across the ontologies for particular physical domains are systems of organization for classes of ontologies. The most commonly used ontologies are the device ontology [de Kleer and Brown, 1984] and the process ontology [Forbus, 1984]. The device ontology is inspired by network theory and system dynamics. Like those formalisms, it construes physical systems as networks of devices whose interactions occur solely through a fixed set of ports. Unlike those formalisms, it provides the ability to write and reason automatically with device models whose governing equations can change over time.

The process ontology is inspired by studies of human mental models and observations of practice in thermodynamics and chemical engineering. It construes physical systems as consisting of entities whose changes are caused by physical processes. Process ontologies thus postulate a separate ontological category for causal mechanisms, unlike device ontologies, where causality arises solely from the interaction of the parts. Another difference between the two classes of ontologies is that in the device ontology the system of devices and connections is fixed over time, whereas in the process ontology entities and processes can come into existence and vanish over time. Each is appropriate in different contexts: for most purposes, an electronic circuit is best modeled as a network of devices, whereas a chemical plant is best modeled as a collection of interacting processes.

62.2.4 State, Time, and Behaviors

A qualitative state is a set of propositions that characterize a qualitatively distinct behavior of a system. A qualitative state describing a falling ball, for instance, would include information about what physical

processes are occurring (e.g., motion downwards, acceleration due to gravity) and how the parameters of the ball are changing (e.g., its position is getting lower and its downward velocity is getting larger). A qualitative state can abstractly represent an infinite number of quantitative states: although the position and velocity of the ball are different at each distinct moment during its fall, until the ball collides with the ground, the qualitative state of its motion is unchanged.

Qualitative representations can be used to partition behavior into natural units. For instance, the time over which the state of the ball falling holds is naturally thought of as an interval, ending when the ball collides with the ground. The collision itself can be described as yet another qualitative state, and the fact that falling leads to a collision with the ground can be represented via a transition between the two states. If the ball has a nonzero horizontal velocity and there is some obstacle in its direction of travel, another possible behavior is that the ball will collide with that object instead of the ground. In general, a qualitative state can have transitions to several next states, reflecting ambiguity in the qualitative representations. Returning to our ball example, and assuming that no collisions with obstacles occur, notice that the qualitative state of the ball falling occurs again once the ball has reached its maximum height after the collision. If continuous values are represented by quantity spaces and the sources of comparisons are limit points, then a finite set of qualitative states is sufficient to describe every possible behavior of a system. A collection of such qualitative states and transitions is called an **envisonment** [de Kleer, 1977]. Many interesting dynamical conclusions can be drawn from an envisonment. For instance, oscillations correspond to cycles of states. Unfortunately, the fixed resolution provided by limit points is not sufficient for other dynamical conclusions, such as ascertaining whether or not the ball's oscillation is damped. If comparisons can include landmark values, such conclusions can sometimes be drawn, for example, by comparing the maximum height on one bounce to the maximum height obtained on the next bounce. The cost of introducing landmark values is that the envisonment no longer need be finite; every cycle in a corresponding fixed-resolution envisonment could give rise to an infinite number of qualitative states in an envisonment with landmarks.

A sequence of qualitative states occurring over a particular span of time is called a behavior. Behaviors can be described using purely qualitative knowledge, purely quantitative knowledge, or a mixture of both. If every continuous parameter is quantitative, the numerical aspects of behaviors coincide with the notion of trajectory in a state-space model. If qualitative representations of parameters are used, a single behavior can represent a family of trajectories through state space.

An idea closely related to behaviors is histories [Hayes, 1985]. Histories can be viewed as local behaviors, that is, how a single individual or property varies through time. A behavior is equivalent to a global history, that is, the union of all the histories for the participating individuals. The distinction is important for two reasons. First, histories are the dual of situations in the situation calculus; histories are bounded spatially and extended temporally, whereas situations are bounded temporally and global spatially. Using histories avoids the frame problem, instead trading it for the more tractable problems of generating histories locally and determining how they interact when they intersect in space and time. The second reason is that history-based simulation algorithms can be more efficient than state-based simulation algorithms because no commitments need to be made concerning irrelevant information.

In a correct envisonment, every possible behavior of the physical system corresponds to some path through the envisonment. Because envisonments reflect only local constraints, the converse is not true; that is, an arbitrary path through an envisonment may not represent a physically possible behavior. All such paths must be tested against global constraints, such as energy conservation, to ensure their physical validity. Because the typical uses of an envisonment are to test whether an observed behavior is plausible or to propose possible behaviors, this limitation is not serious. A more serious limitation is that envisonments are often exponential in the size of the system being modeled. This means that, in practice, envisonments often are not generated explicitly and, instead, possible behaviors are searched in ways similar to those used in other areas of AI.

Many tasks require integrating qualitative states with other models of time, such as numerical models. Including precise information (e.g., algebraic expressions or floating-point numbers) about the endpoints of intervals in a history does not change their essential character.

62.2.5 Space and Shape

Qualitative representations of shape and space play an important role in spatial cognition because they provide a bridge between the perceptual and the conceptual. By discretizing continuous space, they make it amenable to symbolic reasoning. As with qualitative representations of one-dimensional parameters, task constraints govern the choice of qualitative representation. However, problem-independent purely qualitative spatial representations suffice for fewer tasks than in the one-dimensional case, because of the increased ambiguity in higher dimensions [Forbus et al., 1991]. Consider, for example, deciding whether a protrusion can fit snugly inside a hole. If we have detailed information about their shapes, we can derive an answer. If we consider a particular set of protrusions and a particular set of holes, we can construct a qualitative representation of these particular protrusions and holes that would allow us to derive whether or not a specific pair would fit, based on their relative sizes. But if we first compute a qualitative representation for each protrusion and hole in isolation, in general the rules of inference that can be derived for this problem will be very weak. Work in qualitative spatial representations thus tends to take two approaches. The first approach is to explore what aspects do lend themselves to qualitative representations. The second approach is to use a quantitative representation as a starting point and compute problem-specific qualitative representations to reason with. We summarize each in turn.

There are several purely qualitative representations of space and shape that have proven useful. Topological relationships between regions in two-dimensional space have been formalized, with transitivity inferences similar to those used in temporal reasoning identified for various vocabularies of relations [Cohn and Hazarika, 2001]. The beginnings of rich qualitative mechanics have been developed. This includes qualitative representations for vectors using the sign of the vector's quadrant to reason about possible directions of motion [Nielsen, 1988] and using relative inclination of angles to reason about linkages [Kim, 1992].

The use of quantitative representations to ground qualitative spatial reasoning can be viewed as a model of the ways humans use diagrams and models in spatial reasoning. For this reason such work is also known as **diagrammatic reasoning** [Glasgow et al., 1995]. One form of diagram representation is the occupancy array that encodes the location of an object by cells in a (two- or three-dimensional) grid. These representations simplify the calculation of spatial relationships between objects (e.g., whether or not one object is above another), albeit at the cost of making the object's shape implicit. Another form of diagram representation uses symbolic structures with quantitative, for example, numerical, algebraic, or interval (cf. [Forbus et al., 1991]). These representations simplify calculations involving shape and spatial relationships, without the scaling and resolution problems that sometimes arise in array representations. However, they require a set of primitive shape elements that spans all the possible shapes of interest, and identifying such sets for particular tasks can be difficult. For instance, many intuitively natural sets of shape primitives are not closed with respect to their complement, which can make characterizing free space difficult.

Diagram representations are used for qualitative spatial reasoning in two ways. The first is as a decision procedure for spatial questions. This mimics one of the roles diagrams play in human perception. Often, these operations are combined with domain-specific reasoning procedures to produce an analog style of inference, where, for instance, the effects of perturbations on a structure are mapped into the diagram, the effect on the shapes in the diagram noted, and the results mapped back into a physical interpretation. The second way uses the diagram to construct a problem-specific qualitative vocabulary, imposing new spatial entities representing physical properties, such as the maximum height a ball can reach or regions of free space that can contain a motion. This is the **metric diagram/place vocabulary** model of qualitative spatial reasoning.

Representing and reasoning about kinematic mechanisms was one of the early successes in qualitative spatial reasoning. The possible motions of objects are represented by qualitative regions in configuration space representing the legitimate positions of parts of mechanisms [Faltings 1990]. Whereas, in principle, a single high-dimensional configuration space could be used to represent a mechanism's possible motions (each dimension corresponding to a degree of freedom of a part of the mechanism), in practice a collection of configuration spaces, one two-dimensional space for each pair of parts that can interact is used. These techniques suffice to analyze a wide variety of kinematic mechanisms [Joscowicz and Sacks, 1993].

Another important class of spatial representations concerns qualitative representations of spatially distributed phenomena, such as flow structures and regions in phase space. These models use techniques from computer vision to recognize or impose qualitative structure on a continuous field of information, gleaned from numerical simulation or scientific data. This qualitative structure, combined with domain-specific models of how such structures tie to the underlying physics, enables them to interpret physical phenomena in much the same way that a scientist examining the data would (cf. [Yip, 1991], [Nishida, 1994], [Huang and Zhao, 2000]).

An important recent trend is using rich, real-world data as input for qualitative spatial reasoning. For example, several systems provide some of the naturalness of sketching by performing qualitative reasoning on spatial data input as digital ink, for tasks like mechanical design (cf. [Stahovich et al., 1998]) and reasoning about sketch maps (cf. [Forbus et al., 2003]). Qualitative representations are starting to be used in computer vision as well, for example, as a means of combining dynamic scenes across time to interpret events (cf. [Ferryhough et al., 2000]).

62.2.6 Compositional Modeling, Domain Theories, and Modeling Assumptions

There is almost never a single correct model for a complex physical system. Most systems can be modeled in a variety of ways, and different tasks can require different types of models. The creation of a system model for a specific purpose is still something of an art. Qualitative physics has developed formalisms that combine logic and mathematics with qualitative representations to help automate the process of creating and refining models. The compositional modeling methodology [Falkenhainer and Forbus, 1991], which has become standard in qualitative physics, works like this: models are created from domain theories, which describe the kinds of entities and phenomena that can occur in a physical domain. A domain theory consists of a set of **model fragments**, each describing a particular aspect of the domain. Creating a model is accomplished by instantiating an appropriate subset of model fragments, given some initial specification of the system (e.g., the propositional equivalent of a blueprint) and information about the task to be performed. Reasoning about appropriateness involves the use of modeling assumptions. Modeling assumptions are the control knowledge used to reason about the validity or appropriateness of using model fragments. Modeling assumptions are used to express the relevance of model fragments. Logical constraints between modeling assumptions comprise an important component of a domain theory.

An example of a modeling assumption is assuming that a turbine is isentropic. Here is a model fragment that illustrates how this assumption is used:

```
(defEquation Isentropic-Turbine
  ((turbine ?g ?in ?out) (isentropic ?g))
  (= (spec-s ?in) (spec-s ?out)))
```

In other words, when a turbine is isentropic, the specific entropy of its inlet and outlet are equal. Other knowledge in the domain theory puts constraints on the predicate `isentropic`,

```
(for-all (?self (turbine ?self))
  (iff (= (nu-isentropic ?self) 1.0)
  (isentropic ?self)))
```

That is, a turbine is isentropic exactly when its isentropic thermal efficiency is 1. Although no real turbine is isentropic, assuming that turbines are isentropic simplifies early analyses when creating a new design. In later design phases, when tighter performance bounds are required, this assumption is retracted and the impact of particular values for the turbine's isentropic thermal efficiency is explored. The consequences of choosing particular modeling assumptions can be quite complex; the fragments shown here are less than one fourth the knowledge expressing the consequences of assuming that a turbine is isentropic in a typical knowledge base.

Modeling assumptions can be classified in a variety of ways. An ontological assumption describes which ontology should be used in an analysis. For instance, reasoning about the pressure at the bottom of a swimming pool is most simply performed using a contained stuff representation, whereas describing the location of an oil spill is most easily performed using a piece of stuff representation. A perspective assumption describes which subset of phenomena operating in a system will be the subject. For example, in analyzing a steam plant, one might focus on a fluid perspective, a thermal perspective, or both at once. A grain assumption describes how much detail is included in an analysis. Ignoring the implementation details of subsystems, for instance, is useful in the conceptual design of an artifact, but the same implementation details may be critical for troubleshooting that artifact. The relationships between these classes of assumptions can be complicated and domain dependent; for instance, it makes no sense to include a model of a heating coil (a choice of granularity) if the analysis does not include thermal properties (a choice of perspective).

Relationships between modeling assumptions provide global structure to domain theories. Assumptions about the nature of this global structure can significantly impact the efficiency of model formulation, as discussed subsequently. In principle, any logical constraint could be imposed between modeling assumptions. In practice, two kinds of constraints are the most common. The first are implications, such as one modeling assumption requiring or forbidding another. For example,

```
(for-all (?s (system ?s))
  (implies (consider (black-box ?s))
    (for-all (?p (part-of ?p ?s)) (not (consider ?p))))))
```

says that if one is considering a subsystem as a black box, then all of its parts should be ignored. Similarly,

```
(for-all (?l (physical-object ?l))
  (implies (consider (pressure ?l))
    (consider (fluid-properties ?l))))
```

states that if an analysis requires considering something's pressure, then its fluid properties are relevant.

The second kind of constraint between modeling assumptions is assumption classes. An assumption class expresses a choice required to create a coherent model under particular conditions. For example,

```
(defAssumptionClass (turbine ?self)
  (isentropic ?self)
  (not (isentropic ?self)))
```

states that when something is modeled as a turbine, any coherent model including it must make a choice about whether or not it is modeled as isentropic. The choice may be constrained by the data so far (e.g., different entrance and exit specific entropies), or it may be an assumption that must be made in order to complete the model. The set of choices need not be binary. For each valid assumption class there must be exactly one of the choices it presents included in the model.

62.3 Qualitative Reasoning Techniques

A wide variety of qualitative reasoning techniques have been developed that use the qualitative representations just outlined.

62.3.1 Model Formulation

Methods for automatically creating models for a specific task are one of the hallmark contributions of qualitative physics. These methods formalize knowledge and skills typically left implicit by most of traditional mathematics and engineering.

The simplest model formulation algorithm is to instantiate every possible model fragment from a domain theory, given a propositional representation of the particular scenario to be reasoned about. This

algorithm is adequate when the domain theory is very focused and thus does not contain much irrelevant information. It is inadequate for broad domain theories and fails completely for domain theories that include alternative and mutually incompatible perspectives (e.g., viewing a contained liquid as a finite object vs. an infinite source of liquid). It also fails to take task constraints into account. For example, it is possible, in principle, to analyze the cooling of a cup of coffee using quantum mechanics. Even if it were possible in practice to do so, for most tasks simpler models suffice. Just how simple a model can be and remain adequate depends on the task. If I want to know if the cup of coffee will still be drinkable after an hour, a qualitative model suffices to infer that its final temperature will be that of its surroundings. If I want to know its temperature within 5% after 12 min have passed, a macroscopic quantitative model is a better choice. In other words, the goal of model formulation is to create the simplest adequate model of a system for a given task.

More sophisticated model formulation algorithms search the space of modeling assumptions, because they control which aspects of the domain theory will be instantiated. The model formulation algorithm of Falkenhainer and Forbus [1991] instantiated all potentially relevant model fragments and used an assumption-based truth maintenance system to find all legal combinations of modeling assumptions that sufficed to form a model that could answer a given query. The simplicity criterion used was to minimize the number of modeling assumptions. This algorithm is very simple and general but has two major drawbacks: (1) full instantiation can be very expensive, especially if only a small subset of the model fragments is eventually used; and (2) the number of consistent combinations of model fragments tends to be exponential for most problems. The rest of this section describes algorithms that overcome these problems.

Efficiency in model formulation can be gained by imposing additional structure on domain theories. Under at least one set of constraints, model formulation can be carried out in polynomial time [Nayak, 1994]. The constraints are that (1) the domain theory can be divided into independent assumption classes; and (2) within each assumption class, the models can be organized by a (perhaps partial) simplicity ordering of a specific nature, forming a lattice of *causal approximations*. Nayak's algorithm computes a simplest model, in the sense of simplest within each local assumption class, but does not necessarily produce the globally simplest model.

Conditions that ensure the creation of *coherent* models, that is, models that include sufficient information to produce an answer of the desired form, provide powerful constraints on model formulation. For example, in generating "what-if" explanations of how a change in one parameter might affect particular other properties of the system, a model must include a complete causal chain connecting the changed parameter to the other parameters of interest. This insight can be used to treat model formulation as a best-first search for a set of model fragments providing the simplest complete causal chain [Rickel and Porter, 1994]. A novel feature of this algorithm is that it also selects models at an appropriate time scale. It does this by choosing the slowest time-scale phenomenon that provides a complete causal model, because this provides accurate answers that minimize extraneous detail.

As with other AI problems, knowledge can reduce search. One kind of knowledge that experienced modelers accumulate concerns the range of applicability of various modeling assumptions and strategies for how to reformulate when a given model proves inappropriate. Model formulation often is an iterative process. For instance, an initial qualitative model often is generated to identify the relevant phenomena, followed by the creation of a narrowly focused quantitative model to answer the questions at hand. Similarly, domain-specific error criterion can determine that a particular model's results are internally inconsistent, causing the reasoner to restart the search for a good model. Formalizing the decision making needed in iterative model formulation is an area of active research. Formalizing model formulation as a dynamic preference constraint satisfaction problem, where more fine-grained criteria for model preference than "simplest" can be formalized and exploited (cf. [Keppens and Shen, 2002]), is one promising approach.

62.3.2 Causal Reasoning

Causal reasoning explains an aspect of a situation in terms of others in such a way that the aspect being explained can be changed if so desired. For instance, a flat tire is caused by the air inside flowing out, either

through the stem or through a leak. To refill the tire, we must both ensure that the stem provides a seal and that there are no leaks. Causal reasoning is thus at the heart of diagnostic reasoning as well as explanation generation.

The techniques used for causal reasoning depend on the particular notion of causality used, but they all share a common structure. First, causality involving factors within a state are identified. Second, how the properties of a state contribute to a transition (or transitions) to another state are identified, to extend the causal account over time. Because causal reasoning often involves qualitative simulation, we turn to simulation next.

62.3.3 Simulation

The new representations of quantity and mathematical relationships of qualitative physics expand the space of simulation techniques considerably. We start by considering varieties of purely qualitative simulation, and then describe several simulation techniques that integrate qualitative and quantitative information.

Understanding *limit analysis*, the process of finding state transitions, is key to understanding qualitative simulation. Recall that a qualitative state consists of a set of propositions, some of them describing the values of continuous properties in the system. (For simplicity in this discussion, we will assume that these values are described as ordinal relations, although the same method works for sign representations and representations richer than ordinals.) Two observations are critical: (1) the phenomena that cause changes in a situation often depend on ordinal relationships between parameters of the situation, and (2) knowing just the sign of the derivatives of the parameters involved in these ordinal relationships suffices to predict how they might change over time. The effects of these changes, when calculated consistently, describe the possible transitions to other states.

An example will make this more clear. Consider again a pot of water sitting on a stove. Once the stove is turned on, heat begins to flow to the water in the pot because the stove's temperature is higher than that of the water. The causal relationship between the temperature inequality and the flow of heat means that to predict changes in the situation, we should figure out their derivatives and any other relevant ordinal relationships that might change as a result. In this qualitative state, the derivative of the water's temperature is positive, and the derivative of the stove's temperature is constant. Thus, one possible state change is that the water will reach thermal equilibrium with the stove and the flow of heat will stop. That is not the only possibility, of course. We know that boiling can occur if the temperature of the water begins to rise above its boiling temperature. That, too, is a possible transition that would end the state. Which of these transitions occurs depends on the relationship between the temperature of the stove and the boiling temperature of water.

This example illustrates several important features of limit analysis. First, surprisingly weak information (i.e., ordinal relations) suffices to draw important conclusions about broad patterns of physical behavior. Second, limit analysis with purely qualitative information is fundamentally ambiguous: It can identify what transitions might occur but cannot by itself determine in all cases which transition will occur. Third, like other qualitative ambiguities, higher-resolution information can be brought in to resolve the ambiguities as needed. Returning to our example, any information sufficient to determine the ordinal relationship between the stove temperature and boiling suffices to resolve this ambiguity. If we are designing an electric kettle, for instance, we would use this ambiguity as a signal that we must ensure that the heating element's temperature is well above the boiling point; and if we are designing a drink warmer, its heating element should operate well below the boiling point.

Qualitative simulation algorithms vary along four dimensions: (1) their initial states, (2) what conditions they use to filter states or transitions, (3) whether or not they generate new landmarks, and (4) how much of the space of possible behaviors they explore. *Envisioning* is the process of generating an envisionment, that is, generating all possible behaviors. Two kinds of envisioning algorithms have been used in practice: *attainable* envisioners produce all states reachable from a set of initial states, and *total* envisioners produce a complete envisionment. *Behavior generation* algorithms start with a single initial state, generate landmark values, and use a variety of task-dependent constraints as filters and termination criteria (e.g., resource bounds, energy constraints).

Higher-resolution information can be integrated with qualitative simulation in several ways. One method for resolving ambiguities in behavior generation is to provide numerical envelopes to bound mathematical relationships. These envelopes can be dynamically refined to provide tighter situation-specific bounds. Such systems are called **semiquantitative simulators**.

A different approach to integration is to use qualitative reasoning to automatically construct a numerical simulator that has integrated explanation facilities. These *self-explanatory simulators* [Forbus and Falkenhainer, 1990] use traditional numerical simulation techniques to generate behaviors, which are also tracked qualitatively. The concurrently evolving qualitative description of the behavior is used both in generating explanations and in ensuring that appropriate mathematical models are used when applicability thresholds are crossed. Self-explanatory simulators can be compiled in polynomial time for efficient execution, even on small computers, or created in an interpreted environment.

62.3.4 Comparative Analysis

Comparative analysis answers a specific kind of “what-if” questions, namely, the changes that result from changing the value of a parameter in a situation. Given higher-resolution information, traditional analytic or numerical sensitivity analysis methods can be used to answer these questions; however (1) such reasoning is commonly carried out by people who have neither the data nor the expertise to carry out such analyses, and (2) purely quantitative techniques tend not to provide good explanations. Sometimes, purely qualitative information suffices to carry out such reasoning, using techniques such as *exaggeration* [Weld, 1990]. Consider, for instance, the effect of increasing the mass of a block in a spring-block oscillator. If the mass were infinite the block would not move at all, corresponding to an infinite period. Thus, we can conclude that increasing the mass of the block will increase the period of the oscillator.

62.3.5 Teleological Reasoning

Teleological reasoning connects the structure and behavior of a system to its goals. (By its goals, we are projecting the intent of its designer or the observer, because purposes often are ascribed to components of evolved systems.) To describe how something works entails ascribing a function to each of its parts and to explain how these functions together achieve the goals. Teleological reasoning is accomplished by a combination of abduction and recognition. Abduction is necessary because most components and behaviors can play several functional roles [de Kleer, 1984]. A turbine, for instance, can be used to generate work in a power generation system and to expand a gas in a liquefaction system. Recognition is important because it explains patterns of function in a system in terms of known, commonly used abstractions. A complex power-generation system with multiple stages of turbines and reheating and regeneration, for instance, still can be viewed as a Rankine cycle after the appropriate aggregation of physical processes involved in its operation [Everett, 1999].

62.3.6 Data Interpretation

There are two ways that the representations of qualitative physics have been used in data interpretation problems. The first is to explain a temporal sequence of measurements in terms of a sequence of qualitative states; the second is to create a qualitative model of phase space by interpreting the results of successive numerical simulation experiments. The underlying commonality in these problems is the use of qualitative descriptions of physical constraints to formulate compatibility constraints that prune the set of possible interpretations. We describe each in turn.

In measurement interpretation tasks, numerical and symbolic data is partitioned into intervals, each of which can be explained by a qualitative state or sequence of qualitative states. Using precomputed environments or performing limit analysis online, possible transitions between states used as interpretations can be found for filtering purposes. Specifically, if a state S_1 is a possible interpretation for interval I_1 , then at least one transition from S_1 must lead to a state that is an interpretation for the next interval.

This compatibility constraint, applied in both directions, can provide substantial pruning. Additional constraints that can be applied include the likelihood of particular states occurring, the likelihood of particular transitions occurring, and estimates of durations for particular states. Algorithms have been developed that can use all these constraints to maintain a single best interpretation of a set of incoming measurements that operate in polynomial time [de Coste, 1991].

In phase space interpretation tasks, a physical experiment (cf. [Huang and Zhao, 2000]) or numerical simulation (cf. [Yip, 1991], [Nishida, 1994]) is used to gather information about the possible behaviors of a system given a set of initial parameters. The geometric patterns these behaviors form in phase space are described using vision techniques to create a qualitative characterization of the behavior. For example, initially, simulations are performed on a coarse grid to create an initial description of phase space. This initial description is then used to guide additional numerical simulation experiments, using rules that express physical properties visually.

62.3.7 Planning

The ability of qualitative physics to provide predictions with low-resolution information and to determine what manipulations might achieve a desired effect makes it a useful component in planning systems involving the physical world. A tempting approach is to carry out qualitative reasoning entirely in a planner, by *compiling* the domain theory and physics into operators and inference rules. Unfortunately, such straightforward translations tend to have poor combinatorics. A different approach is to treat actions as another kind of state transition in qualitative simulation. This can be effective if qualitative reasoning is interleaved with execution monitoring [Drabble, 1993] or used with a mixture of backward and forward reasoning with partial states.

62.3.8 Spatial Reasoning

Reasoning with purely qualitative representations uses constraint satisfaction techniques to determine possible solutions to networks of relationships. The constraints are generally expressed as transitivity tables. When metric diagrams are used, processing techniques adapted from vision and robotics research are used to extract qualitative descriptions. Some reasoning proceeds purely within these new qualitative representations, while other tasks require the coordination of qualitative and diagrammatic representations. Recently, the flow of techniques has begun to reverse, with vision and robotics researchers adopting qualitative representations because they are more robust to compute from the data and are more appropriate for many tasks (cf. [Kuipers and Byun, 1991, Fernyhough et al., 2000]).

62.4 Applications of Qualitative Reasoning

Qualitative physics began as a research enterprise in the 1980s, with successful fielded applications starting to appear by the early 1990s. For example, applications in supervisory process control (cf. [LeClair et al., 1989]) have been successful enough to be embedded in several commercial systems. Qualitative reasoning techniques were also used in the design of the Mita Corporation's DC-6090 photocopier [Shimomura et al., 1995], which came to market in 1994. By 2000, a commercial tool for FMEA in automobile electrical circuits had been adopted by a major automobile manufacturer [Price, 2000]. Thus, some qualitative reasoning systems are in routine use already, and more such applications are expected as research matures. Here we briefly summarize some of these research efforts.

62.4.1 Monitoring, Control, and Diagnosis

Monitoring, control, and diagnosis, although often treated as distinct problems, are in many applications deeply intertwined. Because these tasks also have deep theoretical commonalities, they are described together here. Monitoring a system requires summarizing its behavior at a level of description that is

useful for taking action. Qualitative representations correspond to descriptions naturally applied by system operators and designers and thus can help provide new opportunities for automation. An important benefit of using qualitative representations is that the concepts the software uses can be made very similar to those of people who interact with software, thus potentially improving human–computer interfaces. Qualitative representations are important for control because qualitative distinctions provide criteria that make different control actions appropriate. Diagnosis tasks impose similar requirements. It is rarely beneficial to spend the resources required to construct a very detailed quantitative model of the way a particular part has failed when the goal is to isolate a problem. Qualitative models often provide sufficient resolution for fault isolation. Qualitative models also provide the framework for organizing fault detection (i.e., noticing that a problem has occurred) and for working around a problem, even when these tasks require quantitative information.

Operative diagnosis tasks are those where the system being monitored must continue being operated despite any faults. One example of operative diagnosis is diagnosing engine trouble in civilian commercial aircraft. FaultFinder [Abbott et al., 1987], under development at NASA Langley Research Center, is intended to detect engine trouble and provide easily understood advice to pilots, whose information processing load is already substantial. FaultFinder prototypes compare engine data with a numerical simulation to detect the onset of a problem. A causal model, using low-resolution qualitative information (essentially, working vs. not working), is used to construct failure hypotheses, to be communicated to the pilot in a combination of natural language and graphics.

Many alarm conditions are specified as thresholds, indicating when a system is approaching a dangerous mode of operation or when a component is no longer behaving normally. Alarms are insufficient for fault detection because they do not reflect the lack of normal behaviors. Experienced operators gain a feel for a system and can sometimes spot potential problems long before they become serious enough to trigger an alarm. Some of this expertise can be replicated using a combination of causal models and statistical reasoning over historical data concerning the system in question [Doyle, 1995].

One commercial success of qualitative reasoning has been in supervisory process control. It has been demonstrated that qualitative representations can be used to provide more robust control than statistical process control in curing composite parts [LeClair et al., 1989]. This technique is called *qualitative process automation* (QPA). In the early stage of curing a composite part, the temperature of the furnace needs to be kept relatively low because the part is outgassing. Keeping the furnace low during the entire curing process is inefficient, however, because lower temperatures means longer cure times. Therefore, it is more productive to keep temperature low until outgassing stops and then increase it to finish the cure process more quickly. Statistical process control methods use a combination of analytic models and empirical tests to figure out an optimal pattern of high/low cooking times. QPA incorporates a qualitative description of behavior into the controller, allowing it to detect the change in qualitative regime and control the furnace accordingly. The use of qualitative distinctions in supervisory control provided both faster curing times and higher yield rates than traditional techniques. QPA-inspired supervisory control techniques are now in regular use in curing certain kinds of composite components and have been incorporated into commercial control software.

Another use of qualitative representations is in describing control strategies used by machine operators, such as unloading cranes on docks. By recording the actions of crane operators, machine learning techniques can be used to reverse-engineer their strategies (cf. [Suc and Bratko, 2002]).

In some applications a small set of fault models can be pre-enumerated. A set of models, which includes the nominal model of the system plus models representing common faults, can then be used to track the behavior of a system with a qualitative or semiquantitative simulator. Any fault model whose simulation is inconsistent with the observed behavior can thus be ruled out. Relying on a pre-existing library of fault models can limit the applicability of automatic monitoring and diagnosis algorithms. One approach to overcoming this limitation is to create algorithms that require only models of normal behavior. Most consistency-based diagnosis algorithms take this approach. For example, in developing on-board diagnostics for Diesel engines, qualitative representations have been found to be useful as a robust level of description for reasoning and for abstracting away from sensor noise (cf. [Sachenbacher et al., 2000]).

One limitation with consistency-based diagnosis is that the ways a system can fail are still governed by natural laws, which impose more constraint than logical consistency. This extra constraint can be exploited by using a domain theory to generate explanations that could account for the problem, via abduction. These explanations are useful because they make additional predictions that can be tested and that also can be important for reasoning about safety in operative diagnosis (e.g., if a solvent tank's level is dropping because it is leaking, then where is the solvent going?). However, in many diagnosis tasks, this limitation is not a concern.

62.4.2 Design

Engineering design activities are divided into conceptual design, the initial phase when the overall goals, constraints, and functioning of the artifact are established; and detailed design, when the results of conceptual design are used to synthesize a constructable artifact or system. Most computer-based design tools, such as computer-aided design (CAD) systems and analysis programs, facilitate detailed design. Yet many of the most costly mistakes occur during the conceptual design phase. The ability to reason with partial information makes qualitative reasoning one of the few technologies that provides substantial leverage during the conceptual design phase. Qualitative reasoning can also help automate aspects of detailed design.

One example is Mita Corporation's DC-6090 photocopier [Shimomura et al., 1995]. It is an example of a *self-maintenance machine*, in which redundant functionality is identified at design time so that the system can dynamically reconfigure itself to temporarily overcome certain faults. An envisionment including fault models, created at design time, was used as the basis for constructing the copier's control software. In operation, the copier keeps track of which qualitative state it is in, so that it produces the best quality copy it can.

In some fields experts formulate general design rules and methods expressed in natural language. Qualitative representations can enable these rules and methods can be further formalized, so that they can be automated. In chemical engineering, for instance, several design methods for distillation plants have been formalized using qualitative representations, and designs for binary distillation plants comparable to those in the chemical engineering research literature have been generated automatically.

Automatic analysis and synthesis of kinematic mechanisms have received considerable attention. Complex fixed-axis mechanisms, such as mechanical clocks, can be simulated qualitatively, and a simplified dynamics can be added to produce convincing animations. Initial forays into conceptual design of mechanisms have been made, and qualitative kinematics simulation has been demonstrated to be competitive with conventional approaches in some linkage optimization problems. Qualitative representations are also useful in case-based design, because they provide a level of abstraction that simplifies adaptation (cf. [Faltings, 2001]).

Qualitative reasoning also is being used to reason about the effects of failures and operating procedures. Such information can be used in failure modes and effects analysis (FMEA). For example, potential hazards in a chemical plant design can be identified by perturbing a qualitative model of the design with various faults and using qualitative simulation to ascertain the possible indirect consequences of each fault. Commercial FMEA software using qualitative simulation for electrical system design is now being used in automotive design [Price, 2000].

62.4.3 Intelligent Tutoring Systems and Learning Environments

One of the original motivations for the development of qualitative physics was its potential applications in intelligent tutoring systems (ITSs) and intelligent learning environments (ILEs). Qualitative representations provide a formal language for a student's mental models [Gentner and Stevens, 1983], and thus they facilitate communication between software and student. For example, a sequence of qualitative models can be designed that helps students learn complex domains such as electronics more easily. Student protocols can be analyzed in qualitative terms to diagnose misconceptions.

Qualitative representations are being used in software for teaching plant operators and engineers. They provide a level of explanation for how things work that facilitates teaching control. For example, systems for teaching the operation of power generation plants, including nuclear plants, are under construction in various countries. Teaching software often uses hierarchies of models to help students understand a typical industrial process and design controllers for it. Qualitative representations also can help provide teaching software with the physical intuitions required to help find students' problems. For instance, qualitative representations are used to detect physically impossible designs in an ILE for engineering thermodynamics.

Qualitative representations can be particularly helpful in teaching domains where quantitative knowledge is either nonexistent, inaccurate, or incomplete. For example, efforts underway to create ITSs for ecology in Brazil, to support conservation efforts, are using qualitative representations to explain how environmental conditions affect plant growth [Salles and Bredeweg, 2001]. For younger students, who have not had algebra or differential equations, the science curriculum consists of learning causal mental models that are well captured by the formalisms of qualitative modeling. By using a student-friendly method of expressing models, such as concept maps, software systems have been built which help students learn conceptual models [Forbus et al., 2001; Leelawong et al., 2001].

62.4.4 Cognitive Modeling

Since qualitative physics was inspired by observations of how people reason about the physical world, one natural application of qualitative physics is cognitive simulation, i.e., the construction of programs whose primary concern is accurately modeling some aspect of human reasoning, as measured by comparison with psychological results. Some research has been concerned with modeling scientific discovery, e.g., how analogy can be used to create new physical theories and modeling scientific discovery [Falkenhainer, 1990]. Several investigations suggest that qualitative representations have major role to play in understanding cognitive processes such as high-level vision [Ferryhough et al., 2000] [Forbus et al., 2003]. Common sense reasoning appears to rely heavily on qualitative representations, although human reasoning may rely more on reasoning from experience than first-principles reasoning [Forbus and Gentner, 1997]. Understanding the robustness and flexibility of human common sense reasoning is an important scientific goal in its own right, and will provide clues as to how to build better AI systems. Thus potential use of qualitative representations by cognitive scientists may ultimately prove to be the most important application of all.

62.5 Research Issues and Summary

Qualitative reasoning is now a mature subfield with a mixture of basic and applied activities, including fielded applications. The substantial increases in available computing power, combined with the now urgent need to make software that is more articulate, suggests that the importance of qualitative reasoning will continue to grow.

Although there is a substantial research base to draw upon, there are many open problems and areas that require additional research. There are still many unanswered questions about purely qualitative representations (e.g., what is the minimum information that is required to guarantee that all predicted behaviors generated from an environment are physically possible?), but the richest vein of research concerns the integration of qualitative knowledge with other kinds of knowledge: numerical, analytic, teleological, etc. One outgrowth of such research is a new area, *hybrid systems*, dedicated to exploring mixtures of qualitative, numerical, and discrete models. The work on modeling to date, although a solid foundation, is still very primitive; better model formulation algorithms, well-tested conventions for structuring domain theories, and robust methods for integrating the results of multiple models are needed. Substantial domain theories for a broad range of scientific and engineering knowledge need to be created. And finally, there are many domains where traditional mathematics has intruded, but where the amount and/or precision of the data available has not enabled it to be very successful. These areas are ripe for qualitative modeling. Examples where such efforts are underway include medicine, organizational theory, economics, and ecology.

Defining Terms

- Comparative analysis:** A particular form of a what if question, i.e., how a physical system changes in response to the perturbation of one of its parameters.
- Compositional modeling:** A methodology for organizing domain theories so that models for specific systems and tasks can be automatically formulated and reasoned about.
- Confluence:** An equation involving sign values.
- Diagrammatic reasoning:** Spatial reasoning, with particular emphasis on how people use diagrams.
- Domain theory:** A collection of general knowledge about some area of human knowledge, including the kinds of entities involved and the types of relationships that can hold between them, and the mechanisms that cause changes (e.g., physical processes, component laws, etc.). Domain theories range from purely qualitative to purely quantitative to mixtures of both.
- Envisionment:** A description of all possible qualitative states and transitions between them for a system. *Attainable envisionments* describe all states reachable from a particular initial state; *total envisionments* describe all possible states.
- FMEA:** Failure Modes and Effects Analysis. Analyzing the possible effects of a failure of a component of a system on the operation of the entire system.
- Landmark:** A comparison point indicating a specific value achieved during a behavior, e.g., the successive heights reached by a partially elastic bouncing ball.
- Limit point:** A comparison point indicating a fundamental physical boundary, such as the boiling point of a fluid. Limit points need not be constant over time, e.g., boiling points depend on pressure.
- Metric diagram:** A quantitative representation of shape and space used for spatial reasoning, the computer analog to or model of the combination of diagram/visual apparatus used in human spatial reasoning.
- Model fragment:** A piece of general domain knowledge that is combined with others to create models of specific systems for particular tasks.
- Modeling assumption:** A proposition expressing control knowledge about modeling, such as when a model fragment is relevant.
- Physical process:** A mechanism that can cause changes in the physical world, such as heat flow, motion, and boiling.
- Place vocabulary:** A qualitative description of space or shape that is grounded in a quantitative representation.
- Qualitative proportionality:** A qualitative relationship expressing partial information about a functional dependency between two parameters.
- Qualitative simulation:** The generation of predicted behaviors for a system based on qualitative information. Qualitative simulations typically include branching behaviors due to the low resolution of the information involved.
- Quantity space:** A set of ordinal relationships that describes the value of a continuous parameter.
- Semiquantitative simulation:** A qualitative simulation that uses quantitative information, such as numerical values or analytic bounds, to constrain its results.

Further Information

There are a variety of qualitative reasoning resources on the World Wide Web, including extensive bibliographies, papers, and software. A large number of edited collections have been published (cf. [Faltings and Struss, 1992]) An excellent textbook on the QSIM approach to qualitative physics is Kuipers [1994]. For an introduction to diagrammatic reasoning, see Glasgow *et al.* [1995].

Papers on qualitative reasoning routinely appear in *Artificial Intelligence*, *Journal of Artificial Intelligence Research (JAIR)*, and *IEEE Intelligent Systems*. Many papers first appear in the proceedings of the American Association for Artificial Intelligence (AAAI), the International Joint Conferences on Artificial Intelligence (IJCAI), and the European Conference on Artificial Intelligence (ECAI). Every year there is an International Qualitative Reasoning Workshop, whose proceedings document the latest developments in the area. Proceedings for a particular workshop are available from its organizers.

63.1 Introduction

Efforts using artificial intelligence (AI) to solve problems with computers — which humans routinely handle by employing innate cognitive abilities, pattern recognition, perception, and experience — invariably must turn to considerations of search. This chapter explores search methods in AI, including both **blind** exhaustive methods and informed **heuristic** and optimal methods, along with some more recent findings. The search methods covered include (for non-optimal, uninformed approaches) **state-space search**, generate and test, means–ends analysis, problem reduction, AND/OR trees, depth–first search, and breadth–first search. Under the umbrella of heuristic (informed) methods, we discuss **hill climbing**, best–first search, bidirectional search, and the A* algorithm. Tree searching algorithms for games have proved to be a rich source of study and provide empirical data about heuristic methods. Included here are the SSS* algorithm, the use of iterative deepening, and variations on the alpha–beta minimax algorithm, including the recent MTD(f) algorithm.

Coincident with the continuing price–performance improvement of small computers is growing interest in reimplementing some of the heuristic techniques developed for problem solving and planning programs, to see whether they can be enhanced or replaced by more algorithmic methods. Because many of the heuristic methods are computationally intensive, the second half of the chapter focuses on parallel methods, which can exploit the benefits of parallel processing. The importance of parallel search is presented through an assortment of relatively recent algorithms, including the parallel iterative deepening algorithm (PIDA*), principal variation splitting (PVSplit), and the young brothers wait concept. In addition, dynamic tree–splitting methods have evolved for both shared memory parallel machines and networks of distributed computers. Here, the issues include load balancing, processor utilization, and communication overhead. For single–agent search problems, we consider not only **work–driven** dynamic parallelism, but also the more recent **data–driven parallelism** employed in transposition table–driven scheduling (TDS). In adversarial

```

Repeat
    Generate a candidate solution
    Test the candidate solution
Until a satisfactory solution is found, or
    no more candidate solutions can be generated:
    If an acceptable solution is found, announce it;
    Otherwise, announce failure.

```

FIGURE 63.1 Generate and test method.

games, tree pruning makes work load balancing particularly difficult, so we also consider some recent advances in dynamic parallel methods for game-tree search.

The application of raw computing power—while anathema to some — often provides better answers than is possible by reasoning or analogy. Thus, brute force techniques form a good basis against which to compare more sophisticated methods designed to mirror the human deductive process.

63.2 Uninformed Search Methods

63.2.1 Search Strategies

All search methods in computer science share in common three necessities:

- A world model or database of facts, based on a choice of representation providing the current state, other possible states, and a goal state
- A set of operators that defines possible transformations of states
- A control strategy that determines how transformations among states are to take place by applying operators

Forward reasoning is one technique for identifying states that are closer to a goal state. Working backward from a goal to the current state is called *backward reasoning*. As such, it is possible to make distinctions between bottom-up and top-down approaches to problem solving. Bottom-up is often goal-oriented — that is, reasoning backward from a goal state to solve intermediary subgoals. Top-down or data-driven reasoning is based on reaching a state that is defined as closer to a goal. Often, application of operators to a problem state may not lead directly to a goal state, so some **backtracking** may be necessary before a goal state can be found [Barr and Feigenbaum, 1981].

63.2.2 State-Space Search

Exhaustive search of a problem space (or search space) is often not feasible or practical because of the size of the problem space. In some instances, however, it is necessary. More often, we are able to define a set of legal transformations of a state space (moves in a board game) from which those that are more likely to bring us closer to a goal state are selected and others are never explored further. This technique in problem solving is known as *split and prune*. In AI, the technique that emulates this approach is called **generate and test**. The basic method is shown in Figure 63.1.

Good generators are complete and will eventually produce all possible solutions, while not proposing redundant ones. They are also informed; that is, they will employ additional information to constrain the solutions they propose.

Means–ends analysis is another state-space technique whose purpose is to reduce the difference (distance) between a current state and a goal state. Determining “distance” between any state and a goal state can be facilitated by *difference-procedure tables*, which can effectively prescribe what the next state might be. To perform means–ends analysis, see [Figure 63.2](#).

```

Repeat
  Describe the current state, the goal state,
    and the difference between the two.
  Use the difference between the current state and goal state,
    to select a promising transformation procedure.
  Apply the promising procedure and update the current state.
Until the GOAL is reached or
  no more procedures are available
If the GOAL is reached, announce success;
Otherwise, announce failure.

```

FIGURE 63.2 Means–ends analysis.

FIGURE 63.3 Problem reduction and the sliding block puzzle.

The technique of problem reduction is another important approach in AI. *Problem reduction* means to solve a complex or larger problem by identifying smaller, manageable problems (or subgoals), which you know can be solved in fewer steps.

For example, Figure 63.3 shows the “donkey” sliding block puzzle. It has been known for over 100 years. Subject to constraints on the movement of pieces in the sliding block puzzle, the task is to slide the blob around the vertical bar with the goal of moving it to the other side. The blob occupies four spaces and needs two adjacent vertical or horizontal spaces to be able to move; the vertical bar needs two adjacent empty vertical spaces to move left or right, or one empty space above or below it to move up or down. The horizontal bars’ movements are complementary to the vertical bar. Likewise, the circles can move to any empty space around them in a horizontal or vertical line. A relatively uninformed state-space search can result in over 800 moves for this problem to be solved, with considerable backtracking required. Using problem reduction, resulting in the subgoal of trying to get the blob on the two rows above or below the vertical bar, it is possible to solve this puzzle in just 82 moves!

Another example of a technique for problem reduction is called **AND/OR trees**. Here, the goal is to find a solution path to a given tree by applying the following rules.

A node is solvable if

1. It is a terminal node (a primitive problem).
2. It is a non-terminal node whose successors are AND nodes that are all solvable.
3. OR it is a non-terminal node whose successors are OR nodes and least one of them is solvable.

Similarly, a node is unsolvable if

1. It is a non-terminal node that has no successors (a non-primitive problem to which no operator applies).
2. It is a non-terminal node whose successors are AND nodes and at least one of them is unsolvable.
3. OR it is a non-terminal node whose successors are OR nodes and all of them are unsolvable.

FIGURE 63.4 AND/OR tree.

In Figure 63.4, nodes B and C serve as exclusive parents to subproblems EF and GH, respectively. One way of viewing the tree is with nodes B, C, and D serving as individual, alternative subproblems representing OR nodes. Node pairs E and F and G and H, respectively, with curved arrowheads connecting them, represent AND nodes. To solve problem B, you must solve both subproblems E and F. Likewise, to solve subproblem C, you must solve subproblems G and H. Solution paths would therefore be {A-B-E-F}, {A-C-G-H}, and {A-D}. In the special case where no AND nodes occur, we have the ordinary graph occurring in a state-space search. However, the presence of AND nodes distinguishes AND/OR trees (or graphs) from ordinary state structures, which call for their own specialized search techniques. Typical problems tackled by AND/OR trees include games, puzzles, and other well defined state-space goal-oriented problems, such as robot planning, movement through an obstacle course, or setting a robot the task of reorganizing blocks on a flat surface.

63.2.3 Breadth-First Search

One way to view search problems is to consider all possible combinations of subgoals, by treating the problem as a tree search. **Breadth-first search** always explores nodes closest to the root node first, thereby visiting all nodes at a given layer first before moving to any longer paths. It pushes uniformly into the search tree. Because of memory requirements, Breadth-first search is only practical on shallow trees or those with an extremely low branching factor. It is therefore not much used in practice, except as a basis for such **best-first search** algorithms such as A* and SSS*.

63.2.4 Depth-First Search

Depth-first search (DFS) is one of the most basic and fundamental blind search algorithms. It is used for bushy trees (with a high branching factor), where a potential solution does not lie too deeply down the tree. That is, “DFS is a good idea when you are confident that all partial paths either reach dead ends or become complete paths after a reasonable number of steps.” In contrast, “DFS is a bad idea if there are long paths, particularly indefinitely long paths, that neither reach dead ends nor become complete paths” [Winston, 1992]. To conduct a DFS, follow these steps:

1. Put the Start Node on the list called OPEN.
2. If OPEN is empty, exit with failure; otherwise, continue.
3. Remove the first node from OPEN and put it on a list called CLOSED. Call this node n.
4. If the depth of n equals the depth bound, go to 2; otherwise, continue.

FIGURE 63.5 Tree example for depth-first and breadth-first search.

5. Expand node n , generating all immediate successors. Put these at the beginning of OPEN (in predetermined order) and provide pointers back to n .
6. If any of the successors are goal nodes, exit with the solution obtained by tracing back through the pointers; otherwise, go to 2.

DFS always explores the deepest node to the left first, that is, the one farthest down from the root of the tree. When a dead end (terminal node) is reached, the algorithm backtracks one level and then tries to go forward again. To prevent consideration of unacceptably long paths, a *depth bound* is often employed to limit the depth of search. At each node, immediate successors are generated and a transition made to the leftmost node, where the process continues recursively until a dead end or depth limit is reached. In Figure 63.5, DFS explores the tree in the order I-E-b-F-B-a-G-c-H-C-a-D-A. Here, the notation using lowercase letters represents the possible storing of provisional information about the subtree. For example, this could be a lower bound on the value of the tree.

Figure 63.6 enhances depth-first search with a form of **iterative deepening** that can be used in a single-agent search like A^* . DFS expands an immediate successor of some node N in a tree. The next successor to be expanded is (N,i) , the one with lowest cost function. Thus, the expected value of node N,i is the estimated cost $C(N,N,i)$ plus $H(N)$, the known value of node N . The basic idea in iterative deepening is that a DFS is started with a depth bound of 1. This bound increases by one at each new iteration. With each increase in depth, the algorithm must reinitiate its depth-first search for the prescribed bound. The idea of iterative deepening, in conjunction with a memory function to retain the best available potential solution paths from iteration to iteration, is credited to Slate and Atkin [1977], who used it in their chess program. Korf [1985] showed how efficient this method is in single-agent searches, with his iterative deepening A^* (IDA*) algorithm.

63.2.5 Bidirectional Search

To this point, all search algorithms discussed (with the exception of means–ends analysis and backtracking) have been based on forward reasoning. Searching backward from goal nodes to predecessors is relatively easy. Pohl [1971] combined forward and backward reasoning in a technique called **bidirectional search**. The idea is to replace a single search graph, which is likely to grow exponentially, with two smaller graphs — one starting from the initial state and one starting from the goal. The search terminates when the two graphs intersect. This algorithm is guaranteed to find the shortest solution path through a general state-space graph. Empirical data for randomly generated graphs shows that Pohl’s algorithm expands

```

// The A* (DFS) algorithm expands the N.i successors of node N
// in best first order. It uses and sets solved, a global indicator.
// It also uses a heuristic estimate function H(N), and a
// transition cost C(N,N.i) of moving from N to N.i
//
IDA* (N) → cost
    bound ← H(N)
    while not solved
        bound ← DFS (N, bound)
    return bound // optimal cost

DFS (N, bound) → value
    if H(N) ≡ 0 // leaf node
        solved ← true
        return 0
    new_bound ← ∞
    for each successor N.i of N
        merit ← C(N, N.i) + H(N.i)
        if merit ≤ bound
            merit ← C(N,N.i) + DFS (N.i, bound - C(N,N.i))
            if solved
                return merit
        if merit < new_bound
            new_bound ← merit
    return new_bound

```

FIGURE 63.6 The A* DFS algorithm for use with IDA*.

only about one-quarter as many nodes as unidirectional search [Barr and Feigenbaum, 1981]. Pohl also implemented heuristic versions of this algorithm. However, determining when and how the two searches will intersect is a complex process.

Russell and Norvig [2003] analyze the bidirectional search and come to the conclusion that it is $o(b^{d/2})$ in terms of average case time and space complexity. They point out that this is significantly better than $o(b^d)$, which would be the cost of searching exhaustively in one direction. Identification of subgoal states could do much to reduce the costs. The large space requirements of the algorithm are considered its weakness.

However, Kaindl and Kainz [1997] have demonstrated that the long-held belief that the algorithm is afflicted by the frontiers passing each other is wrong. They developed a new generic approach, which dynamically improves heuristic values but is only applicable to bidirectional heuristic. Their empirical results have found that the bidirectional heuristic search can be performed very efficiently, with limited memory demands. Their research has resulted in a better understanding of an algorithm whose practical usefulness has been long neglected, with the conclusion that it is better suited to certain problems than corresponding unidirectional searches. For more details, the reader should review their paper [Kaindl and Kainz, 1997]. The next section focuses on heuristic search methods.

63.3 Heuristic Search Methods

George Polya, via his wonderful book *How to Solve It* [1945], may be regarded as the father of heuristics. Polya's efforts focused on problem solving, thinking, and learning. He developed a short "heuristic dictionary" of heuristic primitives. Polya's approach was both practical and experimental. He sought to develop commonalities in the problem-solving process through the formalization of observation and experience.

Present-day notions of heuristics are somewhat different from Polya's [Bolc and Cytowski, 1992]. Current tendencies seek formal and rigid algorithmic solutions to specific problem domains, rather than the development of general approaches that could be appropriately selected and applied to specific problems.

The goal of a heuristic search is to reduce greatly the number of nodes searched in seeking a goal. In other words, problems whose complexity grows combinatorially large may be tackled. Through knowledge, information, rules, insights, analogies, and simplification — in addition to a host of other techniques — heuristic search aims to reduce the number of objects that must be examined. Heuristics do not guarantee the achievement of a solution, although good heuristics should facilitate this. Over the years, heuristic search has been defined in many different ways:

- It is a practical strategy increasing the effectiveness of complex problem solving [Feigenbaum and Feldman, 1963].
- It leads to a solution along the most probable path, omitting the least promising ones.
- It should enable one to avoid the examination of dead ends and to use already gathered data.

The points at which heuristic information can be applied in a search include the following:

1. Deciding which node to expand next, instead of doing the expansions in either a strict breadth-first or depth-first order
2. Deciding which successor or successors to generate when generating a node — instead of blindly generating all possible successors at one time
3. Deciding that certain nodes should be discarded, or pruned, from the search tree.

Bolc and Cytowski [1992] add:

“[U]se of heuristics in the solution construction process increases the uncertainty of arriving at a result . . . due to the use of informal knowledge (rules, laws, intuition, etc.) whose usefulness have never been fully proven. Because of this, heuristic methods are employed in cases where algorithms give unsatisfactory results or do not guarantee to give any results. They are particularly important in solving very complex problems (where an accurate algorithm fails), especially in speech and image recognition, robotics and game strategy construction

“Heuristic methods allow us to exploit uncertain and imprecise data in a natural way The main objective of heuristics is to aid and improve the effectiveness of an algorithm solving a problem. Most important is the elimination from further consideration of some subsets of objects still not examined”

Most modern heuristic search methods are expected to bridge the gap between the completeness of algorithms and their optimal complexity [Romanycia and Pelletier, 1985]. Strategies are being modified in order to arrive at a quasi-optimal, rather than optimal, solution with a significant cost reduction [Pearl, 1984]. Games, especially two-person, zero-sum games of perfect information, like chess and checkers, have proved to be a very promising domain for studying and testing heuristics.

63.3.1 Hill Climbing

Hill climbing is a DFS with a heuristic measure that orders choices as nodes are expanded. The heuristic measure is the estimated remaining distance to the goal. The effectiveness of hill climbing is completely dependent upon the accuracy of the heuristic measure. To conduct a hill climbing search of a tree:

Form a one-element queue consisting of a zero-length path that contains only the root node.

Repeat

Remove the first path from the queue;

Create new paths by extending the first path to all the *neighbors* of the *terminal node*.

If New Path(s) result in a loop Then

 Reject New Path(s).

Sort any New Paths by the estimated distances between their *terminal nodes* and the GOAL.

If any shorter paths exist Then

 Add them to the front of the queue.

Until the first path in the queue terminates at the GOAL node or
the queue is empty

If the GOAL node is found, announce SUCCESS, otherwise announce FAILURE.

In this algorithm, *neighbors* refer to “children” of nodes that have been explored, and *terminal nodes* are equivalent to leaf nodes. Winston [1992] explains the potential problems affecting hill climbing. They are all related to issue of local vision vs. global vision of the search space. The *foothills problem* is particularly subject to local maxima where global ones are sought. The *plateau problem* occurs when the heuristic measure does not hint toward any significant gradient of proximity to a goal. The *ridge problem* illustrates its name: you may get the impression that the search is taking you closer to a goal state, when in fact you traveling along a ridge that prevents you from actually attaining your goal. **Simulated annealing** attempts to combine hill climbing with a random walk in a way that yields both efficiency and completeness [Russell and Norvig, 2003]. The idea is to temper the downhill process of hill climbing in order to avoid some of these pitfalls by increasing the probability of hitting important locations to explore. It is like intelligent guessing.

63.3.2 Best-First Search

Best-first search (Figure 63.7) is a general algorithm for heuristically searching any state-space graph — a graph representation for a problem that includes initial states, intermediate states, and goal states. In this sense, a directed acyclic graph (DAG), for example, is a special case of a state-space graph. Best-first search is equally applicable to data- and goal-driven searches and supports the use of heuristic evaluation functions. It can be used with a variety of heuristics, ranging from a state’s “goodness” to sophisticated measures based on the probability of a state’s leading to a goal that can be illustrated by examples of Bayesian statistical measures.

Similar to the depth-first and breadth-first search algorithms, best-first search uses lists to maintain states: OPEN to keep track of the current fringe of the search and CLOSED to record states already visited. In addition, the algorithm orders states on OPEN according to some heuristic estimate of their proximity to a goal. Thus, each iteration of the loop considers the most promising state on the OPEN list. According to Luger and Stubblefield [1993], best-first search improves at just the point where hill climbing fails with its short-sighted and local vision. The following description of the algorithm closely follows that of Luger and Stubblefield [1993, p. 121]:

“At each iteration, Best First Search removes the first element from the OPEN list. If it meets the goal conditions, the algorithm returns the solution path that led to the goal. Each state retains ancestor information to allow the algorithm to return the final solution path.

“If the first element on OPEN is not a goal, the algorithm generates its descendants. If a child state is already on OPEN or CLOSED, the algorithm checks to make sure that the state records the shorter of the

```

Procedure Best_First_Search (Start) → pointer
  OPEN ← {Start}                                     // Initialize
  CLOSED ← { }
  While OPEN ≠ { } Do                                // States Remain
    remove the leftmost state from OPEN, call it X;
    if X ≡ goal then
      return the path from Start to X
    else
      generate children of X
      for each child of X do
        CASE
        the child is not on OPEN or CLOSED:
          assign the child a heuristic value
          add the child to OPEN
        the child is already on OPEN:
          if the child was reached by a shorter path
            then give the state on OPEN the shorter path
        the child is already on CLOSED:
          if the child was reached by a shorter path then
            remove the state from CLOSED
            add the child to OPEN
        end_CASE
      put X on CLOSED;
      re-order states on OPEN by heuristic merit (best leftmost)
  return NULL                                         // OPEN is empty

```

FIGURE 63.7 The best-first search algorithm (based on Luger and Stubblefield [1993, p. 121]).

FIGURE 63.8 A state-space graph for a hypothetical subway system.

two partial solution paths. Duplicate states are not retained. By updating the ancestor history of nodes on OPEN and CLOSED, when they are rediscovered, the algorithm is more likely to find a quicker path to a goal.

“Best First Search then heuristically evaluates the states on OPEN, and the list is sorted according to the heuristic values. This brings the ‘best’ state to the front of OPEN. It is noteworthy that these estimates are heuristic in nature and therefore the next state to be examined may be from any level of the state space. OPEN, when maintained as a sorted list, is often referred to as a *priority queue*.”

Here is a graph of a hypothetical search space. The problem is to find a shortest path from d1 to d5 in this directed and weighted graph (Figure 63.8), which could represent a sequence of local and express subway train stops. The F train starts at d1 and visits stops d2 (cost 16), d4 (cost 7), and d6 (cost 11). The D train starts at d1 and d3 (cost 7), d4 (cost 13), and d5 (cost 12). Other choices involve combinations of Q, N, R, and A trains with the F and/or D train. By applying the best-first search algorithm, we can find the shortest path from d1 to d5. [Figure 63.9](#) shows a state tree representation of this graph.

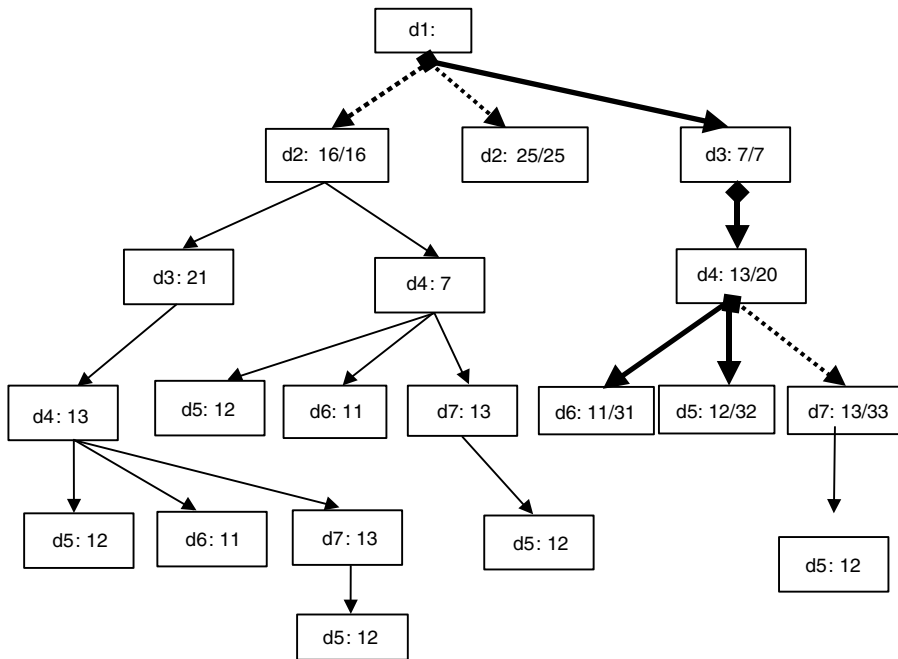

FIGURE 63.9 A search tree for the graph in Figure 63.8.

The thick arrowed path is the shortest path [d1, d3, d4, d5]. The dashed edges are nodes put on the open node queue but not further explored. A trace of the execution of procedure best-first search follows:

1. Open = [d1]; Closed = []
2. Evaluate d1; Open = [d3, d2]; Closed = [d1]
3. Evaluate d3; Open = [d4, d2]; Closed = [d3, d1]
4. Evaluate d4; Open = [d6, d5, d7, d2]; Closed = [d4, d3, d1]
5. Evaluate d6; Open = [d5, d7, d2]; Closed = [d6, d4, d3, d1]
6. Evaluate d5; a solution is found Closed = [d5, d6, d4, d3, d1]

Note that nodes d6 and d5 are at the same level, so we do not take d6 in our search for the shortest path. Hence, the shortest path for this graph is [d1, d3, d4, d5]. After we reach our goal state d5, we can also find the shortest path from d5 to d1 by retracing the tree from d5 to d1.

When the best-first search algorithm is used, the states are sent to the open list in such a way that the most promising one is expanded next. Because the search heuristic being used for measurement of distance from the goal state may prove erroneous, the alternatives to the preferred state are kept on the open list. If the algorithm follows an incorrect path, it will retrieve the next best state and shift its focus to another part of the space. In the preceding example, children of node d2 were found to have poorer heuristic evaluations than sibling d3, so the search shifted there. However, the children of d3 were kept on open and could be returned to later, if other solutions were sought.

63.3.3 The A* Algorithm

The **A* algorithm**, first described by Hart et al. [1968], attempts to find the minimal cost path joining the start node and the goal in a state-space graph. The algorithm employs an ordered state-space search and an estimated heuristic cost to a goal state, f^* (known as an *evaluation function*), as does the best-first search (see Section 63.3.2). It uniquely defines f^* , so that it can guarantee an optimal solution path. The A*

algorithm falls into the **branch and bound** class of algorithms, typically employed in operations research to find the shortest path to a solution node in a graph.

The evaluation function, $f^*(n)$, estimates the quality of a solution path through node n , based on values returned from two components: $g^*(n)$ and $h^*(n)$. Here, $g^*(n)$ is the minimal cost of a path from a start node to n , and $h^*(n)$ is a lower bound on the minimal cost of a solution path from node n to a goal node. As in branch and bound algorithms for trees, g^* will determine the single unique shortest path to node n .

For graphs, on the other hand, g^* can err only in the direction of overestimating the minimal cost; if a shorter path is found, its value readjusted downward. The function h^* is the carrier of *heuristic information*, and the ability to ensure that the value of $h^*(n)$ is less than $h(n)$ — that is, $h^*(n)$ is an underestimate of the actual cost, $h(n)$, of an optimal path from n to a goal node — is essential to the optimality of the A^* algorithm. This property, whereby $h^*(n)$ is always less than $h(n)$, is known as the **admissibility condition**. If h^* is zero, then A^* reduces to the blind uniform-cost algorithm. If two otherwise similar algorithms, A_1 and A_2 , can be compared to each other with respect to their h^* function (i.e., h_1^* and h_2^*) then algorithm A_1 is said to be *more informed* than A_2 if $h_1^*(n) > h_2^*(n)$, whenever a node n (other than a goal node) is evaluated. The cost of computing h^* , in terms of the overall computational effort involved and algorithmic utility, determines the *heuristic power* of an algorithm. That is, an algorithm that employs an h^* which is usually accurate, but sometimes inadmissible, may be preferred over an algorithm where h^* is always minimal but hard to effect [Barr and Feigenbaum, 1981].

Thus, we can summarize that the A^* algorithm is a branch and bound algorithm augmented by the *dynamic programming principle*: the best way through a particular, intermediate node is the best way to that intermediate node from the starting place, followed by the best way from that intermediate node to the goal node. There is no need to consider any other paths to or from the intermediate node [Winston, 1992].

Stewart and White [1991] presented the *multiple-objective A^* algorithm* (MOA^*). Their research is motivated by the observation that most real-world problems have multiple, independent, and possibly conflicting objectives. MOA^* explicitly addresses this problem by identifying the set of all non-dominated paths from a specified start node to given set of goal nodes in an OR graph. This work shows that MOA^* is complete and is admissible, when used with a suitable set of heuristic functions.

63.4 Game-Tree Search

63.4.1 The Alpha-Beta Algorithms

To the human player of two-person games, the notion behind the **alpha-beta algorithm** is understood intuitively as follows:

If I have determined that a move or a sequence of moves is bad for me (because of a refutation move or variation by my opponent), then I do not need to determine just how bad that move is. Instead, I can spend my time exploring other alternatives earlier in the tree.
Conversely, if I have determined that a variation or sequence of moves is bad for my opponent, then I do not determine exactly how good it is for me.

Figure 63.10 illustrates some of these ideas. Here, the thick solid line represents the current solution path. This, in turn, has replaced a candidate solution, here shown with dotted lines. Everything to the right of the optimal solution path represents alternatives that are simply proved inferior. The path of the current solution is called the *principal variation* (PV), and nodes on that path are marked as PV nodes. Similarly, the alternatives to PV nodes are CUT nodes, where only a few successors are examined before a proof of inferiority is found. In time, the successor to a CUT node will be an ALL node, where everything must be examined to prove the cut-off at the CUT node. The number or bound value by each node represents the return to the root of the cost of the solution path.

In the 40 years since its inception, the alpha-beta minimax algorithm has undergone many revisions and refinements to improve the efficiency of its pruning and, until the recent invention of the MTD(f)

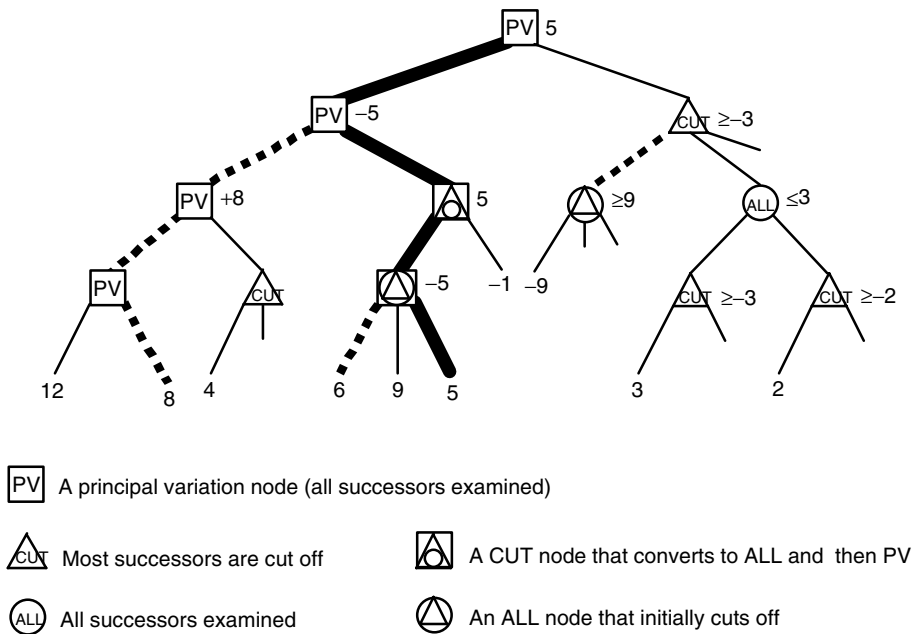

FIGURE 63.10 The PV, CUT, and ALL nodes of a tree, showing its optimal path (bold) and value (5).

variant, it has served as the primary search engine for two-person games. There have been many landmarks on the way, including Knuth and Moore's [1975] formulation in a negamax framework, Pearl's [1980] introduction of Scout, and the special formulation for chess with the principal variation search [Marsland and Campbell, 1982] and NegaScout [Reinefeld, 1983].

The essence of the method is that the search seeks a path whose value falls between two bounds called *alpha* and *beta*, which form a window. With this approach, one can also incorporate an artificial narrowing of the alpha-beta window, thus encompassing the notion of *aspiration search*, with a mandatory research on failure to find a value within the corrected bounds. This leads naturally to the incorporation of null window search (NWS) to improve on Pearl's test procedure. Here, the NWS procedure covers the search at a CUT node (Figure 63.10), where the cutting bound (beta) is negated and increased by 1 in the recursive call. This refinement has some advantage in the parallel search case, but otherwise NWS (Figure 63.11) is entirely equivalent to the minimal window call in NegaScout.

Additional improvements include the use of iterative deepening with *transposition tables* and other move-ordering mechanisms to retain a memory of the search from iteration to iteration. A transposition table is a cache of previously generated states that are typically hashed into a table to avoid redundant work. These improvements help ensure that the better subtrees are searched sooner, leading to greater pruning efficiency (more cut-offs) in the later subtrees. Figure 63.11 encapsulates the essence of the algorithm and shows how the first variation from a set of PV nodes, as well as any superior path that emerges later, is given special treatment. Alternates to PV nodes will always be CUT nodes, where a few successors will be examined. In a minimal game tree, only one successor to a CUT node will be examined, and it will be an ALL node where everything is examined. In the general case, the situation is more complex, as Figure 63.10 shows.

63.4.2 SSS* Algorithm

The **SSS* algorithm** was introduced by Stockman [1979] as a game-searching algorithm that traverses subtrees of the game tree in a best-first fashion similar to the A* algorithm. SSS* was shown to be superior to the original alpha-beta algorithm in the sense that it never looks at more nodes, while occasionally

```

ABS (node, alpha, beta, height) → tree_value
  if height ≡ 0
    return Evaluate(node) // a terminal node
  next ← FirstSuccessor (node) // a PV node
  best ← - ABS (next, -beta, -alpha, height -1)
  next ← SelectSibling (next)
  while next ≠ NULL do
    if best ≥ beta then
      return best // a CUT node
    alpha ← max (alpha, best)
    merit ← - NWS (next, -alpha, height-1)
    if merit > best then
      if (merit ≤ alpha) or (merit ≥ beta) then
        best ← merit
      else best ← -ABS (next, -beta, -merit, height-1)
    next ← SelectSibling (next)
  end
  return best // a PV node
end

NWS (node, beta, height) → bound_value
  if height ≡ 0 then
    return Evaluate(node) // a terminal node
  next ← FirstSuccessor (node)
  estimate ← - ∞
  while next ≠ NULL do
    merit ← - NWS (next, -beta+1, height-1)
    if merit > estimate then
      estimate ← merit
    if merit ≥ beta then
      return estimate // a CUT node
    next ← SelectSibling (next)
  end
  return estimate // an ALL node
end

```

FIGURE 63.11 Scout/PVS version of alpha-beta search (ABS) in the negamax framework.

examining fewer [Pearl, 1984]. Roizen and Pearl [1983], the source of the following description of SSS*, state:

“... the aim of SSS* is the discovery of an optimal solution tree ... In accordance with the best-first split-and-prune paradigm, SSS* considers ‘clusters’ of solution trees and splits (or refines) that cluster having the highest upper bound on the merit of its constituents. Every node in the game tree represents a cluster of solution trees defined by the set of all solution trees that share that node ... the merit of a partially developed solution tree in a game is determined solely by the properties of the frontier nodes it contains, not by the cost of the paths leading to these nodes. The value of a frontier node is an upper bound on each solution tree in the cluster it represents ... SSS* establishes upper bounds on the values of partially developed solution trees by seeking the value of terminal nodes, left to right, taking the minimum value of those examined so far. These monotonically non-increasing bounds are used to order the solution trees so that the tree of highest merit is chosen for development. The development process continues until one solution tree is fully developed, at which point that tree represents the optimal strategy and its value coincides with the minimax value of the root. ...

```

int MTDf ( node_type root, int f, int d)
{
    g = f;
    upperbound = +INFINITY;
    lowerbound = -INFINITY;
    repeat
        if (g == lowerbound)
            beta = g + 1
        else
            beta = g;
        g = AlphaBetaWithMemory(root, beta - 1, beta, d);
        if (g < beta)
            then upperbound = g
            else lowerbound = g;
    until (lowerbound >= upperbound);
    return g;
}

```

FIGURE 63.12 The MTD(f) algorithm pseudocode.

“The disadvantage of SSS* lies in the need to keep in storage a record of all contending candidate clusters, which may require large storage space, growing exponentially with search depth” [p. 245].

Heavy space and time overheads have kept SSS* from being much more than an example of a best-first search, but current research seems destined to relegate SSS* to a historical footnote. Plaat et al. [1995] have formulated the node-efficient SSS* algorithm into the alpha-beta framework using successive NWS search invocations (supported by perfect transposition tables) to achieve a memory-enhanced test procedure that provides a best-first search. With their introduction of the MTD(f) algorithm, Plaat et al. [1995] claim that SSS* can be viewed as a special case of the time-efficient alpha-beta algorithm, as opposed to the earlier view that alpha-beta is a k-partition variant of SSS*. MTD(f) is an important contribution that has now been widely adopted as the standard two-person game-tree search algorithm. It is described next.

63.4.3 The MTD(f) Algorithm

MTD(f) is usually run in an iterative deepening fashion, and each iteration proceeds by a sequence of minimal or NULL window alpha-beta calls. The search works by zooming in on the minimax value, as Figure 63.12 shows.

The bounds stored in *upperbound* and *lowerbound* form an interval around the true minimax value for a particular search depth d . The interval is initially set to $[-\infty, +\infty]$. Starting with the value f , returned from a previous call to MTD(f), each call to alpha-beta returns a new minimax value g , which is used to adjust the bounding interval and to serve as the pruning value for the next alpha-beta call. For example, if the initial minimax value is 50, alpha-beta will be called with the pruning values 49 and 50. If the new minimax value returned, g , is less than 50, upperbound is set to g . If the minimax value returned, g , is greater than or equal to 50, lowerbound is set to g . The next call to alpha-beta will use $g - 1$ and g for the pruning values (or g and $g + 1$, if g is equal to lowerbound). This process continues until upperbound and lowerbound converge to a single value, which is returned. MTD(f) will be called again with this newly returned minimax estimate and an increased depth bound, until the tree has been searched to a sufficient depth.

As a result of the iterative nature of MTD(f), the use of transposition tables is essential to its efficient implementation. In tests with a number of tournament game-playing programs, MTD(f) outperformed ABS (Scout/PVS, Figure 63.11). It generally produces trees that are 5% to 15% smaller than ABS [Plaat et al., 1996]. MTD(f) is now recognized as the most efficient variant of ABS and has been rapidly adopted as the new standard in minimax search.

63.4.4 Recent Developments

Sven Koenig has developed minimax learning real-time A* (Min-Max LRTA*), a real-time heuristic search method that generalizes Korf's [1990] earlier LRTA* to nondeterministic domains. Hence it can be applied to "robot navigation tasks in mazes, where robots know the maze but do not know their initial position and orientation (pose). These planning tasks can be modeled as planning tasks in non-deterministic domains whose states are sets of poses." Such problems can be solved quickly and efficiently with Min-Max LRTA*, requiring only a small amount of memory [Koenig, 2001].

Martin Mueller [2001] introduces the use of partial order bounding (POB) rather than scalar values for construction of an evaluation function for computer game playing. Propagation of partially ordered values through a search tree has been known to lead to many problems in practice. Instead, POB compares values in the leaves of a game tree and backs up Boolean values through the tree. The effectiveness of this method was demonstrated in examples of capture races in the game of GO [Mueller, 2001].

Schaeffer et al. [2001] demonstrate that the distinctions for evaluating heuristic search should not be based on whether the application is for single-agent or two-agent search. Instead, they argue that the search enhancements applied to both single-agent and two-agent problems for creating high-performance applications are the essentials. Focus should be on generality, for creating opportunities for reuse. Examples of some of the generic enhancements (as opposed to problem-specific ones) include the alpha-beta algorithm, transposition tables, and IDA*. Efforts should be made to enable more generic application of algorithms.

Hong et al. [2001] present a **genetic algorithm** approach that can find a good next move by reserving the board evaluation of new offspring in partial game-tree search. Experiments have proved promising in terms of speed and accuracy when applied to the game of GO.

The fast forward (FF) planning system of Hoffman and Nebel [2001] uses a heuristic that estimates goal distances by ignoring delete lists. Facts are not assumed to be independent. The system uses a new search strategy that combines hill climbing with systematic search. Powerful heuristic information is extended and used to prune the search space.

63.5 Parallel Search

The easy availability of low-cost computers has stimulated interest in the use of multiple processors for parallel traversals of decision trees. The few theoretical models of parallelism do not accommodate communication and synchronization delays that inevitably impact the performance of working systems. There are several other factors to consider, including the following:

- How best to employ the additional memory and I/O resources that become available with the extra processors.
- How best to distribute the work across the available processors.
- How to avoid excessive duplication of computation.

Some important combinatorial problems have no difficulty with the last point, because every eventuality must be considered, but these tend to be less interesting in an AI context.

One problem of particular interest is game-tree search, where it is necessary to compute the value of the tree while communicating an improved estimate to the other parallel searchers as it becomes available. This can lead to an *acceleration anomaly* when the tree value is found earlier than is possible with a sequential algorithm. Even so, uniprocessor algorithms can have special advantages in that they can be optimized for best pruning efficiency, while a competing parallel system may not have the right information in time to achieve the same degree of pruning, and so do more work (suffer from search overhead). Further, the very fact that pruning occurs makes it impossible to determine in advance how big any piece of work (subtree to be searched) will be, leading to a potentially serious work imbalance and heavy synchronization (waiting for more work) delays.

Although the standard basis for comparing the efficiency of parallel methods is simply

$$\text{speedup} = \frac{\text{time taken by a sequential single-processor algorithm}}{\text{time taken by a P-processor system}}$$

this basis is often misused, because it depends on the efficiency of the uniprocessor implementation.

The exponential growth of the tree size (solution space) with depth of search makes parallel search algorithms especially susceptible to anomalous speedup behavior. Clearly, acceleration anomalies are among the welcome properties, but more commonly, anomalously bad performance is seen, unless the algorithm has been designed with care.

In game-playing programs of interest to AI, parallelism is not primarily intended to find the answer more quickly, but to get a more reliable result (e.g., based on a deeper search). Here, the emphasis lies on scalability instead of speedup. Although speedup holds the problem size constant and increases the system size to get a result sooner, scalability measures the ability to expand the sizes of both the problem and the system at the same time:

$$\text{scale-up} = \frac{\text{time taken to solve a problem of size } s \text{ by a single-processor}}{\text{time taken to solve a } (P \times s) \text{ problem by an P-processor system}}$$

Thus, scale-up close to unity reflects successful parallelism.

63.5.1 Parallel Single-Agent Search

Single-agent game-tree search is important because it is useful for several robot-planning activities, such as finding the shortest path through a maze of obstacles. It seems to be more amenable to parallelization than the techniques used in adversary games, because a large proportion of the search space must be fully seen — especially when optimal solutions are sought. This traversal can safely be done in parallel, since there are no cut-offs to be missed. Although move ordering can reduce node expansions, it does not play the same crucial role as in dual-agent game-tree search, where significant parts of the search space are often pruned away. For this reason, parallel single-agent search techniques usually achieve better speedups than their counterparts in adversary games.

Most parallel single-agent searches are based on A* or IDA*. As in the sequential case, parallel A* outperforms IDA* on a node count basis, although parallel IDA* needs only linear storage space and runs faster. In addition, cost-effective methods exist (e.g., parallel window search described in [Section 63.5.1.3](#)) that determine non-optimal solutions with even less computing time.

63.5.1.1 Parallel A*

Given P processors, the simplest way to parallelize A* is to let each machine work on one of the current best states on a global open list (a place holder for nodes that have not yet been examined). This approach minimizes the search overhead, as confirmed in practice by Kumar et al. [1988]. Their relevant experiments were run on a shared memory BBN Butterfly machine with 100 processors, where a search overhead of less than 5% was observed for the traveling salesperson (TSP) problem.

Elapsed time is more important than the node expansion count, however, because the global open list is accessed both before and after each node expansion, so memory contention becomes a serious bottleneck. It turns out that a centralized strategy for managing the open list is useful only in domains where the node expansion time is large compared to the open list access time. In the TSP problem, near linear time speedups were achieved with up to about 50 processors, when a sophisticated heap data structure was used to significantly reduce the open list access time [Kumar et al., 1988].

Distributed strategies using local open lists reduce the memory contention problem. But again, some communication must be provided to allow processors to share the most promising state descriptors, so that no computing resources are wasted in expanding inferior states. For this purpose, a global blackboard table can be used to hold state descriptors of the current best nodes. After selecting a state from its local

open list, each processor compares its f-value (lower bound on the solution cost) to that of the states contained in the blackboard. If the local state is much better (or much worse) than those stored in the blackboard, then node descriptors are sent (or received), so that all active processors are exploring states of almost equal heuristic value. With this scheme, a 69-fold speedup was achieved on an 85-processor BBN Butterfly [Kumar et al., 1988].

Although a blackboard is not accessed as frequently as a global open list, it still causes memory contention with increasing parallelism. To alleviate this problem, Huang and Davis [1989] proposed a distributed heuristic search algorithm called *parallel iterative A** (PIA*), which works solely on local data structures. On a uniprocessor, PIA* expands the same nodes as A*; in the multiprocessor case, it performs a parallel best-first node expansion. The search proceeds by repetitive synchronized iterations, in which processors working on inferior nodes are stopped and reassigned to better ones. To avoid unproductive waiting at the synchronization barriers, the processors are allowed to perform speculative processing. Although Huang and Davis [1989] claim that “this algorithm can achieve almost linear speedup on a large number of processors,” it has the same disadvantage as the other parallel A* variants, namely, excessive memory requirements.

63.5.1.2 Parallel IDA*

IDA* (Figure 63.6) has proved to be effective when excessive memory requirements undermine best-first schemes. Not surprisingly, it has also been a popular algorithm to parallelize. Rao et al. [1987] proposed PIDA*, an algorithm with almost linear speedup even when solving the 15-puzzle with its trivial node expansion cost. The 15-puzzle is a popular game made up of 15 tiles that slide within a 4×4 matrix. The object is to slide the tiles through the one empty spot until all tiles are aligned in some goal state. An optimal solution to a hard problem might take 66 moves. PIDA* splits the search space into disjoint parts, so that each processor performs a local cost-bounded depth-first search on its private portion of the state space. When a process has finished its job, it tries to get an unsearched part of the tree from other processors. When no further work can be obtained, all processors detect global termination and compute the minimum of the cost bounds, which is used as a new bound in the next iteration.

Note that more than a P-fold speedup is possible when a processor finds a goal node early in the final iteration. In fact, Rao et al. [1987] report an average speedup of 9.24 with nine processors on the 15-puzzle! Perhaps more relevant is the all-solution case, where no superlinear speedup is possible. Here, an average speedup of $0.93P$ with up to 30 (P) processors on a bus-based multiprocessor architecture (Sequent Balance 21000) was achieved. This suggests that only low multiprocessing overheads (locking, work transfer, termination detection, and synchronization) were experienced.

PIDA* employs a task attraction scheme like that shown in Figure 63.13 for distributing the work among the processors. When a processor becomes idle, it asks a neighbor for a piece of the search space. The donor then splits its depth-first search stack and transfers to the requester some nodes (subtrees) for parallel expansion. An optimal splitting strategy would depend on the regularity (uniformity of width and height) of the search tree, although short subtrees should never be given away. When the tree is regular (as in the 15-puzzle), a coarse-grained work transfer strategy can be used (e.g., transferring only nodes near the root); otherwise, a slice of nodes (e.g., nodes A, B, and C in Figure 63.13) should be transferred.

63.5.1.3 A Comparison with Parallel Window Search

Another parallel IDA* approach borrows from Baudet’s [1978] parallel window method for searching adversary games (described subsequently). Powley and Korf [1991] adapted this method to single-agent search, under the title *parallel window search* (PWS). Their basic idea was to start simultaneously as many iterations as there are processors. This works for a small number of processors, which either expand the tree up to their given thresholds until a solution is found (and the search is stopped) or completely expand their search space. A global administration scheme then determines the next larger search bound, and node expansion starts over again.

Note that the first solution found by PWS need not necessarily be optimal. Suboptimal solutions are often found in searches of poorly ordered trees. There, a processor working with a higher cut-off bound finds a goal node in a deeper tree level, while other processors are still expanding shallower tree parts (which

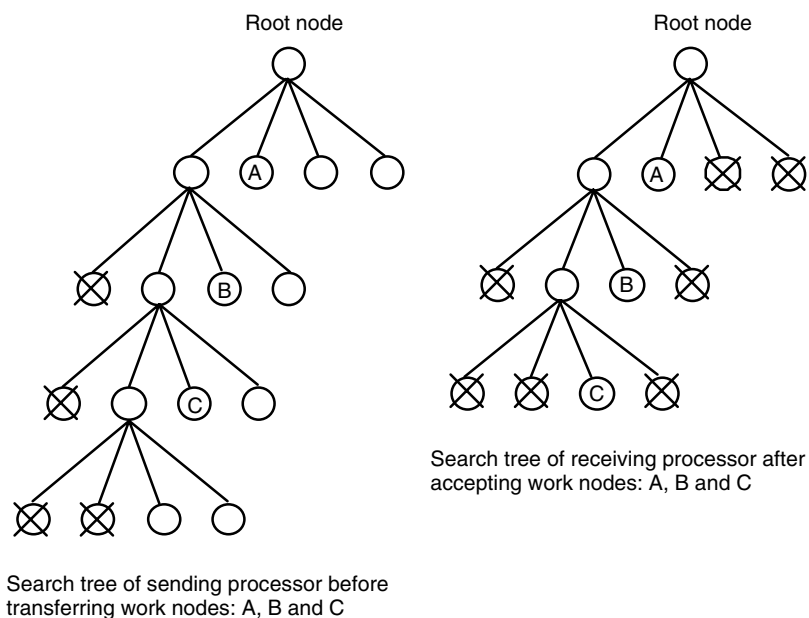

FIGURE 63.13 A work distribution scheme.

may contain cheaper solutions). According to Powley and Korf [1991], PWS is not primarily meant to compete with IDA*, but it “can be used to find a nearly optimal solution quickly, improve the solution until it is optimal, and then finally guarantee optimality, depending on the amount of time available.” Compared to PIDA*, the degree of parallelism is limited, and it remains unclear how to apply PWS in domains where the cost-bound increases are variable.

In summary, PWS and PIDA* complement each other, so it seems natural to combine them to form a single search scheme that runs PIDA* on groups of processors administered by a global PWS algorithm. The amount of communication needed depends on the work distribution scheme. A fine-grained distribution requires more communication, whereas a coarse-grained work distribution generates fewer messages (but may induce unbalanced work load). Note that the choice of the work distribution scheme also affects the frequency of good acceleration anomalies. Along these lines, perhaps the best results have been reported by Reinefeld [1995]. Using AIDA* (asynchronous parallel IDA*), near linear speedup was obtained on a 1024 transputer-based system solving 13 instances of the 19-puzzle. Reinefeld’s paper includes a discussion of the communication overheads in both ring and toroid systems, as well as a description of the work distribution scheme.

63.5.2 Adversary Games

In the area of two-person games, early simulation studies with a **mandatory work first** (MWF) scheme [Akl et al., 1982] and the **PVSplit algorithm** [Marsland and Campbell, 1982] showed that a high degree of parallelism was possible, despite the work imbalance introduced by pruning. Those papers saw that in key applications (e.g., chess), the game-trees are well ordered, because of the wealth of move-ordering heuristics that have been developed [Slate and Atkin, 1977], so the bulk of the computation occurs during the search of the first subtree. The MWF approach uses the shape of the critical tree that must be searched. Because that tree is well defined and has regular properties, it is easy to generate.

In their simulation, Akl et al. [1982] considered the merits of searching the critical game tree in parallel, with the balance of the tree being generated algorithmically and searched quickly by simple tree splitting. Marsland and Campbell [1982], on the other hand, recognized that the first subtree of the critical game

tree has the same properties as the whole tree, but its maximum height is one less. This so-called *principal variation* can be recursively split into parts of about equal size for parallel exploration. PVSplit, an algorithm based on this observation, was tested and analyzed by Marsland and Popowich [1985]. Even so, the static processor allocation schemes, like MWF and PVSplit, cannot achieve high levels of parallelism, although PVSplit does very well with up to half a dozen processors. MWF in particular ignores the true shape of the average game tree, and so is at its best with shallow searches, where the pruning imbalance from the so called *deep cut-offs* has less effect. Other working experience includes the first parallel chess program by Newborn, who later presented performance results [Newborn, 1988]. For practical reasons, Newborn only split the tree down to some pre-specified common depth from the root (typically 2), where the greatest benefits from parallelism can be achieved. This use of a common depth has been taken up by Hsu [1990] in his proposal for large-scale parallelism. Depth limits are also an important part of changing search modes and managing transposition tables.

63.5.2.1 Parallel Aspiration Window Search

In an early paper on parallel game-tree search, Baudet [1978] suggested partitioning the range of the alpha-beta window rather than the tree. In his algorithm, all processors search the whole tree, but each with a different, non-overlapping alpha-beta window. The total range of values is subdivided into P smaller intervals (where P is the number of processors), so that approximately one-third of the range is covered. The advantage of this method is that the processor having the true minimax value inside its narrow window will complete more quickly than a sequential algorithm running with a full window. Even the unsuccessful processors return a result: they determine whether the true minimax value lies below or above their assigned search window, providing important information for rescheduling idle processors until a solution is found.

Its low communication overhead and lack of synchronization needs are among the positive aspects of Baudet's approach. On the negative side, however, Baudet estimates a maximum speedup of between 5 and 6, even when using infinitely many processors. In practice, parallel window search can only be effectively employed on systems with two or three processors. This is because even in the best case (when the successful processor uses a minimal window), at least the critical game tree must be expanded. The critical tree has about the square root of the leaf nodes of a uniform tree of the same depth, and it represents the smallest tree that must be searched under any circumstances.

63.5.2.2 Advanced Tree-Splitting Methods

Results from fully recursive versions of PVSplit using the Parabelle chess program [Marsland and Popowich, 1985] confirmed earlier simulations and offered some insight into a major problem: in a P -processor system, $P - 1$ processors are often idle for an inordinate amount of time, thus inducing a high synchronization overhead for large systems. Moreover, the synchronization overhead increases as more processors are added, accounting for most of the total losses, because the search overhead (number of unnecessary node expansions) becomes almost constant for the larger systems.

This led to the development of variations that dynamically assign processors to the search of the principal variation. Notable is the work of Schaeffer [1989], which uses a loosely coupled network of workstations, and the independent implementation of Hyatt et al. [1989] for a shared-memory computer. These dynamic splitting works have attracted growing attention through a variety of approaches. For example, the results of Feldmann et al. [1990] show a speedup of 11.8 with 16 processors (far exceeding the performance of earlier systems), and Felten and Otto [1988] measured a 101 speedup on a 256-processor hypercube. This latter achievement is noteworthy because it shows an effective way to exploit the 256 times bigger memory that was not available to the uniprocessor. Use of the extra transposition table memory to hold results of search by other processors provides a significant benefit to the hypercube system, thus identifying clearly one advantage of systems with an extensible address space.

These results show a wide variation not only of methods but also of apparent performance. Part of the improvement is accounted for by the change from a static assignment of processors to the tree search (e.g., from PVSplit) to the dynamic processor reallocation schemes of Hyatt et al. [1989] and Schaeffer

[1989]. These later systems try to identify dynamically the ALL nodes of [Figure 63.10](#) and search them in parallel, leaving the CUT nodes (where only a few successors might be examined) for serial expansion. In a similar vein, Ferguson and Korf [1988] proposed a bound-and-branch method that only assigned processors to the leftmost child of the tree-splitting nodes where no bound (subtree value) exists. Their method is equivalent to the static PVSplit algorithm and realizes a speedup of 12 with 32 processors for alpha-beta trees generated by Othello programs. This speedup result might be attributed to the smaller average branching factor of about 10 for Othello trees, compared to an average branching factor of about 35 for chess. If that uniprocessor solution is inefficient — for example, by omitting an important node-ordering mechanism like transposition tables [Reinefeld and Marsland, 1994] — the speedup figure may look good. For that reason, comparisons with a standard test suite from a widely accepted game are often done and should be encouraged.

Most of the working experience with parallel methods for two-person games has centered on the alpha-beta algorithm. Parallel methods for more node count-efficient sequential methods, like SSS*, have not been successful until recently, when the potential advantages of using heuristic methods like hash tables to replace the open list were exploited [Plaat et al., 1995].

63.5.2.3 Dynamic Distribution of Work

The key to successful large-scale parallelism lies in the dynamic distribution of work. There are four primary issues in dynamic search:

Search overhead — This measures the size of the tree searched by the parallel method with respect to the best sequential algorithm. As mentioned previously, in some cases superlinear speedup can occur when the parallel algorithm actually visits fewer nodes.

Synchronization overhead — Problems occur when processors are idle, waiting for results from other processors, thus reducing the effective use of the parallel computing power (processor utilization).

Load balancing — This reflects how evenly the work has been divided among available processors and similarly affects processor utilization.

Communication overhead — In a distributed memory system, this occurs when results must be communicated between processors via message passing.

Each of these issues must be considered in designing a dynamic parallel algorithm. The distribution of work to processors can either be accomplished in a work-driven fashion, whereby idle processors must acquire new work either from a blackboard or by requesting work from another processor.

The **young brothers wait concept** [Feldmann, 1993] is a work-driven scheme in which the parallelism is best described with the help of a definition: the search for a successor $N.j$ of a node N in a game tree must not be started until after the leftmost sibling $N.1$ of $N.j$ is completely evaluated. Thus, $N.j$ can be given to another processor if and only if it has not yet been started and the search of $N.1$ is complete. This is also the requirement for the PVSplit algorithm. So how do the two methods differ and what are the trade-offs?

There are two significant differences. The first is at startup and the second is in the potential for parallelism. PVSplit starts much more quickly, because all the processors traverse the first variation (first path from the root to the search horizon of the tree) and then split the work at the nodes on the path as the processors back up the tree to the root. Thus, all the processors are busy from the beginning. On the other hand, this method suffers from increasingly large synchronization delays as the processors work their way back to the root of the game tree [Marsland and Popowich, 1985]. Thus, good performance is possible only with relatively few processors, because the splitting is purely static. In the work of Feldmann et al. [1990], the startup time for this system is lengthy, because initially only one processor (or a small group of processors) is used to traverse the first path. When that is complete, the right siblings of the nodes on the path can be distributed for parallel search to the waiting processors. For example, in the case of 1000 such processors, possibly less than 1% would initially be busy. Gradually, the idle processors are brought in to help the busy ones, but this takes time. However — and here comes the big advantage — the system

is now much more dynamic in the way it distributes work, so it is less prone to serious synchronization loss. Further, although many of the nodes in the tree will be CUT nodes (which are a poor choice for parallelism because they generate high search overhead), others will be ALL nodes, where every successor must be examined, and they can simply be done in parallel. Usually CUT nodes generate a cut-off quite quickly, so by being cautious about how much work is initially given away once N.1 has been evaluated, one can keep excellent control of the search overhead, while getting full benefit from the dynamic work distribution that Feldmann's method provides.

On the other hand, **transposition table-driven scheduling** (TDS) for parallel single-agent and game-tree searches, proposed by Romein et al. [1999], is a data-driven technique that in many cases offers considerable improvements over work-driven scheduling on distributed memory architectures. TDS reduces the communication and memory overhead associated with the remote lookups of transposition tables partitioned among distributed memory resources. This permits lookup communication and search computation to be integrated. The use of the transposition tables in TDS, as in IDA*, prevents the repeated searching of previously expanded states.

TDS employs a distributed transposition table that works by assigning to each state a *home processor*, where the transposition entry for that state is stored. A signature associated with the state indicates the number of its home processor. When a given processor expands a new state, it evaluates its signature and sends it to its home processor without having to wait for a response, thus permitting the communication to be carried out asynchronously. In other words, the work is assigned to where the data on a particular state is stored, rather than having to look up a remote processor's table and wait for the results to be transmitted back. Alternatively, when a processor receives a node, it performs a lookup of its local transposition table to determine whether the node has been searched before. If not, the node is stored in the transposition table and added to the local work queue. Furthermore, since each transposition table entry includes a search bound, this prevents redundant processing of the same subtree by more than one processor. The resulting reduction in both communication and search overhead yields significant performance benefits. Speedups that surpass IDA* by a factor of more than 100 on 128 processors [Romein et al., 1999] have been reported in selected games.

Cook and Varnell [1998] report that TDS may be led into doing unnecessary work at the goal depth, however, and therefore they favor a hybrid combination of techniques that they term *adaptive parallel iterative deepening search*. They have implemented their ideas in the system called EUREKA, which employs machine learning to select the best technique for a given problem domain.

63.6 Recent Developments

Despite advances in parallel single-agent search, significant improvement in methods for game-tree search has remained elusive. Theoretical studies have often focused on showing that linear speedup is possible on worst-order game trees. While not wrong, they make only the trivial point that where exhaustive search is necessary and where pruning is impossible, even simple work distribution methods may yield excellent results. The true challenge, however, is to consider the case of average game trees, or even better, the strongly ordered model (where extensive pruning can occur), resulting in asymmetric trees with a significant work distribution problem and significant search overhead. The search overhead occurs when a processor examines nodes that would be pruned by the sequential algorithm but has not yet received the relevant results from another processor.

The intrinsic difficulty of searching game trees under pruning conditions has been widely recognized. Hence, considerable research has been focused on the goal of dynamically identifying when unnecessary search is being performed, thereby freeing processing resources for redeployment. For example, Feldmann et al. [1990] used the concept of making young brothers wait to reduce search overhead, and developed the *helpful master* scheme to eliminate the idle time of masters waiting for their slaves' results. On the other hand, young brothers wait can still lead to significant synchronization overhead.

Generalized depth-first searches are fundamental to many AI problems. In this vein, Kumar and Rao [1990] have fully examined a method that is well suited to doing the early iterations of single-agent IDA* search. The unexplored parts of the trees are marked and are dynamically assigned to any idle processor. In principle, this work distribution method (illustrated in Figure 63.13) could also be used for deterministic adversary game trees. Shoham and Toledo [2001] developed a parallel, randomized best-first minimax search (RBFM). RBFM expands randomly chosen terminal nodes, with higher probabilities assigned to nodes with better values. This method seems amenable to parallelism but also seems to suffer from speculative search overhead.

The advent of MTD(f) as the primary sequential search algorithm has greatly improved circumstances and seems likely to lead to significant advances in parallel game-tree search. The use of a minimal window, and hence a single bound for pruning the tree, can greatly reduce the search overhead. Local pruning is no longer sensitive to results obtained by different processors searching other parts of the game tree. Romein [2000] developed a parallel version of MTD(f) that achieved speedup over other parallel game tree algorithms. Since MTD(f) is iterative in nature, its use of transposition tables is especially critical to performance. Kishimoto and Schaeffer [2002] have developed an algorithm called TDSAB, which combines MTD(f) with the transposition table-driven scheduling of TDS to achieve significant performance gains in a number of selected games.

Many researchers feel that hardware advances will ultimately increase parallel processing power to the point where we will simply overwhelm the problem of game-tree search with brute force. They feel that this will make the need for continued improvement of parallel game tree algorithms less critical. Perhaps in time we will know whether massive parallelism solves all our game-tree search problems. However, the results of complexity theory should assure us that unless $P = NP$, improvements in search techniques and heuristics will remain both useful and desirable.

The advent of the World Wide Web in 1993 naturally led to interest in search techniques for the Internet, especially when intelligence can be applied. *Search engines* are computer programs that can automatically contact other network resources on the Internet, searching for specific information or key words, and report the results of their search. *Intelligent agents* are computer programs that help users to conduct routine tasks, search and retrieve information, support decision making, and act as domain experts. They do more than just search and match. There are intelligent agents for consumers that search and filter information. Intelligent agents have been developed for product and vendor finding, for negotiation, and for learning. They can help determine what to buy to satisfy a specific need by looking for specific product information and then critically evaluating the products. One example is Firefly, which uses a *collaborative filtering* process that can be described as word-of-mouth to build the profile. It asks a consumer to rate a number of products, then matches those ratings with the ratings of other consumers with similar tastes and recommends products that have not yet been rated by the consumer.

Intelligent agents for product and vendor finding can also find bargains. An example is Jango from NetBot/Excite. It originates requests from the user's site (rather than Jango's). Vendors have no way to determine whether the request is from a real customer or from the agent. Jango provides product reviews. Intelligent agents for consumers can act as negotiation agents, helping to determine the price and other terms of transactions. Kasbah, from MIT Lab, is for users who want to sell or buy a product. It assigns the task to an agent, which is then sent out to seek buyers or sellers proactively. Kasbah has multiple agents. Users create agents, which can exemplify three strategies: anxious, cool-headed, or frugal. Tete-@-Tete is an intelligent agent for considering a number of different parameters: price, warranty, delivery time, service contracts, return policy, loan options, and other value-added services. Upon request, it can even be argumentative.

Finally, there are learning agents capable of learning individuals' preferences and making suitable suggestions based on these preferences. Memory Agent from IBM and Learn Sesame from Open Sesame use learning theory for monitoring customers' interactions. The agent learns customers' interests, preferences, and behavior and delivers customized service accordingly [Deitel et al., 2001]. Expect many interesting developments in this arena, combining some of the theoretical findings we have presented with practical results.

Defining Terms

- A* algorithm:** A best-first procedure that uses an admissible heuristic estimating function to guide the search process to an optimal solution.
- Admissibility condition:** The necessity that the heuristic measure never overestimates the cost of the remaining search path, thus ensuring that an optimal solution will be found.
- Alpha-beta algorithm:** The conventional name for the bounds on a depth-first minimax procedure used to prune away redundant subtrees in two-person games.
- AND/OR tree:** A tree that enables the expression of the decomposition of a problem into subproblems; hence, alternate solutions to subproblems through the use of AND/OR node-labeling schemes can be found.
- Backtracking:** A component process of many search techniques whereby recovery from unfruitful paths is sought by backing up to a juncture where new paths can be explored.
- Best-first search:** A heuristic search technique that finds the most promising node to explore next by maintaining and exploring an ordered open node list.
- Bidirectional search:** A search algorithm that replaces a single search graph, which is likely to grow exponentially, with two smaller graphs — one starting from the initial state and one starting from the goal state.
- Blind search:** A characterization of all search techniques that are heuristically uninformed. Included among these would normally be state-space search, means–ends analysis, generate and test, depth-first search, and breadth-first search.
- Branch and bound algorithm:** A potentially optimal search technique that keeps track of all partial paths contending for further consideration, always extending the shortest path one level.
- Breadth-first search:** An uninformed search technique that proceeds level by level, visiting all the nodes at each level (closest to the root node) before proceeding to the next level.
- Data-driven parallelism:** A load-balancing scheme in which work is assigned to processors based on the characteristics of the data.
- Depth-first search:** A search technique that first visits each node as deeply and as far to the left as possible.
- Generate and test:** A search technique that proposes possible solutions and then tests them for their feasibility.
- Genetic algorithm:** A stochastic hill-climbing search in which a large population of states is maintained. New states are generated by mutation and crossover, which combines pairs of earlier states from the population.
- Heuristic search:** An informed method of searching a state space with the purpose of reducing its size and finding one or more suitable goal states.
- Iterative deepening:** A successive refinement technique that progressively searches a longer and longer tree until an acceptable solution path is found.
- Mandatory work first:** A static two-pass process that first traverses the minimal game tree and uses the provisional value found to improve the pruning during the second pass over the remaining tree.
- Means–ends analysis:** An AI technique that tries to reduce the “difference” between a current state and a goal state.
- MTD(f) algorithm:** A minimal window minimax search recognized as the most efficient alpha-beta variant.
- Parallel window aspiration search:** A method in which a multitude of processors search the same tree, each with different (non-overlapping) alpha-beta bounds.
- PVSplit (principal variation splitting):** A static parallel search method that takes all the processors down the first variation to some limiting depth, then splits the subtrees among the processors as they back up to the root of the tree.
- Simulated annealing:** A stochastic algorithm that returns optimal solutions when given an appropriate “cooling schedule.”
- SSS* algorithm:** A best-first search procedure for two-person games.

Transposition table-driven scheduling (TDS): A data-driven, load-balancing scheme for parallel search that assigns a state to a processor based on the characteristics or signature of the given state.

Work-driven parallelism: A load-balancing scheme in which idle processors explicitly request work from other processors.

Young brothers wait concept: A dynamic variation of PVSplit in which idle processors wait until the first path of leftmost subtree has been searched before giving work to an idle processor.

For Further Information

The most regularly and consistently cited source of information for this chapter is the *Journal of Artificial Intelligence*. There are numerous other journals including, for example, *AAAI Magazine*, *CACM*, *IEEE Expert*, *ICGA Journal*, and the *International Journal of Computer Human Studies*, which frequently publish articles related to this subject. Also prominent have been the volumes of the *Machine Intelligence Series*, edited by Donald Michie with various others. An excellent reference source is the three-volume *Handbook of Artificial Intelligence* by Barr and Feigenbaum [1981].

In addition, there are numerous national and international conferences on AI with published proceedings, headed by the International Joint Conference on AI (IJCAI). Classic books on AI methodology include Feigenbaum and Feldman's *Computers and Thought* [1963] and Nils Nilsson's *Problem-Solving Methods in Artificial Intelligence* [1971]. There are a number of popular and thorough textbooks on AI. Two relevant books on the subject of search are *Heuristics* [Pearl, 1984] and the more recent *Search Methods for Artificial Intelligence* [Bolc and Cytowski, 1992]. An AI texts that has considerable focus on search techniques is George Luger's *Artificial Intelligence* [2002]. Particularly current is Russell and Norvig's *Artificial Intelligence: A Modern Approach* [2003].

64.1 Introduction

Computers are fast becoming a ubiquitous part of our lives, and our appetite for information is ever increasing. As a result, many researchers have sought to develop convenient human–computer interfaces, so that ordinary people can effortlessly access, process, and manipulate vast amounts of information — any time and anywhere — for education, decision making, purchasing, or entertainment. A speech interface, in a user’s own language, is ideal because it is the most natural, flexible, efficient, and economical form of human communication.

After many years of research, spoken input to computers is just beginning to pass the threshold of practicality. The last decade has witnessed dramatic improvement in **speech recognition** (SR) technology, to the extent that high-performance algorithms and systems are becoming available. In some cases, the transition from laboratory demonstration to commercial deployment has already begun. Speech input capabilities are emerging that can provide functions such as voice dialing (e.g., “call home”), call routing (e.g., “I would like to make a collect call”), simple data entry (e.g., entering a credit card number), and preparation of structured documents (e.g., a radiology report).

64.1.1 Defining the Problem

Speech recognition is a very challenging problem in its own right, with a well-defined set of applications. However, many tasks that lend themselves to spoken input, making travel arrangements or selecting a movie, as illustrated in [Figure 64.1](#), are in fact exercises in interactive problem solving. The solution is

Book me a flight on American to Dallas tomorrow morning.

FIGURE 64.1 An illustration of the types of queries a user is likely to produce for interactive problem solving.

often built up incrementally, with both the user and the computer playing active roles in the conversation. Therefore, several language-based input and output technologies must be developed and integrated to reach this goal. Regarding the former, speech recognition must be combined with **natural language** (NL) processing so that the computer can understand spoken commands (often in the context of previous parts of the dialogue). On the output side, some of the information provided by the computer, and any of the computer's requests for clarification, must be converted to natural sentences, perhaps delivered verbally.

This chapter describes the technologies that are utilized by computers to achieve spoken language understanding. Spoken language understanding by machine has been the focus of much research over the past 10 years around the world. In contrast, spoken **language generation** has not received nearly as much attention, even though it is a critical component of a fully interactive, conversational system. The remainder of this chapter will focus mainly on the input side. Although such an imbalance in treatment may be viewed as being inappropriate, it is, unfortunately, an accurate reflection of the research landscape.

Spoken language communication is an active process that utilizes many different sources of knowledge, some of them deeply embedded in the linguistic competence of the talker and the listener. For example, the two phrase, "lettuce spray" and "let us pray" differ in subtle ways at the acoustic level. In the first phrase, the /s/ phonemes ending the first word and starting the second merge into a longer acoustic segment than the /s/ in "us." Furthermore, the /p/ in "spray" is *unaspirated*, because it is embedded in a consonant cluster with the preceding /s/ in the syllable onset, thus sounding more like a /b/. Other very similar word sequences are more problematic, because in some cases the acoustic realizations can be essentially identical. For the pair "meter on Main Street," and "meet her on Main Street," *syntactic* constraints would suggest that the first one is not a well-formed sentence. For the contrastive pair, "is the baby crying," and "is the bay bee crying," the acoustic differences would be very subtle, and both phrases are *syntactically* legitimate. However, the second one could be ruled out as implausible on the basis of *semantic* constraints. A popular example among speech researchers is the pair, "recognize speech," and "wreck a nice beach." These two are surprisingly similar acoustically, but it is hard to imagine a **discourse** context that would support both. In practice, acoustics, syntax, semantics, and discourse context should all be utilized to contribute to a goodness score for all competing hypotheses.

Higher level linguistic knowledge can play an important role in helping to constrain the permissible word sequences. Thus, for example, the phoneme sequence /w ε r i z i t/ is linguistically much more likely to be "where is it" than "wear is it," simply because the first one makes more sense. On the other hand, if used too aggressively, syntactic and semantic constraints can cause a system to fail even though enough of the content words have been recognized correctly to infer a plausible action to take. Problems arise not only because people often violate syntactic rules in conversational speech, but also because recognition errors can lead to pathological syntactic forms. For instance, if the recognizer's top choice hypothesis is

FIGURE 64.2 A generic block diagram for a typical spoken language system.

the nonsense phrase, “between four in five o’clock,” a parser may fail to recognize the intended meaning. Three alternative and contrastive strategies to cope with such problems have been developed. The first would be to analyze “between four” and “five o’clock” as separate units, and then infer the relationship between them after the fact through plausibility constraints. A second approach would be to permit “in” to substitute for “and” at selected places in the grammar rules, based on the assumption that these are confusable pairs acoustically. The final, and intuitively most appealing method, is to tightly integrate the natural language component into the recognizer search, so that “and” is so clearly preferred over “in” in the preceding situation that the latter is never chosen. Although this final approach seems most logical, it turns out that researchers have not yet solved the problem of computational overload that occurs when a **parser** is used to predict the next word hypotheses. A compromise that is currently popular is to allow the recognizer to propose a list of N ordered theories, and have the linguistic analysis examine each theory in turn, choosing the one that appears the most plausible.

64.1.2 System Architecture and Research Issues

Figure 64.2 shows the major components of a typical **conversational system**. The spoken input is first processed through the speech recognition component. The natural language component, working in concert with the recognizer, produces a meaning representation. For information retrieval applications illustrated in this figure, the meaning representation can be used to retrieve the appropriate information in the form of text, tables, and graphics. If the information in the utterance is insufficient or ambiguous, the system may choose to query the user for clarification. Natural language generation and **text-to-speech synthesis** can be used to produce spoken responses that may serve to clarify the tabular information. Throughout the process, discourse information is maintained and fed back to the speech recognition and language understanding components, so that sentences can be properly understood in context.

The development of conversational systems offers a set of significant challenges to speech and natural language researchers, and raises several important research issues. First, the system must begin to deal with conversational, extemporaneously produced speech. Spontaneous speech is often extremely difficult to recognize and understand, since it may contain false starts, hesitations, and words and linguistic constructs unknown to the system.

Second, the system must have an effective strategy for coupling speech recognition with language understanding. Speech recognition systems typically implement linguistic constraints as a statistical grammar that specifies the probability of a word given its predecessors. Although these simple language models have been effective in reducing the search space and improving performance, they do not begin to address the issue of speech understanding. On the other hand, most natural language systems are developed with text input in mind; it is usually assumed that the entire word string is known with certainty. This assumption is clearly false for speech input, where many words are competing for the same time span, and some words may be more reliable than others because of varying signal robustness. Researchers in each discipline need

to investigate how to exchange and utilize information so as to maximize overall system performance. In some cases, one may have to make fundamental changes in the way systems are designed.

Similarly, the natural language generation and text-to-speech components on the output side of conversational systems should also be closely coupled in order to produce natural-sounding spoken language. For example, current systems typically expect the language generation component to produce a textual surface form of a sentence (throwing away valuable linguistic and prosodic knowledge) and then require the text-to-speech component to produce linguistic analysis anew. Clearly, these two components would benefit from a shared knowledge base. Furthermore, language generation and dialogue modeling should be intimately coupled, especially for applications over the phone and without displays. For example, if there is too much information in the table to be delivered verbally to the user, a clarification subdialogue may be necessary to help the system narrow down the choices before enumerating a subset.

64.2 Underlying Principles

64.2.1 Procedure for System Development

Figure 64.3 illustrates the typical procedure for system development. For a newly emerging domain or language, an initial system is developed with some limited natural language capabilities, based on the inherent knowledge and intuitions of system developers. Once the system has some primitive capabilities, a **wizard** mode data collection episode can be initiated, in which a human wizard helps the system answer questions posed by naive subjects. The resulting data (both speech and text) are then used for further development and training of both the speech recognizer and the natural language component. As these components begin to mature, it becomes feasible to give the system increasing responsibility in later data collection episodes. Eventually, the system can stand alone without the aid of a wizard, leading to less costly and more efficient data collection possibilities. As the system evolves, its changing behaviors have a profound influence on the subjects' speech, so that at times there is a *moving target* phenomenon. Typically, some of the collected data are set aside for performance evaluation, in order to test how well the system can handle previously unseen material. The remainder of this section provides some background

FIGURE 64.3 An illustration of the spoken language system development cycle.

information on speech recognition and language understanding components, as well as the data collection and performance evaluation procedures.

64.2.2 Data Collection

Development of spoken language systems is driven by the availability of representative training data, capturing how potential users of a system would want to talk to it. For this reason, data collection and evaluation have been important areas of research focus. Data collection enables application development and training of the recognizer and language understanding systems; evaluation techniques make it possible to compare different approaches and to measure progress. It is difficult to devise a way to collect realistic data reflecting how a user would use a spoken language system when there is no such system; indeed, the data are needed in order to *build* the system.

Most researchers in the field have now adopted an approach to data collection which uses a system in the loop to facilitate data collection and provide realistic data. At first, some limited natural language understanding capabilities are developed for the particular application. In early stages, the data are collected in a simulation mode, where the speech recognition component is replaced by an expert typist. An experimenter in a separate room types in the utterances spoken by the subject, typically after removing false starts and hesitations. The natural language component then translates the typed input into a query to the database, returning a display to the user, perhaps along with a verbal response clarifying what is being shown. In this way, data collection and system development are combined into a single tightly coupled cycle. Since only a transcriber is needed, not an expert wizard, this approach is quite cost effective, allowing data collection to begin quite early in the application development process, and permitting realistic data to be collected (see Figure 64.4.). As system development progresses, the simulated portions of the system can be replaced with their real counterparts, ultimately resulting in stand-alone data collection, yielding data that accurately reflect the way system would be used in practice.

Since the subjects brought in for data collection are not true users with clear goals, it is critical to provide a mechanism to help them focus their dialogue with the computer. A popular approach is to devise a set of short scenarios for them to solve. These are necessarily artificial, and the exact wording of the sentences in the scenarios often has a profound influence on the subjects' choices of linguistic constructs. An alternative is to allow the subjects complete freedom to design their own scenarios. This is perhaps somewhat more realistic, but subjects may wander from topic to topic because of a lack of a clearly defined problem.

As the system's dialogue model evolves, data previously collected can become somewhat obsolete, since the users' utterances are markedly influenced by the computer feedback. Hence it is problematic to achieve advances in the dialogue model without suffering from temporary inadequacies in recognition, until the system can bootstrap from new releases of training material.

FIGURE 64.4 A person-behind-the-curtain, or wizard, paradigm for data collection.

64.2.3 Speech Recognition

The past decade has witnessed unprecedented progress in speech recognition technology. Word error rates continue to drop by a factor of 2 every two years while barriers to speaker independence, continuous speech, and large vocabularies have all but fallen. There are several factors that have contributed to this rapid progress. First, there is the coming of age of the stochastic modeling techniques known as **hidden Markov modeling (HMM)**. HMM is a doubly stochastic model, in which the generation of the underlying phoneme string and its surface acoustic realizations are *both* represented probabilistically as Markov processes [Rabiner 1986]. HMM is powerful in that, with the availability of training data, the parameters of the model can be trained automatically to give optimal performance. The systems typically operate with the support of an ***n*-gram (statistical) language model** and adopt either a **Viterbi** (time-synchronous) or an **A* (best fit) search** strategy. Although the application of HMM to speech recognition began nearly 20 years ago [Jelinek et al. 1974], it was not until the past few years that it has gained wide acceptance in the research community.

Second, much effort has gone into the development of large speech corpora for system development, training, and testing [Zue et al. 1990, Hirschman et al. 1992]. Some of these corpora are designed for acoustic phonetic research, whereas others are highly task specific. Nowadays, it is not uncommon to have tens of thousands of sentences available for system training and testing. These corpora permit researchers to quantify the acoustic cues important for phonetic contrasts and to determine parameters of the recognizers in a statistically meaningful way.

Third, progress has been brought about by the establishment of standards for performance evaluation. Only a decade ago, researchers trained and tested their systems using locally collected data and had not been very careful in delineating training and testing sets. As a result, it was very difficult to compare performance across systems, and the system's performance typically degraded when it was presented with previously unseen data. The recent availability of a large body of data in the public domain, coupled with the specification of evaluation standards [Pallett et al. 1994], has resulted in uniform documentation of test results, thus contributing to greater reliability in monitoring progress.

Finally, advances in computer technology have also indirectly influenced our progress. The availability of fast computers with inexpensive mass storage capabilities has enabled researchers to run many large-scale experiments in a short amount of time. This means that the elapsed time between an idea and its implementation and evaluation is greatly reduced. In fact, speech recognition systems with reasonable performance can now run in real time using high-end workstations without additional hardware — a feat unimaginable only a few years ago. However, recognition results reported in the literature are usually based on more sophisticated systems that are too computationally intensive to be practical in live interaction. An important research area is to develop more efficient computational methods that can maintain high-recognition accuracy without sacrificing speed.

Historically, speech recognition systems have been developed with the assumption that the speech material is read from prepared text. Spoken language systems offer new challenges to speech recognition technology in that the speech is extemporaneously generated, often containing **disfluencies** (i.e., unfilled and filled pauses such as “umm” and “aah,” as well as word fragments) and words outside the system's working vocabulary. Thus far, some attempts have been made to deal with these problems, although this is a research area that deserves greater attention. For example, researchers have improved their system's recognition performance by introducing explicit acoustic models for the filled pauses [Ward 1990, Butzberger et al. 1992]. Similarly, *trash* models have been introduced to detect the presence of unknown words, and procedures have been devised to learn the new words once they have been detected [Asadi et al. 1991].

Most recently, researchers are beginning to seriously address the issue of recognition of telephone quality speech. It is highly likely that the first several spoken language systems to become available to the general public will be accessible via telephone, in many cases replacing presently existing touch-tone menu driven systems. Telephone-quality speech is significantly more difficult to recognize than high-quality recordings, both because the band-width has been limited to under 3.3 kHz and because noise and distortions are

introduced in the line. Furthermore, the background environment could include disruptive sounds such as other people talking or babies crying.

64.2.4 Language Understanding

Natural language analysis has traditionally been predominantly syntax driven — a complete syntactic analysis is performed which attempts to account for *all* words in an utterance. However, when working with spoken material, researchers quickly came to realize that such an approach [Bobrow et al. 1990, Seneff 1992b], although providing some linguistic constraints to the speech recognition component and a useful structure for further linguistic analysis, can break down dramatically in the presence of unknown words, novel linguistic constructs, recognition errors, and spontaneous speech events such as false starts. Spoken language tends to be quite informal; people are perfectly capable of speaking, and willing to accept, sentences that are ungrammatical.

Due to these problems, many researchers have tended to favor more semantic-driven approaches, at least for spoken language tasks in limited domains. In such approaches, a meaning representation or **semantic frame** is derived by *spotting* key words and phrases in the utterance [Ward 1990]. Although this approach loses the constraint provided by syntax, and may not be able to adequately interpret complex linguistic constructs, the need to accommodate spontaneous speech input has outweighed these potential shortcomings. At the present time, almost all viable systems have abandoned their original goal of achieving a complete syntactic analysis of every input sentence, favoring a more robust strategy that can still answer when a full parse is not achieved [Jackson et al. 1991, Seneff 1992a, Stallard and Bobrow 1992]. This can be achieved by identifying parsable phrases and clauses, and providing a separate mechanism for gluing them together to form a complete meaning analysis [Seneff 1992a]. Ideally, the parser includes a probabilistic framework with a smooth transition to parsing fragments when full linguistic analysis is not achievable. Examples of systems that incorporate such *stochastic* modeling techniques can be found in Pieraccini et al. [1992] and Miller et al. [1994].

64.2.5 Speech Recognition/Natural Language Integration

One of the critical research issues in the development of spoken language systems is the mechanism by which the speech recognition component interacts with the natural language component in order to obtain the correct meaning representation. At present, the most popular strategy is the so-called ***N*-best interface** [Soong and Huang 1990], in which the recognizer can propose its best *N* complete sentence hypotheses* one by one, stopping with the first sentence that is successfully analyzed by the natural language component. In this case, the natural language component acts as a filter on *whole sentence* hypotheses. However, it is still necessary to provide the recognizer with an inexpensive language model that can partially constrain the theories. Usually, a statistical language model such as a bigram is used, in which every word in the lexicon is assigned a probability reflecting its likelihood in following a given word.

In the *N*-best interface, a natural language component filters hypotheses that span the entire utterance. Frequently, many of the candidate sentences differ minimally in regions where the acoustic information is not very robust. Although confusions such as “an” and “and” are acoustically reasonable, one of them can often be eliminated on linguistic grounds. In fact, many of the top *N* sentence hypotheses could have been eliminated before reaching the end if syntactic and semantic analyses had taken place early on in the search. One possible control strategy, therefore, is for the speech recognition and natural language components to be tightly coupled, so that only the acoustically promising hypotheses that are linguistically meaningful are advanced. For example, partial theories are arranged on a stack, prioritized by score. The most promising partial theories are extended using the natural language component as a predictor of all possible next-word candidates; any other word hypotheses are not allowed to proceed. Therefore, any theory that completes

* *N* is a parameter of the system that can be set arbitrarily as a compromise between accuracy and computation.

is guaranteed to parse. Researchers are beginning to find that such a tightly coupled integration strategy can achieve higher performance than an *N*-best interface, often with a considerably smaller stack size [Goodine et al. 1991, Goddeau 1992, Moore et al. 1995]. The future is likely to see increasing instances of systems making use of linguistic analysis at early stages in the recognition process.

64.2.6 Discourse and Dialogue

Human verbal communication is a two-way process involving multiple, active participants. Mutual understanding is through direct and indirect speech acts, turn taking, clarification, and pragmatic considerations. An effective spoken language interface for information retrieval and interactive transactions must incorporate extensive and complex **dialogue modeling**: initiating appropriate clarification subdialogues based on partial understanding, and taking an active role in directing the conversation toward a valid conclusion. Although there has been some theoretical work on the structure of human–human dialogue [Grosz and Sidner 1990], this has not yet led to effective insights for building human–machine interactive systems.

Systems can maintain an active or a passive role in the dialogue, and each of these extremes has advantages and disadvantages. An extreme case is a system which asks a series of prescribed questions, and requires the user to answer each question in turn before moving on. This is analogous to the interactive voice response systems that are now available via the touch-tone telephone, and users are usually annoyed by their inflexibility. At the opposite extreme is a system that never asks any questions or gives any unsolicited advice. In such cases the user may feel uncertain as to what capabilities exist, and may, as a consequence, wander quite far from the domain of competence of the system, leading to great frustration because nothing is understood. Researchers are still experimenting with setting an important balance between these two extremes in managing the dialogue.

It is absolutely essential that a system be able to interpret a user's queries in context. For instance, if the user says, "I want to go from Boston to Denver," followed with, "show me only United flights," they clearly do not want to see *all* United flights, but rather just the ones that fly from Boston to Denver. The ability to inherit information from preceding sentences is particularly helpful in the face of recognition errors. The user may have asked a complex question involving several restrictions, and the recognizer may have misunderstood a single word, such as a flight number or an arrival time. If a good context model exists, the user can now utter a very short correction phrase, and the system will insert the correction for the misunderstood word correctly, preventing the user from having to reutter the entire sentence, running the risk of further recognition errors.

At this point, it is probably educational to give an example of a real dialogue between a spoken language system and a human. For this purpose, we have selected the Pegasus system, a system developed at Massachusetts Institute of Technology (MIT), which is capable of helping a user make flight plans [Zue et al. 1994]. Pegasus connects, via a modem over the telephone line, to the Easys Sabre flight database, offered by American Airlines. As a consequence, users can make explicit flight reservations on real flights using Pegasus. [Figure 64.5](#) and [figure 64.6](#) contain an example of the log of an actual round-trip booking to illustrate the system's capability. This dialogue shows examples where the system asks directed questions, cases where a great deal of context information is carried over from one query to the next, "please wait" requests where the system is warning the user of possible delays, and instances where the system provides additional information that was not explicitly requested, such as the ticket summary.

64.2.7 Evaluation

Over the past few years, the speech recognition and natural language communities have placed strong emphasis on performance evaluation. With the use of common corpora and metrics, the relative merits of different approaches and systems can be assessed, using both subjective and objective measures.

Spoken language systems can be evaluated along several dimensions. First, the *accuracy* of the system and its various modules can be documented. Thus, for example, a given system's phonetic, word, and sentence accuracy can be measured, as well as linguistic and task completion accuracy. Second, the *coverage*

USER: I WANT TO GO FROM BOSTON TO SAN FRANCISCO

FIGURE 64.5 An example of an actual verbal booking dialogue using Pegasus. Due to space limitations, irrelevant parts of the system's responses have been omitted.

and *habitability* of the system can be evaluated. Coverage can be measured with respect to the lexicon, the language model, and the application back-end. Third, the system's *flexibility* can be established. For example, how easy is it to add new knowledge to the system? How easy is it for a naive user to learn how to communicate with the system? How difficult is it for researchers, and, more especially, for nonexperts, to port the system to a different application or language? Finally, the *efficiency* of the system can be assessed. One such measure may be the task completion time.

Whether one wants to evaluate the accuracy of a spoken language system in part or as a whole, one must first establish what the *reference* should be. For example, determining word accuracy for speech recognizers requires that the reference string of words first be transcribed. Similarly, assessing the appropriateness of a syntactic parse presupposes that we know what the correct parse is. In some cases, establishing the reference is relatively straightforward and can be done almost objectively. In other cases, such as specifying the correct system response, the process can be highly subjective. For example, should the correct answer to the query, "Do you know of any Chinese restaurants?" be simply, "Yes," or a list of the restaurants that the system knows?

USER: THE CHEAPEST ONE
PEGASUS: I'll book United flight 93 from Boston to San Francisco on Wednesday October twentieth for you. Your reservation has been entered. Now I'll help you with the return flight. What date will you be returning on?

FIGURE 64.6 Continuation of the example shown in Figure 64.5.

The outputs of the system modules naturally become more general at the higher levels of the system, since these outputs represent more abstract information. Unfortunately, this makes an automatic comparison with a reference output more difficult, both because the *correct* response may become more ambiguous and because the output representation must become more flexible. The added flexibility that is necessary to express more general concepts also allows a given concept to be expressed in many ways, making the comparison with a reference more difficult.

Objective evaluation of spoken language systems comes with large overhead costs, particularly if it is applied on a common evaluation dataset across a wide community. Researchers must first agree on formal definitions of the *correct* answers, which becomes particularly problematic when discourse context may lead to ambiguities. If a pool of systems are to be evaluated on a common set of dialogues, then the systems used to collect the dialogues must be extremely passive, since users' responses to system queries may not be interpretable in the absence of knowledge about the collection system's half of the conversation. Yet, if systems are not evaluated on common data, it becomes impossible to make objective comparisons of their performance.

A possible alternative is to utilize more subjective evaluations, where an evaluator examines a prior dialogue between a subject and a computer, and decides whether each exchange in the dialogue was effective. A small set of categories, such as correct, incorrect, partially correct, and out of domain, can be used to tabulate statistics on the performance. If the scenario comes with a single unique correct answer, then it is also straightforward to measure how many times users solved their problem successfully, as well as how long it took them to do so. The time is rapidly approaching when real systems will be accessible to the general public via the telephone line, and so the ultimate evaluation will be successful active use of such systems in the real world.

64.3 Best Practices

Spoken language systems are a relatively new technology, having first come into existence in the late 1980s. Prior to that time, computer processing and memory limitations precluded the possibility of real-time speech recognition making it difficult for researchers to conceive of interactive human computer dialogues. All of the systems focus within a narrowly defined area of expertise, and vocabulary sizes are generally limited to under 3000 words. Nowadays, these systems can typically run in real time on standard workstations with no additional hardware.

During the late 1980s, two major government-funded efforts involving multiple sites on two continents provided the momentum to thrust spoken language systems into a highly visible and exciting success story, at least within the computer speech research community. The two programs were the Esprit speech understanding and dialog (SUNDIAL) program in Europe [Peckham 1992] and the Advanced Research Projects Agency (ARPA) spoken language understanding program in the U.S. These two programs were remarkably parallel in that both involved database access for travel planning, with the European one including both flight and train schedules, and the American one being restricted to air travel. The European program was a multilingual effort involving four languages (English, French, German, and Italian), whereas the American effort was, understandably, restricted to English.

64.3.1 The Advanced Research Projects Agency Spoken Language System (SLS) Project

64.3.1.1 The Air Travel Information Service (ATIS) Common Task

The spoken language systems (SLS) program sponsored by ARPA of the Department of Defense in the U.S. has provided major impetus for spoken language system development. In particular, the program adopted the approach of developing the underlying technologies within a common domain called Air Travel Information Service (ATIS) [Price 1990]. ATIS permits users to verbally query for air travel information, such as flight schedules from one city to another, obtained from a small **relational database** excised from the Official Airline Guide. By requiring that all system developers use the same database, it has been possible to compare the performance of various spoken language systems based on their ability to extract the correct information from the database, using a set of prescribed training and test data, and a set of interpretation guidelines. Indeed, periodic common evaluations have occurred at regular intervals, and steady performance improvements have been observed for all systems. [Figure 64.7](#) shows the error rates for the best ATIS systems, measured in several dimensions over the past four years. Many of the systems currently run in real time on high-end workstations with no additional hardware, although with some performance degradation.

As shown in [Figure 64.7](#), the speech recognition performance has improved steadily over the past four years. Word error rate (WE) decreased by more than eightfold, while sentence error rate (SE) decreased more than fourfold in this period. In both cases, the reduction in error rate for spontaneous speech has followed the trend set forth for read speech, namely, halving the error every two years. In the most recent formal evaluation of the ARPA-SLS program in the ATIS domain, the best system achieved a word error rate of 2.3% and a sentence error rate of 15.2% [Pallett et al. 1994]. The vocabulary size was more than 2500 words, and the bigram and trigram language models had a **perplexity** of about 20 and 14, respectively.

TABLE 64.1 Examples Illustrating Particularly Difficult Sentences Within the ATIS Domain That Systems Are Capable of Handling

GIVE ME A FLIGHT FROM MEMPHIS TO LAS VEGAS AND NEW YORK CITY TO LAS VEGAS ON SUNDAY THAT ARRIVE AT THE SAME TIME

I WOULD LIKE A LIST OF THE ROUND TRIP FLIGHTS BETWEEN INDIANAPOLIS AND ORLANDO ON THE TWENTY SEVENTH OR THE TWENTY EIGHTH OF DECEMBER

I WANT A ROUND TRIP TICKET FROM PHOENIX TO SALT LAKE CITY AND BACK. I WOULD LIKE THE FLIGHT FROM PHOENIX TO SALT LAKE CITY TO BE THE EARLIEST FLIGHT IN THE MORNING AND THE FLIGHT FROM SALT LAKE CITY TO PHOENIX TO BE THE LATEST FLIGHT IN THE AFTERNOON.

FIGURE 64.7 Best performance achieved by systems in the ATIS domain over the past four years. See text for a detailed description.

Note that all of the performance results quoted in this section are for the so-called *evaluable* queries, i.e., those queries that are within the ATIS domain and for which an appropriate answer is available from the database.

The ARPA-SLS community has carefully defined a common answer specification (CAS) evaluation protocol, whereby a system's performance is determined by comparing its output, expressed as a set of database tuples, with one or more predetermined reference answers [Bates et al. 1991]. The CAS protocol has the advantage that system evaluation can be carried out automatically, once the principles for generating the reference answers have been established and a corpus has been annotated accordingly. Since direct comparison across systems can be performed relatively easily with this procedure, the community has been able to achieve cross fertilization of research ideas, leading to rapid research progress. Figure 64.7 shows that language understanding error rate (NL) has declined by more than threefold in the past four years.* This error rate is measured by passing the transcription of the spoken input, after removing partial words, through the natural language component. In the most recent formal evaluation in the ATIS domain, the best natural language system achieved an understanding error rate of only 5.9% on all the evaluable sentences in the test set [Pallett et al. 1994]. Table 64.1 contains several examples of relatively complex sentences that some of the NL systems being evaluated are able to handle.

The performance of the entire spoken language system can be assessed using the same CAS protocol for the natural language component, except with speech rather than text as input. Figure 64.7 shows that this speech understanding error rate (SLS) has fallen from 42.6% to 8.9% over the four-year interval.

*The error rate for both text (NL) and speech (SLS) input increased somewhat in the 1993 evaluation. This was largely due to the fact that the database was increased from 11 cities to 46 that year, and some of the travel-planning scenarios used to collect the newer data were considerably more difficult.

It is interesting to note that this error rate is considerably less than the sentence recognition error rate, suggesting that a large number of sentences can be understood even though the transcription may contain errors.

64.3.1.2 Other Advanced Research Projects Agency Projects

The major ARPA sites are Carnegie Mellon University (CMU), MIT, SRI International, and Bolt, Beranek, and Newman (BBN) Systems and Technology. Most of these sites have developed other interesting spoken language systems besides the ATIS task. These systems are at varying stages of completion, and it is fair to say that none of them are as yet sufficiently robust to be deployable. However, each one has revealed interesting new research areas where gaps remain in our understanding of how to build truly practical spoken language systems. Active ongoing research in these domains should provide interesting new developments in the future.

Probably the most impressive early system was the MIT Voyager system, first assembled for English dialogues in 1989 [Zue et al. 1989]. Voyager can engage in verbal dialogues with users about a restricted geographical region within Cambridge, Massachusetts, in the U.S. The system can provide information about distances, travel times, or directions between landmarks located within this area (e.g., restaurants, hotels, banks, libraries, etc.) as well as handling specific requests for information such as address, phone number, or location on the map. Voyager has remained under active development since 1989, particularly in the dimension of multilingual capabilities. Voyager can now help a user solve ground travel planning problems in three languages: English, Japanese, and Italian [Glass et al. 1995]. The process of porting to new languages has motivated researchers to redesign the system so that language-dependent aspects can be contained in external tables and rules.

The CMU office manager system is designed to provide users with voice access to a set of application programs such as a calendar, an on-line Rolodex, a voice mail system, and a calculator for the office of the future [Rudnicky et al. 1991]. For speech recognition the office manager relies on a version of the Sphinx system [Lee 1989]. Language understanding support is provided either by a finite-state language model or a frame-based representation that extracts the meaning of an utterance by spotting key words and phrases [Ward 1990].

In early 1991, researchers at BBN demonstrated a spoken language interface [Bates et al. 1991] to the dynamic analysis and replanning tool (DART), which is a system for military logistical transportation planning. A spoken language interface to DART has the potential advantage of reducing task completion time by allowing the user to access information more efficiently and naturally than would be possible with the keyboard and mouse buttons. Their spoken language system demonstration centers around the task of database query and information retrieval by combining the BYBLOS speech recognition system [Chow et al. 1987] and the Delphi natural language system [Bates et al. 1990] for speech understanding.

An interesting realistic system, which grew out of the ARPA ATIS effort, is the previously mentioned Pegasus system, which is an extension of an existing ATIS system. The distinguishing feature of Pegasus is that it connects via a modem over the phone line to a real flight reservation system. The system has knowledge of flights to and from some 220 cities worldwide. Pegasus has a fairly extensive dialogue model to help it cope with difficult problems such as date restrictions imposed by discount fares or aborted flight plans due to selections being sold out. A *displayless* version of Pegasus is under development, which will ultimately enable users to make flight reservations by speaking with a computer over the telephone [Seneff et al. 1992].

In 1994, researchers at MIT started the development of Galaxy [Goddeau et al. 1994], a system that enables universal information access using spoken dialogue. Galaxy differs from current spoken language systems in a number of ways. First, it is distributed and decentralized: Galaxy uses a client-server architecture to allow sharing of computationally expensive processes (such as large vocabulary speech recognition), as well as knowledge intensive processes. Second, it is multidomain, intended to provide access to a wide variety of information sources and services while insulating the user from the details of database location and format. It is presently connected to many real, on-line databases, including the National Weather Services, the NYNEX Electronic Yellow Pages, and the World Wide Web. Users can query Galaxy in natural

English (e.g., “what is the weather forecast for Miami tomorrow,” “how many hotels are there in Boston,” and “do you have any information on Switzerland,” etc.), and receive verbal and visual responses. Finally, it is extensible; new knowledge domain servers can be added to the system incrementally.

64.3.2 The SUNDIAL Program

Whereas the ARPA ATIS program in the U.S. emphasized competition through periodic common evaluations, the European SUNDIAL program [Peckham 1992] promoted cooperation and plug compatibility by requiring different sites to contribute distinct components to a single multisite system. Another significant difference was that the European program made dialogue modeling an integral and important part of the research program, whereas the American program was focused more strictly on speech understanding, minimizing the effort devoted to usability considerations. The common evaluations carried out in America led to an important breakthrough in forcing researchers to devise robust **parsing** techniques that could make some sense out of even the most garbled spoken input. At the same time, the emphasis on dialogue in Europe led to some interesting advances in dialogue control mechanisms.

Although the SUNDIAL program formally terminated in 1993, some of the systems it spawned have continued to flourish under other funding resources. Most notable is the Philips Automatic Train Timetable Information System, which is probably the foremost real system in existence today [Eckert et al. 1993]. This system operates in a displayless mode and thus is capable of communicating with the user solely by voice. As a consequence, it is accessible from any household in Germany via the telephone line. The system is presently under field trial, and has been actively promoted through German press releases in order to encourage people to try it. Data are continuously collected from the callers, and can then be used directly to improve system performance. The system runs on a UNIX workstation, and has a vocabulary of 1800 words, 1200 of which are distinct railway station names. The dialogue relies heavily on confirmation requests to permit correction of recognition errors, but the overall success rate for usage is remarkably high.

64.3.3 Other Systems

There are a few other spoken language systems that fall outside of the ARPA ATIS and Esprit SUNDIAL efforts. A notable system is the Berkeley restaurant project (BeRP) [Jurafsky et al. 1994], which acts as a restaurant guide in the Berkeley area. This system is currently distinguished by its neural networks-based recognizer and its probabilistic natural language system. Another novel emergent system is the Waxholm system, being developed by researchers at KTH in Sweden [Blomberg et al. 1993]. Waxholm provides timetables for ferries in the Stockholm archipelago as well as port locations, hotels, camping sites, and restaurants that can be found on the islands. The Waxholm developers are designing a flexible, easily controlled dialogue module based on a scripting language that describes dialogue flow.

64.4 Research Issues and Summary

As we can see, significant progress has been made over the past few years in research and development of systems that can understand spoken language. To meet the challenges of developing a language-based interface to help users solve real problems, however, we must continue to improve the core technologies while expanding the scope of the underlying Human Language Technology (HLT) base. In this section, we outline some of the new research challenges that have heretofore received little attention.

64.4.1 Working in Real Domains

The rapid technological progress that we are witnessing raises several timely questions. When will this technology be available for productive use? What technological barriers still exist that will prevent large-scale HLT deployment? An effective strategy for answering these questions is to develop the underlying

technologies within *real* applications, rather than relying on mockups, however realistic they might be, since this will force us to confront some of the critical technical issues that may otherwise elude our attention. Consider, for example, the task of accessing information in the Yellow Pages of a medium-sized metropolitan area such as Boston, a task that can be viewed as a logical extension of the Voyager system developed at MIT. The vocabulary size of such a task could easily exceed 100,000, considering the names of the establishments, street and city names, and listing headings. A task involving such a huge vocabulary presents a set of new technical challenges. Among them are:

- How can adequate acoustic and language models be determined when there is little hope of obtaining a sufficient amount of domain-specific data for training?
- What search strategy would be appropriate for very large vocabulary tasks? How can natural language constraints be utilized to reduce the search space while providing adequate coverage?
- How can the application be adapted and/or customized to the specific needs of a given user?
- How can the system be efficiently ported to a different task in the same domain (e.g., changing the geographical area from Boston to Washington D.C.), or to an entirely different domain (e.g., library information access)?

There are many other research issues that will surface when one is confronted with the need to make human language technology truly useful for solving real problems, some of which will be described in the remainder of this section. Aside from providing the technological impetus, however, working within real domains also has some practical benefits. While years may pass before we can develop unconstrained spoken language systems, we are fast approaching a time when systems with limited capabilities can help users interact with computers with greater ease and efficiency. Working on real applications thus has the potential benefit of shortening the interval between technology demonstration and its ultimate use. Besides, applications that can help people solve problems *will* be used by real users, thus providing us with a rich and continuing source of useful data.

64.4.2 The New Word Problem

Yet another important issue concerns unknown words. The traditional approach to spoken language recognition and understanding research and development is to define the working vocabulary based on domain-specific corpora [Hetherington and Zue 1991]. However, experience has shown that, no matter how large the size of the training corpora, the system will invariably encounter previously unseen words. This is illustrated in [Figure 64.8](#). For the ATIS task, for example, a 100,000-word training corpus will yield a vocabulary of about 1,000 words. However, the probability of the system encountering an unknown word, is about 0.002. Assuming that an average sentence contains 10 words, this would mean that approximately 1 in 50 sentences will contain an unknown word.

In a *real* domain such as Electronic Yellow Pages, a much larger fraction of the words uttered by users will not be in the system's working vocabulary. This is unavoidable partly because it is not possible to anticipate all of the words that all users are likely to use, and partly because the database is usually changing with time (e.g., new restaurants opening up). In the past, we have not paid much attention to the unknown word problem because the tasks we have chosen assume a closed vocabulary. In the limited cases where the vocabulary has been open, unknown words have accounted for a small fraction of the word tokens in the test corpus. Thus researchers could either construct generic *trash word* models and hope for the best, or ignore the unknown word problem altogether and accept a small penalty on word error rate. In real applications, however, the system must be able to cope with unknown words simply because they will always be present, and ignoring them will not satisfy the user's needs; if a person wants to know how to go from MIT to Lucia's restaurant, they will not settle for a response such as, "I am sorry I don't understand you. Please rephrase the question." The system must be able not only to *detect* new words, taking into account acoustic, phonological, and linguistic evidence, but also to adaptively *acquire* them, both in terms of their orthography and linguistic properties. In some cases, fundamental changes in the problem formulation and search strategy may be necessary.

(a)

(b)

FIGURE 64.8 (a) The number of unique words (i.e., task vocabulary) as a function of the size of the training corpora, for several spoken language tasks and (b) the percentage of unknown words in previously unseen data as a function of the size of the training corpora used to determine the vocabulary empirically. The sources of the data are: F-ATIS = French ATIS, I-VOYAGER = Italian Voyager, BREF = French *La Monde*, NYT = *New York Times*, WSJ = *Wall Street Journal*, and CITRON = Directory Assistance.

64.4.3 Spoken Language Generation

With few exceptions [Zue et al. 1989, 1994], current research in spoken language systems has focused on the input side, i.e., the understanding of the input queries, rather than the *conveyance* of the information.

Spoken language generation is an extremely important aspect of the human–computer interface problem, especially if the transactions are to be conducted over a telephone. Models and methods must be developed that will generate natural sentences appropriate for spoken output, across many domains and languages [Glass et al. 1994]. In many cases, particular attention must be paid to the interaction between language generation and dialogue management; the system may have to initiate clarification dialogue to reduce the amount of information returned from the backend, in order not to generate unwieldy verbal responses. On the speech side, we must continue to improve speech synthesis capabilities, particularly with regard to the encoding of prosodic and paralinguistic information such as emotion and mood. As is the case on the input side, we must also develop integration strategies for language generation and speech synthesis. Finally, evaluation methodologies for spoken language generation technology must be developed, and comparative evaluation performed.

64.4.4 Portability

Currently, the development of speech recognition and language understanding technologies has been domain specific, requiring a large amount of annotated training data. However, it may be costly, or even impossible, to collect a large amount of training data for certain applications, such as Yellow Pages.

Therefore, we must address the problems of producing a spoken language system in a new domain given at most a small amount of domain-specific training data. To achieve this goal, we must strive to cleanly separate the algorithmic aspects of the system from the application-specific aspects. We must also develop automatic or semiautomatic methods for acquiring the acoustic models, language models, grammars, semantic structures for language understanding, and dialogue models required by a new application. The issue of portability spans across different acoustic environments, databases, knowledge domains, and languages. Real deployment of spoken language technology cannot take place without adequately addressing this issue.

Defining Terms

A* (best first) search: A search strategy for speech recognition in which the theories are prioritized by score, and the best scoring theory is incrementally advanced and returned to the stack. An estimated future score is included to normalize theories. The search is admissible if the estimated future score is an *upper-bound* estimate, in which case it can be guaranteed that the overall best-scoring theory will arrive at the end first.

Conversational system: A computer system that is able to carry on a spoken dialogue with a user in order to solve some problem. Usually there is a database of information that the user is attempting to access, and it may involve explicit goals such as making a reservation.

Dialogue modeling: The part of a conversational system that is concerned with interacting with the user in an effective way. This includes planning what to say next and keeping track of the state of completion of a task such as form filling. Important considerations are the ability to offer help at certain critical points in the dialogue or to recover gracefully from recognition errors. A good dialogue model can help tremendously to improve the usability of the system.

Discourse modeling: The part of a conversational system that is concerned with interpreting user queries in context. Often information that was mentioned earlier must be retained in interpreting a new query. The obvious cases are pronominal reference such as *it* or *this one*, but there are many difficult cases where inheritance is only implicit.

Disfluencies (false starts): Portions of a spoken sentence that are not fluent language. These can include false starts (a word or phrase that is abruptly ended prior to being fully uttered, and then verbally replaced with an alternative form), filled pauses (such as “umm” and “er”), or agrammatical constructs due to a changed plan midstream. Dysfluencies are particularly problematic for recognition systems.

Hidden Markov modeling (HMM): A very prevalent recognition framework that begins with an observation sequence derived from an acoustic waveform, and searches through a sequence of states, each of which has a set of hidden observation probabilities and a set of state transition probabilities, to seek an optimal solution. A distinguished *begin* state starts it off, and a distinguished *end* state concludes the search. In recognition, each phoneme is typically associated with an explicit state transition matrix, and each word is encoded as a sequence of specific phonemes. In some cases, phonological pronunciation rules may expand a word’s phonetic realization into a set of alternate choices.

Language generation: The process of generating a well-formed expression in English (or some other language) that conveys appropriate information to a user based on diverse sources such as a database, a user query, a partially completed electronic form, and a discourse context (narrow definition for conversational systems).

- Natural language understanding:** The process of converting an utterance (text string) into a meaning representation (e.g., semantic frame).
- N*-best interface:** An interface between a speech recognition system and a natural language system in which the recognizer proposes *N* whole-sentence hypotheses, and the NL system selects the most plausible alternative from among the *N* theories. In an alternative tightly coupled mode, the NL system is allowed to influence partial theories during the initial recognizer search.
- n*-Gram (statistical) language models:** A powerful mechanism for providing linguistic constraint to a speech recognizer. The models specify the set of follow words with associated probabilities, based on the preceding *n* – 1 words. Statistical language models depend on large corpora of training data within the domain to be effective.
- Parser:** A program that can analyze an input sentence into a hierarchical structure (a parse tree) according to a set of prescribed rules (a grammar) as an intermediate step toward obtaining a meaning representation (semantic frame).
- Perplexity:** A measure associated with a statistical language model, characterizing the geometric mean of the number of alternative choices at each branching point. Roughly, it indicates the average number of words the recognizer must consider at each decision point.
- Relational database:** An electronic database in which a collection of tables contain database entries along with sets of attributes, such that the data can be accessed along complex dimensions using the standard query language (SQL). Such databases make it convenient to look up information based on specifications derived from a semantic frame.
- Semantic frame:** A meaning representation associated with a user query. For very restricted domains it could be a flat structure of (key: value) pairs. Parsers that retain the syntactic structure can produce semantic frames that preserve the clause structure of the sentence.
- Speech recognition:** The process of converting an acoustic waveform (digitally recorded spoken utterance) into a sequence of hypothesized words (an orthographic transcription).
- Text-to-speech synthesis:** The process of converting a text string representing a sentence in English (or some other language) into an acoustic waveform that appropriately expresses the phonetics of the text string.
- Viterbi search:** A search strategy for speech recognition in which all partial theories are advanced lock-stepped in time. Inferior theories are pruned prior to each advance.
- Wizard-of-Oz paradigm:** A procedure for collecting speech data to be used for training a conversational system in which a human wizard aids the system in answering the subjects' queries. The wizard may simply enter user queries verbatim to the system, eliminating recognition errors, or may play a more active role by extracting appropriate information from the database and formulating canned responses. As the system becomes more fully developed it can play an ever-increasing role in the data collection process, eventually standing alone in a wizardless mode.

Further Information

Fundamentals of Speech Recognition, by Larry Rabiner and Bing-Huang Juang (Prentice–Hall, Englewood Cliffs, NJ, 1993) provides a good description of the basic speech recognition technology.

Natural Language Understanding, by James Allen (2nd ed., Benjamin Cummings, 1995) provides a good description of basic natural language technology.

Proceedings of ICASSP, *Proceedings of Eurospeech*, *Proceedings of ICSLP*, and *Proceedings of DARPA Speech and Natural Language Workshop* all provide excellent coverage of state-of-the-art spoken language systems.

65.1 Introduction

This chapter looks at two of the common learning paradigms used in artificial intelligence (AI), both of which are also well known in statistics. These methods share an approach to learning that is based on exploiting regularities among observations, so that predictions are made on the basis of similar previously encountered situations. The methods differ, however, in the way that similarity is expressed; trees make important shared properties explicit, whereas instance-based approaches equate (dis)similarity with some measure of distance.

65.1.1 Attribute-Value Representation

Decision tree and instance-based methods both represent each **instance** using a collection $\{A_1, A_2, \dots, A_x\}$ of properties or **attributes**. Attributes are grouped into two broad types: *continuous* attributes have real or integer values, whereas *discrete* attributes have unordered nominal values drawn from a (usually small) set of possibilities defined for that attribute. Each instance also belongs to one of a fixed set of mutually exclusive **classes** c_1, c_2, \dots, c_k . Both families of methods use a **training set** of classified instances to develop a mapping from attribute values to classes; this mapping can then be used to predict the class of a new instance from its attribute values.

Figure 65.1 shows a small collection of instances described in terms of four attributes. Attributes Outlook and Windy are discrete, with possible values $\{\text{sunny, overcast, rain}\}$ and $\{\text{true, false}\}$, respectively, whereas the other two attributes have numeric values. Each instance belongs to one of the classes yes or no.

Outlook	Temp, -F	Humidity, %	Windy	Class
rain	70	96	false	yes
sunny	80	90	true	no
overcast	64	65	true	yes
sunny	75	70	true	yes
sunny	85	85	false	no
sunny	72	95	false	no
rain	75	80	false	yes
sunny	69	70	false	yes
overcast	83	78	false	yes
rain	65	70	true	no
overcast	72	90	true	yes
overcast	81	75	false	yes
rain	68	80	false	yes
rain	71	80	true	no

FIGURE 65.1 An illustrative training set of instances.

The x attributes define an x -dimensional **description space** in which each instance becomes a point. From this geometrical perspective, both instance-based and decision tree approaches divide the description space into regions, each associated with one of the classes.

65.2 Decision Trees

Methods for generating decision trees were pioneered by Hunt and his co-workers in the 1960s, although their popularity in statistics stems from the independent work of Breiman et al. [1984]. The techniques are embodied in software packages such as CART [Breiman et al. 1984] and C 4.5 [Quinlan 1993].

Decision tree learning systems have been used in numerous industrial applications, particularly diagnosis and control. In one early success, Leech [1986] learned comprehensible trees from data logged from a complex and imperfectly understood uranium sintering process. The trees pointed the way to improved control of the process with substantial gains in throughput and quality. Evans and Fisher [1994] describe the use of decision trees to prevent banding, a problem in high-speed rotogravure printing. The trees are used to predict situations in which banding is likely to occur so that preventive action can be taken, leading to a dramatic reduction in print delays. Several other tree-based applications are discussed in Langley and Simon [1995].

65.2.1 Method for Constructing Decision Trees

Decision trees are constructed by a recursive *divide-and-conquer* algorithm that generates a partition of the data. The tree for set D of instances is formed as follows:

- If D satisfies a specified **stopping criterion**, the tree for D is a **leaf** that identifies the most frequent class among the instances. The most common stopping criterion is that all instances of D belong to the same class, but some systems also stop when D contains very few instances.
- Otherwise, select some **test** T with mutually exclusive outcomes T_1, T_2, \dots, T_n and let D_i be the subset of D containing those instances with outcome T_i , $1 \leq i \leq n$. The decision tree for D then has T as its root with a subtree for each outcome T_i of T . If D_i is empty, the subtree corresponding to outcome T_i is a leaf that nominates the majority class in D ; otherwise, the subtree for T_i is obtained by applying the same procedure to subset D_i of D .

FIGURE 65.2 Decision tree for training instances of Figure 65.1.

Outlook	Temp, -F	Humidity, %	Windy	Class
sunny	75	70	true	yes
sunny	69	70	false	yes
sunny	80	90	true	no
sunny	85	85	false	no
sunny	72	95	false	no
overcast	72	90	true	yes
overcast	83	78	false	yes
overcast	64	65	true	yes
overcast	81	75	false	yes
rain	71	80	true	no
rain	65	70	true	no
rain	75	80	false	yes
rain	68	80	false	yes
rain	70	96	false	yes

FIGURE 65.3 Partition of the instances of Figure 65.1.

In the example of Figure 65.1, the test chosen for the root of the tree might be Outlook = ? with possible outcomes sunny, overcast, and rain. The subset of instances with outcome sunny might then be further subdivided by a test Humidity ≤ 75 with outcomes true and false. All instances with outlook overcast belong to the same class, so no further subdivision would be necessary. The instances with outlook rain might be further divided by a test Windy = ? with outcomes true and false. The resulting decision tree appears in Figure 65.2 and the corresponding partition of the training instances is in Figure 65.3.

The tree provides a mechanism for classifying any instance. Starting at the root, the outcome of the test for that instance is determined and the process continues with the corresponding subtree. When a leaf is encountered, the instance is predicted to belong to the class identified by the leaf. In the preceding example, a new instance

Outlook = sunny, Temp = 82, Humidity = 85, Windy = true

would follow the outcome sunny, then the outcome false before reaching a leaf labeled no.

65.2.2 Choosing Tests

The example does not explain how tests like Outlook = ? or Humidity ≤ 75 came to be used. Provided that the chosen test T always produces a nontrivial partition of the instances so that no subset D_i contains all of them, the process will terminate. Nevertheless, the choice of T determines the structure of the final

tree and so can affect the class predicted for a new instance. Most decision tree systems are biased toward producing compact trees since, if two trees account equally well for the training instances, the simpler tree seems likely to have higher predictive accuracy.

The first step in selecting a test is to delineate the possibilities. Many systems consider only tests that involve a single attribute as follows:

- For a discrete attribute A_i with possible values v_1, v_2, \dots, v_m , a single test $A_i = ?$ with m outcomes could be considered. Additional possibilities are the m binary tests $A_i = v_j$, each with outcomes true and false.
- A continuous attribute A_i usually appears in a thresholded test such as $A_i \leq t$ (with outcomes true and false) for some constant t . Although there are infinitely many possible thresholds t , the number of distinct values of A_i that appear in a set D of instances is at most $|D|$. If these values are sorted into an ascending sequence, say, $n_1 < n_2 < \dots < n_l$, any value of t in the interval $[n_i, n_{i+1})$ will give the same partition of D , so only one threshold in each interval need be considered.

Most systems carry out an exhaustive comparison of simple tests such as those just described, although more complex tests (see “Extensions” subsections) may be examined heuristically.

Tests are evaluated with respect to some **splitting criterion** that allows the desirability of different tests to be assessed and compared. Such criteria are often based on the class distributions in the set D and subsets $\{D_i\}$ induced by a test. Two examples should illustrate the idea.

65.2.2.1 Gini Index and Impurity Reduction

Breiman et al. [1984] determine the *impurity* of a set of instances from its class distribution. If the relative frequency of instances belonging to class c_j in D is denoted by r_j , $1 \leq j \leq k$, then

$$Gini(D) = 1 - \sum_{j=1}^k (r_j)^2$$

The Gini index of a set of instances assumes its minimum value of zero when all instances belong to a single class.

Suppose now that test T partitions D into subsets D_1, D_2, \dots, D_n as before. The expected reduction in impurity associated with this test is given by

$$Gini(D) - \sum_{i=1}^n \frac{|D_i|}{|D|} \times Gini(D_i)$$

whose value is always greater than or equal to zero.

65.2.2.2 Gain Ratio

Criteria such as impurity reduction tend to improve with the number of outcomes n of a test. If possible tests have very different numbers of outcomes, such metrics do not provide a fair basis for comparison.

The gain ratio criterion [Quinlan 1993] is an information-based measure that attempts to allow for different numbers (and different probabilities) of outcomes. The residual uncertainty about the class to which an instance in D belongs can be expressed in a form similar to the preceding Gini index as

$$Info(D) = - \sum_{j=1}^k r_j \times \log_2(r_j)$$

and the corresponding information gained by a test T as

$$Info(D) - \sum_{i=1}^n \frac{|D_i|}{|D|} \times Info(D_i)$$

Like reduction in impurity, information gain focuses on class distributions. On the other hand, the potential information obtained by partitioning a set of instances is based on knowing the subset D_i into which an instance falls; this *split information* is given by

$$-\sum_{i=1}^n \frac{|D_i|}{|D|} \times \log_2 \left(\frac{|D_i|}{|D|} \right)$$

and tends to increase with the number of outcomes of a test. The gain ratio criterion uses the ratio of the information gain of a test T to its split information as the measure of its usefulness.

There have been numerous studies of the behavior of different splitting criteria, e.g., Liu and White [1994]. Some authors, including Breiman et al. [1984], see little operational difference among a broadly defined class of metrics.

65.2.3 Overfitting

Most data collected in practical applications involve some degree of *noise*. Values of continuous attributes are subject to measurement errors, discrete attributes such as color depend on subjective interpretation, instances are misclassified, and mistakes are made in recording.

When the divide-and-conquer algorithm is applied to such data, it often results in very large trees that *fit* the noise in addition to the meaningful structure in the task. The resulting over-elaborate trees are more difficult to understand and generally exhibit degraded predictive accuracy when classifying unseen instances.

Overfitting can be prevented either by restricting the growth of the tree, usually by means of significance tests of one form or another, or by **pruning** back the full tree to an appropriate size. The latter is generally preferred since it allows interactions of tests to be explored before deciding how much structure is justifiable; on the downside, though, growing and then pruning a tree requires more computation. Three common pruning strategies illustrate the idea.

65.2.3.1 Cost-Complexity Pruning

Breiman et al. [1984] describe a two-stage process in which a sequence of trees Z_0, Z_1, \dots, Z_z is generated, one of which is then selected as the final pruned tree. Consider a decision tree Z used to classify each of the $|D|$ instances in the training set from which it was constructed, and let e of them be misclassified. If $L(Z)$ is the number of leaves in Z , the *cost complexity* of Z is defined as the sum

$$\frac{e}{|D|} + \alpha \times L(Z)$$

for some value of the parameter α . Now, suppose we were to replace a subtree S of Z by a leaf identifying the most frequent class among the instances from which S was constructed. In general, the new tree would misclassify Δe more of the instances in the training set but would contain $L(S) - 1$ fewer leaves. This new tree would have the same cost complexity as Z if

$$\alpha = \frac{\Delta e}{|D| \times (L(S) - 1)}$$

The sequence of trees starts with Z_0 as the original tree. To produce Z_{i+1} from Z_i , each nonleaf subtree of Z_i is examined to find the minimum value of α . All subtrees with that value of α are then replaced by their respective best leaves, and the process continues until the final tree Z_z consists of a single leaf.

If a *pruning set* of instances separate from the training set D is available, a final tree can be selected simply by evaluating each Z_i on this set and picking the most accurate tree. If no pruning set is available, Breiman et al. [1984] employ a strategy based on **cross validation** that allows the **true error rate** of each Z_i to be estimated.

65.2.3.2 Reduced Error Pruning

The previous method considers only some subtrees of the original tree as candidates for the final pruned tree. Reduced error pruning [Quinlan 1987] presumes the existence of a separate pruning set and identifies among all subtrees of the original tree the one with the lowest error on the pruning set. This can be accomplished efficiently as follows.

Every instance in the pruning set is classified by the tree. The method records the number of errors at each leaf and also notes, for each internal node, the number of errors that would be made if that node were to be changed to a leaf. (As with a leaf, the class associated with an internal node is the most frequent class among the instances from which that subtree was constructed.) When all of these error counts have been determined, each internal node is investigated starting from the bottom levels of the tree. The number of errors made by the subtree rooted at that node is compared with the number of errors that would result from changing the node to a leaf and, if the latter is not greater than the former, the change is effected. Since the total number of errors made by a tree is the sum of the errors at its leaves, it is clear that the final subtree minimizes the number of errors on the pruning set.

65.2.3.3 Minimum Description Length Pruning

Rissanen's minimum description length (MDL) principle and Wallace and Boulton's similar minimum message length principle provide a rationale for offsetting fit on the training data against the complexity of the tree. The idea is to encode, as a single message, a theory (such as a tree) derived from training data together with the data given the theory. A complex theory that explains the data well might be expensive to encode, but the second part of the message should then be short. Conversely, a simple theory can be encoded cheaply but will not account for the data as well as a more complex theory, so that the second part of the message will require more bits. These principles advocate choosing a theory to minimize the length of the complete message; under certain measures of error or *loss functions*, this policy can be shown to maximize the probability of the theory given the data.

In this context, the alternative theories are pruned variants of the original tree. The scheme does not require a separate pruning set and is computationally simple, but its performance is sensitive to the encoding schemes used: the method for encoding a tree, for instance, implies different prior probabilities for trees of various shapes and sizes. The details would take us too far afield here, but Quinlan and Rivest [1989] and Wallace and Patrick [1993] discuss coding schemes and present comparative results.

65.2.4 Missing Attribute Values

Another problem often encountered with real-world datasets is that they are rarely complete; some instances do not have a recorded value for every attribute. This can impact decision tree methods at three stages:

- When comparing tests on attributes with different numbers of missing values
- When partitioning a set D on the outcomes of the chosen test, since the outcomes for some instances may not be known
- When classifying an unseen instance whose outcome for a test is again undetermined

These problems are usually handled in one of three ways:

- Filling in missing values. For example, if the value of a discrete attribute is not known, it can be assumed to be that attribute's most frequent value, and a missing numeric value can be replaced by the mean of the known values.
- Estimating test outcomes by some other means. Breiman et al. [1984] define the notion of a *surrogate split* for test T , viz., a test on a different attribute that produces a similar partition of D . When the value of a tested attribute is not known, the best surrogate split whose outcome is known is used to predict the outcome of the original test.
- Treating test outcomes probabilistically. Rather than determining a single outcome, this approach uses the probabilities of the outcomes as determined by their relative frequencies in the training

data. In the task of Figure 65.1, for instance, the probabilities of the outcomes sunny, overcast, and rain for the test Outlook = ? are 5/14, 4/14, and 5/14, respectively. If the tree of Figure 65.2 is used to classify an instance whose value of Outlook is missing, all three outcomes are explored. The predicted classes associated with each outcome are then combined with the corresponding relative frequencies to give a probability distribution over the classes; this is straightforward, since the outcomes are mutually exclusive. Finally, the class with highest probability is chosen as the predicted class.

The approaches are discussed in more detail in Quinlan [1989] together with comparative trials of different combinations of methods.

65.2.5 Extensions

The previous sections sketch what might be called the fundamentals of constructing and using decision trees. We now look at extensions in various directions aimed at producing trees with higher predictive accuracies on new instances and/or reducing the computation required for learning.

65.2.5.1 More Complex Tests

Many authors have considered ways of enlarging the repertoire of possible tests beyond those set out in the section on choosing tests. More flexible tests allow greater freedom in dividing the description space into regions and so increase the number of classification functions that can be represented as decision trees.

65.2.5.1.1 Subset Tests

If an attribute A_i has numerous discrete values v_1, v_2, \dots, v_m , a test $A_i = ?$ with one branch for every outcome will divide D into many small subsets. The ability to find meaningful structure in data depends on having sufficient instances to distinguish random and systematic association between attribute values and classes, so this *data fragmentation* generally makes learning more difficult.

One alternative to tests of this form is to group the values of A_i into a small number of subsets S_1, S_2, \dots, S_q ($q \ll m$), giving a test with outcomes $A_i \in S_j$, $1 \leq j \leq q$. Since there are $\sum_{q=2}^{m-1} q^{m-1}$ possible groupings of values, it is generally impossible to evaluate all of them.

In two-class learning tasks where the values are to be grouped into two subsets, Breiman et al. [1984] give the following algorithm for finding the subsets that optimize convex splitting criteria such as impurity reduction:

- For each value v_j , determine the proportion of instances with this value that belong to one of the classes (the majority class, say)
- Order the values on this proportion, giving v'_1, v'_2, \dots, v'_m
- The optimal subsets are then $\{v'_1, v'_2, \dots, v'_l\}$ and $\{v'_{l+1}, v'_{l+2}, \dots, v'_m\}$ for some value of l in the range 1 to $m - 1$

This reduces the number of candidate subsets from 2^{m-1} to $m - 1$ and makes it feasible to find the true optimal grouping. This procedure depends on there being only two classes, but CART extends the idea to multiclass tasks by first assembling the classes themselves into two superclasses and then finding the optimal subsets with respect to the superclasses.

Another approach is to grow the subsets heuristically. C4.5 [Quinlan 1993] starts with each subset containing a single value and iteratively merges subsets. At each stage, the subsets to be merged are chosen so that the gain ratio of the new test is maximized; the process stops when merging any pair of subsets would lead to a lower value. Since this algorithm is based on greedy search, optimality of the final subsets cannot be guaranteed.

65.2.5.1.2 Linear Multiattribute Tests

If tests all involve a single attribute, the resulting regions in the description space are bounded by hyperplanes that are orthogonal to one of the axes. When the real boundaries are not so simple, the divide-and-conquer

algorithm will tend to produce complex trees that approximate general boundaries by successions of small axis-orthogonal segments.

One generalization allows tests that involve a linear combination of attribute values, such as

$$w_0 + \sum_{i=1}^x w_i \times A_i \leq 0$$

with outcomes true and false. This clearly makes sense only when each attribute A_i has a numeric value. However, a discrete attribute with m values can be replaced by m binary-valued attributes, each having the value 1 when A_i has the particular value and 0 otherwise; when this is done, the linear test can also include multivalued discrete attributes. Systems such as LMDT [Utgoff and Brodley 1991] and OC1 [Murthy et al. 1994] that implement linear tests of this kind have been found to produce smaller trees, often with higher predictive accuracy on unseen instances. Brodley and Utgoff [1995] provide a summary of methods used to find the coefficients w_0, w_1, \dots, w_x and compare their performance empirically on several real-world datasets.

65.2.5.1.3 Symbolic Multiattribute Tests

One disadvantage of tests that compute a linear combination of attributes is that the tree can become more difficult to understand (although the complexity of the tests must be offset against the smaller overall tree size). Other multiattribute tests that do not use weights suffer less in this respect.

FRINGE [Pagallo and Haussler 1990] uses conjunctions of single-attribute tests. Consider the situation in which an instance belongs to a class if p Boolean conditions are satisfied. A conventional tree using p single-attribute tests would have to partition the training data into $p + 1$ subsets to represent this rule, risking the same problems with data fragmentation mentioned earlier. If a single test consisting of the conjunction of the p tests were used instead, the data would be split into only two subsets. FRINGE finds such conjunctions iteratively, starting with pairs of tests near the leaves of the tree and adding the conjunctions as new attributes for subsequent tree-building stages. In contrast, LFC [Ragavan and Rendell 1993] constructs conjunctive tests directly, in a manner reminiscent of the lookahead employed by the pioneering CLS system [Hunt et al. 1966].

Another form of combination is seen in the m -of- n test whose outcome is true if at least m of n single-attribute tests are satisfied and false otherwise. Tests of this kind are commonly used in biomedical domains but are extremely cumbersome to represent as trees with single-attribute tests. ID2-of-3 [Murphy and Pazzani 1991] constructs m -of- n tests at each node using a greedy search and often produces smaller trees as a result. Zheng [1995] generalized the idea to an x -of- n test that has one outcome for each possible number of conditions that can be satisfied, rather than just two outcomes based on a specified threshold number m of conditions being satisfied. Zheng shows that x -of- n tests are easier to construct than their m -of- n counterparts and have greater representational power.

65.2.5.2 Multiclass Problems

The effectiveness of decision tree methods is most easily seen in two-class learning tasks when each test contributes to discriminating one class from the other. When there are more than two classes, and especially when classes are very numerous, the goal of a test becomes less clear: should it try to separate one class from all of the others or one group of classes from other groups?

A task with k classes can also be viewed as k two-class tasks, each focusing on distinguishing a single class from all other classes. A separate decision tree can be grown for each class, and a new instance can be classified by looking at the predictions from all k trees. This poses a problem if two or more of the class trees claim the instance, or if none do; the procedure has to be augmented with conflict resolution and default strategies.

A similar idea motivates the *error-correcting output codes* of Dietterich and Bakiri [1995]. With each class is associated a pattern of d binary digits chosen so that the minimum Hamming distance h between any two patterns (i.e., the number of bits in which the patterns differ) is as large as possible. A separate tree is then learned to predict each bit of the class patterns. When a new instance is classified by the d trees,

the d output bits may not correspond to the pattern for any class. However, if there are at most $(h - 1)/2$ errors in the output bits, the nearest class pattern will indicate the correct class. Case studies presented by Dietterich and Bakiri demonstrate that this technique can result in a large improvement in classification accuracy for domains with numerous classes.

65.2.5.3 Growing Multiple Trees

An interesting feature of the divide-and-conquer procedure is its sensitivity to the training data. Often two or more attributes will have nearly equal values of the splitting criterion and removing even a single instance from the training set will cause the selected attribute and the associated subtrees to change. (This can be seen as follows: Suppose that omitting one instance typically makes no difference to the learned tree. The correctness or otherwise with which the tree classifies this instance would then be the same whether or not the instance is included in the training set. That is, the **resubstitution error rate** of the tree on the training instances would be the same as the error rate determined by leave-one-out cross validation. However, the resubstitution error rate is known to be an extremely biased measure, substantially underestimating the error rate on new instances, whereas the error rate obtained from leave-one-out cross validation is unbiased.)

The greedy search employed by the divide-and-conquer algorithm will generate only one tree, but a more careful exploration of the space of possible trees will generally uncover many equally appealing trees, compounding the problem of selecting one of them. Buntine [1990] suggests a way around this difficulty that avoids choice altogether! Conceptually, Buntine's idea is to retain all trees that are strong candidates and, when an unseen instance is to be classified, to determine a consensus result by averaging over all predictions. Since it is computationally intractable to explore the complete space of candidate trees, Buntine approximates the process by the use of limited lookahead and by incorporating a small random component in the splitting criterion so that several trees can be constructed from the same set of instances D . Even this constrained search involves substantial increases in computation but, in domains for which classification accuracy is paramount, the additional effort seems justifiable. In a comparison of four methods over 10 learning task domains, Buntine found that the averaging approach using two-ply lookahead gave consistently more accurate predictions on unseen instances. Similarly, Breiman [1996] uses bootstrap samples from the original training set to generate different trees, leading to dramatic improvements on several real-world datasets.

65.2.5.4 Efficiency Issues

Divide-and-conquer is an efficient algorithm, and current decision tree systems require only seconds on a workstation to generate trees from thousands of instances. In some tasks, however, very large numbers of training instances or the need to constantly regrow trees makes even this computational requirement too demanding.

65.2.5.4.1 Determining Thresholds for Continuous Attributes

The most time-consuming operation in growing a tree is finding the possible thresholds for tests on continuous attributes since the values of the attribute that are present in the current set of instances must be sorted, a process of complexity $\Omega(|D| \times \log(|D|))$. This could be avoided, of course, if continuous attributes were thresholded once and for all before growing the tree, thus converting all continuous attributes to discrete attributes. Although this is an active research area, it is clear that continuous attributes will have to be divided into more than just two intervals; papers by Fayyad and Irani [1993] and Van de Merckt [1993] suggest algorithms for finding multiple thresholds.

65.2.5.4.2 Peepholing

Catlett [1991] investigates efficiency of induction from very large datasets. He first demonstrates that speedup cannot be achieved trivially by learning from samples of the data; in the several domains studied, the accuracy of the final classifier is always reduced when a significant fraction of the data is ignored. In Catlett's approach, a small subset of the training data is studied to determine which continuous-valued

attributes can be eliminated from contention for the next test and, for the remainder, the interval in which a good threshold might lie. For the small overhead cost of processing the sample, this method allows the learning algorithm to avoid sorting on some attributes altogether and to sort only those values of the candidate attributes that lie within the indicated limits. As a result, the growth of learning time with the number of training instances is very much closer to linear.

65.2.5.4.3 Incremental Tree Construction

In some applications the data available for learning grow continually as new information comes to hand. The divide-and-conquer method is a batch-type process that uses all of the training instances to decide questions such as the choice of the next test. When the training set is enlarged, the previous tree must be discarded and the whole process repeated from scratch to generate a new tree. In contrast, Utgoff [1994] has developed incremental tree-growing algorithms that allow the existing tree to be modified as new training data arrive. Two key ideas are the retention of sufficient counting information at each node to determine whether the test at that node must be changed and a method of pulling up a test from somewhere in a subtree to its root. Utgoff's approach carries an interesting guarantee: the revised tree is identical to the tree that would be produced by divide-and-conquer using the enlarged training set.

65.3 Instance-Based Approaches

Although these approaches (usually under the name of *nearest neighbor* methods) have long interested researchers in pattern recognition, their use in the machine learning community has largely dated from Aha's influential work [Aha et al. 1991]. A useful summary of key developments from the perspective of someone outside AI is provided by the introductory chapter of Dasarthy [1991].

65.3.1 Outline of the Method

Recall that, in the geometrical view, attributes define a description space in which each instance is represented by a point. The fundamental assumption that underlies instance-based classification is that nearby instances in the description space will tend to belong to the same class, i.e., that closeness implies similarity. This does not suggest the converse (similarity implies closeness); there is no implicit assumption that instances belonging to a single class will form one cluster in the description space.

Unlike decision tree methods, instance-based approaches do not rely on a symbolic theory formed from the training instances to predict the class of an unseen instance. Instead, some or all of the training instances are remembered and a new instance is classified by finding instances that lie close to it in the description space and taking the most frequent class among them as the predicted class of the new instance. The central questions in this process are as follows:

- How should closeness in the description space be measured?
- Which training instances should be retained?
- How many neighbors should be used when making a prediction?

These are addressed in the following subsections.

65.3.2 Similarity Metric, or Measuring Closeness

65.3.2.1 Continuous Attributes

If all attributes are continuous, as was generally the case in early pattern recognition work [Nilsson 1965], the description space is effectively Euclidean. The square of the distance between two instances P and Q , described by their values for the x attributes ($P = \langle p_1, p_2, \dots, p_x \rangle$ and $Q = \langle q_1, q_2, \dots, q_x \rangle$) is

$$d^2(P, Q) = \sum_{i=1}^x (p_i - q_i)^2$$

and closeness can be equated with small distance. Alternatively, the attributes can be ascribed weights that reflect their relative magnitudes or importances, giving

$$d_w^2(P, Q) = \sum_{i=1}^x w_i^2 \times (p_i - q_i)^2$$

Common choices for weights to normalize magnitudes are as follows:

- $w_i = 1/\text{range}_i$. Here range_i is the difference between the largest and smallest values of attribute A_i observed in the training set.
- $w_i = 1/\text{sd}_i$. Here sd_i is the standard deviation of the values of A_i .

The former has the advantage that differences in values of an individual attribute range from 0 to 1, whereas the latter is particularly useful when attribute A_i is known to have a normal distribution.

65.3.2.2 Discrete Attributes

The difference between unordered values of a discrete attribute is more problematic. The obvious approach is to map the difference $p_i - q_i$ between two values of a discrete attribute A_i to 0 if p_i equals q_i and to 1 otherwise.

Stanfill and Waltz [1986] describe a significant improvement to this two-valued difference that takes account of the similarity of values with respect to the classes. Their *value difference metric* (VDM) first computes a weight for each discrete value of an instance and for each pair of discrete values. Let $n_i(v, c_j)$ denote the number of training instances that have value v for attribute A_i and also belong to class c_j , and let $n_i(v, \cdot)$ denote the sum of these over all classes. An attribute value is important to the extent that it differentiates among the classes. The weight associated with attribute A_i and instance P is taken as

$$w_i(P) = \sqrt{\sum_{j=1}^k \left(\frac{n_i(p_i, c_j)}{n_i(p_i, \cdot)} \right)^2}$$

The value difference between p_i and q_i is given by an analogous expression

$$\Delta v_i^2(P, Q) = \sum_{j=1}^k \left(\frac{n_i(p_i, c_j)}{n_i(p_i, \cdot)} - \frac{n_i(q_i, c_j)}{n_i(q_i, \cdot)} \right)^2$$

Combining these, the distance between instances P and Q becomes

$$d_{\text{VDM}}(P, Q) = \sum_{i=1}^x w_i(P) \times \Delta v_i^2(P, Q)$$

In the task of learning how to pronounce English words, Stanfill and Waltz [1986] found that VDM gave substantially improved performance over simple use of a 0–1 value difference.

Cost and Salzberg [1993] point out that VDM is not symmetric; $d_{\text{VDM}}(P, Q)$ is not generally equal to $d_{\text{VDM}}(Q, P)$ since only the first instance is used to determine the attribute weights. Their *modified value difference metric* (MVDM) drops the attribute weights in favor of an instance weight. They also prefer computing the value difference as the sum of the absolute values of the differences for each class rather than using the square of these differences. In summary,

$$d_{\text{MVDM}}(P, Q) = w(P) \times w(Q) \times \sum_{i=1}^x |\Delta v|_i(P, Q)$$

where

$$|\Delta v|_i(P, Q) = \sum_{j=1}^k \left| \frac{n_i(p_i, c_j)}{n_i(p_i, \cdot)} - \frac{n_i(q_i, c_j)}{n_i(q_i, \cdot)} \right|$$

The instance weights $w(P)$ and $w(Q)$ depend on their relative success in previous classification trials. If an instance P has been found to be closest to a test instance in t trials, in e of which the test instance belongs to a class different from P , the weight of P is

$$w(P) = \frac{t + 1}{t - e + 1}$$

This means that instances with a poor track record of classification will have a high weight and so appear to be more distant from (and thus less similar to) an unseen instance.

65.3.2.3 Mixed Continuous and Discrete Attributes

In learning tasks that involve attributes of both types, one strategy to measure distance would be simply to sum the different components as shown earlier, using the weighted square of distance (say) for continuous attributes and the MVDM difference for discrete attributes. Ting [1995] has found that instance-based learners employing nonuniform metrics of this kind have relatively poor performance. His experimental results suggest that it is preferable to convert continuous attributes to discrete attributes using thresholding (as discussed by Fayyad and Irani [1993] or Van de Merckt [1993]) and then to employ a uniform MVDM scheme throughout.

65.3.3 Choosing Instances to Remember

The performance of instance-based methods degrades in the presence of noisy training data. Dasarthy [1991, p. 4] states:

[Nearest neighbor] classifiers perform best when the training data set is essentially noise free, unlike the other parametric and non-parametric classifiers that perform best when trained in an environment paralleling the operational environment in its noise characteristics.

Performance should improve, then, if noisy training instances are discarded or **edited**. Two approaches to selecting the instances to retain give a flavor of the methods.

IB3 [Aha et al. 1991] starts with training instances arranged in an arbitrary sequence. Each in turn is classified with reference to the (initially empty) pool of retained instances. Those that are classified correctly by the current pool are discarded, whereas misclassified instances are held as potential additions to the pool. Performance statistics for these potential instances are kept and an instance is pooled when a significance test indicates that it would lead to improved classification.

Cameron-Jones [1992] uses an MDL-based approach (see the section on minimum description length pruning). A subset of training instances is chosen heuristically, the goal being to minimize the number of bits in a message specifying the retained instances and the exceptions to the classes that they predict for the training data. This approach usually retains remarkably few instances and yet leads to excellent predictive accuracy.

65.3.4 How Many Neighbors?

Most instance-based approaches use a fixed number of neighbors when classifying a new instance. The size of the neighborhood is important for good classification performance: if it is too small, predictions will be unduly sensitive to the presence of misclassified training instances, whereas too large a value will cause regions of the description space containing fewer exemplars to be merged with surrounding regions. The number of neighbors is usually odd so as to minimize problems with tied class frequencies. Popular choices are one (e.g., Cost and Salzberg [1993]), three, five, and even more (Stanfill and Waltz [1986]).

It is also possible to determine an appropriate number of neighbors from the training instances themselves. A leave-one-out cross validation is performed: each instance in turn is classified using the remaining instances with various neighborhood sizes. The number of neighbors that gives the least number of errors over all instances is then chosen.

65.3.5 Irrelevant Attributes

Instance-based approaches are *parallel* classifiers that use the values of all attributes for each prediction, in contrast with *sequential* classifiers like decision trees that use only a subset of the attributes in each prediction [Quinlan 1994]. When some of the attributes are irrelevant, a random element is introduced to the measurement of distance between instances. Consequently, the performance of instance-based methods can degrade sharply in tasks that have many irrelevant attributes, whereas decision trees are more robust in this respect.

Techniques like MVDM go a long way toward relieving this problem. If a discrete attribute A_i is not related to the instances's classes, the ratio $n_i(v, c_j)/n_i(v, \cdot)$ should not change much for different attribute values v , so that $|\Delta v|_i$ should be close to zero. As a result, the contribution of A_i to the distance calculation should be slight, so that irrelevant attributes are effectively ignored.

Irrelevant attributes can also be excluded more directly by finding the subset of attributes that gives the highest accuracy on a leave-one-out cross validation. There are, of course, $2^x - 1$ nonempty subsets of x attributes, a number that can be too large to investigate if x is greater than 20 or so. Moore and Lee [1994] describe techniques called *racing* and *schemata search* that increase the efficiency of exploring large combinatorial spaces like this. The essence of racing is that competitive subsets are investigated in parallel and a subset is eliminated as soon as it becomes unlikely to win. Schemata search allows subsets of attributes to be described stochastically, using values 0, 1, and * to indicate whether each attribute is definitely excluded, definitely included, or included with probability 0.5. As it becomes clear that subsets including (or excluding) an attribute are performing better, the asterisks for this attribute are resolved in remaining schemata to 1 or 0, respectively.

65.4 Composite Classifiers

This short discussion of decision trees and instance-based methods should not leave the impression that they are solved problems; both are the subject of considerable research. One of the more interesting areas concerns the use of multiple approaches in classifier design. This is motivated by the observation that, even within a single task, there are likely to be regions of the description space in which one or another type of classifier has the edge. For example, instance-based approaches support more general region boundaries than the axis-orthogonal hyperplanes constructed by decision trees. In regions whose true boundaries are complex, the former should provide better models and so lead to more accurate predictions. Conversely, in regions where some attributes are irrelevant, decision trees are likely to prove more robust.

The most general scheme for combining classifiers is *stacking* [Wolpert 1992]. Suppose that y different learning methods are available. For each training instance in turn, y classifiers can be constructed from the remaining instances and used to predict the class of the training instance. This instance thus gives rise to a *first-level* instance with $x + y$ attributes, namely, all of the original attributes plus the y predictions. One of the learning methods can be used with this new dataset; its predictions may employ (selectively) the predictions made by other methods. The process can be repeated to form second-level data with $x + 2y$ attributes, and so on.

In contrast, Brodley [1993] uses hand-crafted rules to decide when a particular classification method is appropriate. One such rule relates to the use of single attribute versus multiattribute tests and can be paraphrased as: If the number of instances is less than the number of attributes, use a single-attribute test, otherwise prefer multiattribute tests.

Finally, Jordan [1994] generalizes the idea of a decision tree to one in which the outcomes of all tests are inherently fuzzy or probabilistic. Constructing a tree then involves not only determining its structure, but

also learning a model for estimating the outcome probabilities at each node. Since the latter can involve techniques such as hidden Markov models, the resulting structure is a flexible hybrid.

Acknowledgments

I am most grateful for comments and suggestions from Nitin Indurkha, Kai Ming Ting, Will Uther, and Zijian Zheng.

Defining Terms

Attribute: A property or feature of all instances. May have *discrete* (nominal) or *continuous* (numeric) values. In statistical terms, an independent variable.

Class: The nominal category to which an instance belongs. The goal of learning is to be able to predict an instance's class from its attribute values. In statistical terms, a dependent variable.

Cross validation: A method for estimating the true error rate of a theory learned from a set of instances. The data are divided into N (e.g., 10) equal-sized groups and, for each group in turn, a theory is learned from the remaining groups and tested on the hold-out group. The estimated true error rate is the total number of test misclassifications divided by the number of instances.

Description space: A conceptual space with one dimension for each attribute. An instance is represented by a point in this space.

Editing: A process of discarding instances from the training set.

Instance: A single observation or datum described by its values of the attributes.

Leaf: A terminal node of a decision tree; has a class label.

Pruning: A process of simplifying a decision tree; each subtree that is judged to add little to the tree's predictive accuracy is replaced by a leaf.

Resubstitution error rate: The misclassification rate of a learned theory on the data from which it was constructed.

Similarity metric: The method used to measure the closeness of two instances in instance-based learning.

Splitting criterion: The basis for selecting one of a set of possible tests.

Stopping criterion: The conditions under which a set of instances is not further subdivided.

Test: An internal node of a decision tree that computes an *outcome* as some function of the attribute values of an instance. A test node is linked to subtrees, one for every possible outcome.

Training set: The collection of instances with known classes that is given to a learning system.

True error rate: The misclassification rate of a theory on unseen instances.

66.4 Graphical Models

66.1 Introduction

Within the broad scope of the study of artificial intelligence (AI), research in neural networks is characterized by a particular focus on pattern recognition and pattern generation. Many neural network methods can be viewed as generalizations of classical pattern-oriented techniques in statistics and the engineering areas of signal processing, system identification, and control theory. As in these parent disciplines, the notion of “pattern” in neural network research is essentially probabilistic and numerical. Neural network methods have had their greatest impact in problems where statistical issues dominate and where data are easily obtained.

A neural network is first and foremost a graph, with patterns represented in terms of numerical values attached to the nodes of the graph and transformations between patterns achieved via simple message-passing algorithms. Many neural network architectures, however, are also statistical processors, characterized by making particular probabilistic assumptions about data. As we will see, this conjunction of graphical algorithms and probability theory is not unique to neural networks but characterizes a wider family of probabilistic systems in the form of chains, trees, and networks that are currently being studied throughout AI [Spiegelhalter et al. 1993].

Neural networks have found a wide range of applications, the majority of which are associated with problems in pattern recognition and control theory. In this context, neural networks can best be viewed as a class of algorithms for statistical modeling and prediction. Based on a source of *training data*, the aim is to produce a statistical model of the process from which the data are generated, so as to allow the best predictions to be made for new data. We shall find it convenient to distinguish three broad types of statistical modeling problem, which we shall call **density estimation**, **classification**, and **regression**.

For density estimation problems (also referred to as *unsupervised learning* problems), the goal is to model the unconditional distribution of data described by some vector \mathbf{x} . A practical example of the application of density estimation involves the interpretation of X-ray images (mammograms) used for breast cancer screening [Tarassenko 1995]. In this case, the training vectors \mathbf{x} form a sample taken from

normal (noncancerous) images, and a network model is used to build a representation of the density $p(\mathbf{x})$. When a new input vector \mathbf{x}' is presented to the system, a high value for $p(\mathbf{x}')$ indicates a normal image, whereas a low value indicates a novel input which might be characteristic of an abnormality. This is used to label regions of images that are unusual, for further examination by an experienced clinician.

For classification and regression problems (often referred to as *supervised learning* problems), we need to distinguish between *input* variables, which we again denote by \mathbf{x} , and *target* variables, which we denote by the vector \mathbf{t} . Classification problems require that each input vector \mathbf{x} be assigned to one of C classes C_1, \dots, C_C , in which case the target variables represent class labels. As an example, consider the problem of recognizing handwritten digits [LeCun et al. 1989]. In this case, the input vector would be some (preprocessed) image of the digit, and the network would have 10 outputs, one for each digit, which can be used to assign input vectors to the appropriate class (as discussed in [Section 66.2](#)).

Regression problems involve estimating the values of continuous variables. For example, neural networks have been used as part of the control system for adaptive optics telescopes [Sandler et al. 1991]. The network input \mathbf{x} consists of one in-focus and one defocused image of a star and the output \mathbf{t} consists of a set of coefficients that describe the phase distortion due to atmospheric turbulence. These output values are then used to make real-time adjustments of the multiple mirror segments to cancel the atmospheric distortion.

Classification and regression problems also can be viewed as special cases of density estimation. The most general and complete description of the data is given by the probability distribution function $p(\mathbf{x}, \mathbf{t})$ in the joint input-target space. However, the usual goal is to be able to make good predictions for the target variables when presented with new values of the inputs. In this case, it is convenient to decompose the joint distribution in the form

$$p(\mathbf{x}, \mathbf{t}) = p(\mathbf{t} | \mathbf{x})p(\mathbf{x}) \quad (66.1)$$

and to consider only the conditional distribution $p(\mathbf{t} | \mathbf{x})$, in other words the distribution of \mathbf{t} given the value of \mathbf{x} . Thus, classification and regression involve the estimation of *conditional* densities, a problem which has its own idiosyncracies.

The organization of the chapter is as follows. In [Section 66.2](#) we present examples of network representations of unconditional and conditional densities. In [Section 66.3](#) we discuss the problem of adjusting the parameters of these networks to fit them to data. This problem has a number of practical aspects, including the choice of optimization procedure and the method used to control network complexity. We then discuss a broader perspective on probabilistic network models in [Section 66.4](#). The final section presents further information and pointers to the literature.

66.2 Representation

In this section we describe a selection of neural network architectures that have been proposed as representations for unconditional and conditional densities. After a brief discussion of density estimation, we discuss classification and regression, beginning with simple models that illustrate the fundamental ideas and then progressing to more complex architectures. We focus here on representational issues, postponing the problem of learning from data until the following section.

66.2.1 Density Estimation

We begin with a brief discussion of density estimation, utilizing the Gaussian **mixture model** as an illustrative model. We return to more complex density estimation techniques later in the chapter.

Although density estimation can be the main goal of a learning system, as in the diagnosis example mentioned in the Introduction, density estimation models arise more often as components of the solution to a more general classification or regression problem. To return to Equation 66.1, note that the joint density is composed of $p(\mathbf{t} | \mathbf{x})$, to be handled by classification or regression models, and $p(\mathbf{x})$, the (unconditional) input density. There are several reasons for wanting to form an explicit model of the input density. First,

FIGURE 66.1 A network representation of a Gaussian mixture distribution. The input pattern \mathbf{x} is represented by numerical values associated with the input nodes in the lower level. Each link has a weight μ_{ij} , which is the j th component of the mean vector for the i th Gaussian. The i th intermediate node contains the covariance matrix Σ_i and calculates the Gaussian conditional probability $p(\mathbf{x} | i, \mu_i, \Sigma_i)$. These probabilities are weighted by the mixing proportions π_i and the output node calculates the weighted sum $p(\mathbf{x}) = \sum_i \pi_i p(\mathbf{x} | i, \mu_i, \Sigma_i)$.

real-life data sets often have missing components in the input vector. Having a model of the density allows the missing components to be filled in in an intelligent way. This can be useful both for training and for prediction (cf. Bishop [1995]). Second, as we see in Equation 66.1, a model of $p(\mathbf{x})$ makes possible an estimate of the joint probability $p(\mathbf{x}, \mathbf{t})$. This in turn provides us with the necessary information to estimate the inverse conditional density $p(\mathbf{x} | \mathbf{t})$. The calculation of such inverses is important for applications in control and optimization.

A general and flexible approach to density estimation is to treat the density as being composed of a set of M simpler densities. This approach involves modeling the observed data as a sample from a *mixture density*,

$$p(\mathbf{x} | \mathbf{w}) = \sum_{i=1}^M \pi_i p(\mathbf{x} | i, \mathbf{w}_i) \quad (66.2)$$

where the π_i are constants known as *mixing proportions*, and the $p(\mathbf{x} | i, \mathbf{w}_i)$ are the *component densities*, generally taken to be from a simple parametric family. A common choice of component density is the multivariate Gaussian, in which case the parameters \mathbf{w}_i are the means and covariance matrices of each of the components. By varying the means and covariances to place and orient the Gaussians appropriately, a wide variety of high-dimensional, multimodal data can be modeled. This approach to density estimation is essentially a probabilistic form of clustering.

Gaussian mixtures have a representation as a network diagram, as shown in Figure 66.1. The utility of such network representations will become clearer as we proceed; for now, it suffices to note that not only mixture models, but also a wide variety of other classical statistical models for density estimation, are representable as simple networks with one or more layers of adaptive weights. These methods include *principal component analysis*, *canonical correlation analysis*, *kernel density estimation*, and *factor analysis* [Anderson 1984].

66.2.2 Linear Regression and Linear Discriminants

Regression models and classification models both focus on the conditional density $p(\mathbf{t} | \mathbf{x})$. They differ in that in regression the target vector \mathbf{t} is a real-valued vector, whereas in classification \mathbf{t} takes its values from a discrete set representing the class labels.

The simplest probabilistic model for regression is one in which \mathbf{t} is viewed as the sum of an underlying deterministic function $f(\mathbf{x})$ and a Gaussian random variable ϵ ,

$$\mathbf{t} = f(\mathbf{x}) + \epsilon \quad (66.3)$$

If ϵ has zero mean, as is commonly assumed, $f(\mathbf{x})$ then becomes the *conditional mean* $E(\mathbf{t} | \mathbf{x})$. It is this function that is the focus of most regression modeling. Of course, the conditional mean describes only the first moment of the conditional distribution, and, as we discuss in a later section, a good regression model will also generally report information about the second moment.

In a linear regression model, the conditional mean is a linear function of \mathbf{x} : $E(\mathbf{t} | \mathbf{x}) = W\mathbf{x}$, for a fixed matrix W . Linear regression has a straightforward representation as a network diagram in which the j th input unit represents the j th component of the input vector \mathbf{x}_j , each output unit i takes the weighted sum of the input values, and the weight w_{ij} is placed on the link between the j th input unit and the i th output unit.

The conditional mean is also an important function in classification problems, but most of the focus in classification is on a different function known as a **discriminant function**. To see how this function arises and to relate it to the conditional mean, we consider a simple two-class problem in which the target is a simple binary scalar that we now denote by t . The conditional mean $E(t | \mathbf{x})$ is equal to the probability that t equals one, and this latter probability can be expanded via Bayes rule

$$p(t = 1 | \mathbf{x}) = \frac{p(\mathbf{x} | t = 1)p(t = 1)}{p(\mathbf{x})} \quad (66.4)$$

The density $p(t | \mathbf{x})$ in this equation is referred to as the *posterior probability* of the class given the input, and the density $p(\mathbf{x} | t)$ is referred to as the *class-conditional density*. Continuing the derivation, we expand the denominator and (with some foresight) introduce an exponential,

$$\begin{aligned} p(t = 1 | \mathbf{x}) &= \frac{p(\mathbf{x} | t = 1)p(t = 1)}{p(\mathbf{x} | t = 1)p(t = 1) + p(\mathbf{x} | t = 0)p(t = 0)} \\ &= \frac{1}{1 + \exp\left\{-\ln\left[\frac{p(\mathbf{x} | t=1)}{p(\mathbf{x} | t=0)}\right] - \ln\left[\frac{p(t=1)}{p(t=0)}\right]\right\}} \end{aligned} \quad (66.5)$$

We see that the posterior probability can be written in the form of the *logistic function*:

$$y = \frac{1}{1 + e^{-z}} \quad (66.6)$$

where z is a function of the likelihood ratio $p(\mathbf{x} | t = 1)/p(\mathbf{x} | t = 0)$, and the prior ratio $p(t = 1)/p(t = 0)$. This is a useful representation of the posterior probability if z turns out to be simple.

It is easily verified that if the class conditional densities are multivariate Gaussians with identical covariance matrices, then z is a linear function of \mathbf{x} : $z = \mathbf{w}^T \mathbf{x} + w_0$. Moreover, this representation is appropriate for any distribution in a broad class of densities known as the exponential family (which includes the Gaussian, the Poisson, the gamma, the binomial, and many other densities). All of the densities in this family can be put in the following form:

$$g(\mathbf{x}; \theta, \phi) = \exp\{(\theta^T \mathbf{x} - b(\theta))/a(\phi) + c(\mathbf{x}, \phi)\} \quad (66.7)$$

where θ is the *location parameter* and ϕ is the *scale parameter*. Substituting this general form in Equation 66.5, where θ is allowed to vary between the classes and ϕ is assumed to be constant between classes, we see that z is in all cases a linear function. Thus, the choice of a linear-logistic model is rather robust.

The geometry of the two-class problem is shown in Figure 66.2, which shows Gaussian class-conditional densities, and suggests the logistic form of the posterior probability.

The function z in our analysis is an example of a discriminant function. In general, a discriminant function is any function that can be used to decide on class membership [Duda and Hart 1973]; our analysis has produced a particular form of discriminant function that is an intermediate step in the calculation of a posterior probability. Note that if we set $z = 0$, from the form of the logistic function we obtain a probability of 0.5, which shows that $z = 0$ is a *decision boundary* between the two classes.

The discriminant function that we found for exponential family densities is linear under the given conditions on ϕ . In more general situations, in which the class-conditional densities are more complex

FIGURE 66.2 This shows the Gaussian class-conditional densities $p(x | C_1)$ (dashed curves) for a two-class problem in one dimension, together with the corresponding posterior probability $p(C_1 | x)$ (solid curve) which takes the form of a logistic sigmoid. The vertical line shows the decision boundary for $y = 0.5$, which coincides with the point at which the two density curves cross.

than a single exponential family density, the posterior probability will not be well characterized by the linear-logistic form. Nonetheless, it still is useful to retain the logistic function and focus on *nonlinear* representations for the function z . This is the approach taken within the neural network field.

To summarize, we have identified two functions that are important for regression and classification, respectively: the conditional mean and the discriminant function. These are the two functions that are of concern for simple linear models and, as we now discuss, for more complex nonlinear models as well.

66.2.3 Nonlinear Regression and Nonlinear Classification

The linear regression and linear discriminant functions introduced in the previous section have the merit of simplicity, but are severely restricted in their representational capabilities. A convenient way to see this is to consider the geometrical interpretation of these models. When viewed in the d -dimensional \mathbf{x} -space, the linear regression function $\mathbf{w}^T \mathbf{x} + w_0$ is constant on hyperplanes which are orthogonal to the vector \mathbf{w} . For many practical applications, we need to consider much more general classes of function. We therefore seek representations for nonlinear mappings which can approximate any given mapping to arbitrary accuracy. One way to achieve this is to transform the original \mathbf{x} using a set of M nonlinear functions $\phi_j(\mathbf{x})$ where $j = 1, \dots, M$, and then to form a linear combination of these functions, so that

$$y_k(\mathbf{x}) = \sum_j w_{kj} \phi_j(\mathbf{x}) \quad (66.8)$$

For a sufficiently large value of M , and for a suitable choice of the $\phi_j(\mathbf{x})$, such a model has the desired universal approximation properties. A familiar example, for the case of one-dimensional input spaces, is the simple polynomial, for which the $\phi_j(\mathbf{x})$ are simply successive powers of \mathbf{x} and the w are the polynomial coefficients. Models of the form in Equation 66.8 have the property that they can be expressed as network diagrams in which there is a *single* layer of adaptive weights.

There are a variety of families of functions in one dimension that can approximate any continuous function to arbitrary accuracy. There is, however, an important issue which must be addressed, called the *curse of dimensionality*. If, for example, we consider an M th-order polynomial then the number of independent coefficients grows as d^M [Bishop 1995]. For a typical medium-scale application with, say, 30 inputs, a fourth-order polynomial (which is still quite restricted in its representational capability) would have over 46,000 adjustable parameters. As we shall see in the section on complexity control, in order to achieve good generalization it is important to have more data points than adaptive parameters in the model, and this is a serious problem for methods that have a power law or exponential growth in the number of parameters.

FIGURE 66.3 An example of a feedforward network having two layers of adaptive weights. The bias parameters in the first layer are shown as weights from an extra input having a fixed value of $x_0 = 1$. Similarly, the bias parameters in the second layer are shown as weights from an extra hidden unit, with activation again fixed at $z_0 = 1$.

A solution to the problem lies in the fact that, for most real-world data sets, there are strong (often nonlinear) correlations between the input variables such that the data do not uniformly fill the input space but are effectively confined to a subspace whose dimensionality is called the *intrinsic dimensionality* of the data. We can take advantage of this phenomenon by considering again a model of the form in Equation 66.8 but in which the basis functions $\phi_j(\mathbf{x})$ are *adaptive* so that they themselves contain weight parameters whose values can be adjusted in the light of the observed dataset. Different models result from different choices for the basis functions, and here we consider the two most common examples. The first of these is called the **multilayer perceptron (MLP)** and is obtained by choosing the basis functions to be given by linear-logistic functions Equation 66.6. This leads to a multivariate nonlinear function that can be expressed in the form

$$y_k(\mathbf{x}) = \sum_{j=1}^M w_{kj} g \left(\sum_{i=1}^d w_{ji} x_i + w_{j0} \right) + w_{k0} \quad (66.9)$$

Here w_{j0} and w_{k0} are *bias* parameters, and the basis functions are called *hidden units*. The function $g(\cdot)$ is the logistic sigmoid function of Equation 66.6. This also can be represented as a network diagram as in Figure 66.3. Such a model is able to take account of the intrinsic dimensionality of the data because the first-layer weights w_{ji} can adapt and hence orient the surfaces along which the basis function response is constant. It has been demonstrated that models of this form can approximate to arbitrary accuracy any continuous function, defined on a compact domain, provided the number M of hidden units is sufficiently large. The MLP model can be extended by considering several successive layers of weights. Note that the use of nonlinear activation functions is crucial, because if $g(\cdot)$ in Equation 66.9 was replaced by the identity, the network would reduce to several successive linear transformations, which would itself be linear.

The second common network model is obtained by choosing the basis functions $\phi_j(\mathbf{x})$ in Equation 66.8 to be functions of the radial variable $\|\mathbf{x} - \boldsymbol{\mu}_j\|$ where $\boldsymbol{\mu}_j$ is the *center* of the j th basis function, which gives rise to the **radial basis function (RBF) network** model. The most common example uses Gaussians of the form

$$\phi_j(\mathbf{x}) = \exp \left\{ -\frac{1}{2} (\mathbf{x} - \boldsymbol{\mu}_j)^T \boldsymbol{\Sigma}_j^{-1} (\mathbf{x} - \boldsymbol{\mu}_j) \right\} \quad (66.10)$$

Here both the mean vector $\boldsymbol{\mu}_j$ and the covariance matrix $\boldsymbol{\Sigma}_j$ are considered to be adaptive parameters. The curse of dimensionality is alleviated because the basis functions can be positioned and oriented in input space such as to overlay the regions of high data density and hence to capture the nonlinear correlations between input variables. Indeed, a common approach to training an RBF network is to use a two-stage procedure [Bishop 1995]. In the first stage, the basis function parameters are determined using

the input data alone, which corresponds to a density estimation problem using a mixture model in which the component densities are given by the basis functions $\phi_j(\mathbf{x})$. In the second stage, the basis function parameters are frozen and the second-layer weights w_{kj} are found by standard least-squares optimization procedures.

66.2.4 Decision Trees

MLP and RBF networks are often contrasted in terms of the support of the basis functions that compose them. MLP networks are often referred to as “global,” given that linear-logistic basis functions are bounded away from zero over a significant fraction of the input space. Accordingly, in an MLP, each input vector generally gives rise to a distributed pattern over the hidden units. RBF networks, on the other hand, are referred to as “local,” due to the fact that their Gaussian basis functions typically have support over a local region of the input space. It is important to note, however, that local support does not necessarily mean nonoverlapping support; indeed, there is nothing in the RBF model that prefers basis functions that have nonoverlapping support. A third class of model that does focus on basis functions with nonoverlapping support is the **decision tree** model [Breiman et al. 1984]. A decision tree is a regression or classification model that can be viewed as asking a sequence of questions about the input vector. Each question is implemented as a linear discriminant, and a sequence of questions can be viewed as a recursive partitioning of the input space. All inputs that arrive at a particular leaf of the tree define a polyhedral region in the input space. The collection of such regions can be viewed as a set of basis functions. Associated with each basis function is an output value which (ideally) is close to the average value of the conditional mean (for regression) or discriminant function (for classification; a majority vote is also used). Thus, the decision tree output can be written as a weighted sum of basis functions in the same manner as a layered network.

As this discussion suggests, decision trees and MLP/RBF neural networks are best viewed as being different points along the continuum of models having overlapping or nonoverlapping basis functions. Indeed, as we show in the following section, decision trees can be treated probabilistically as mixture models, and in the mixture approach the sharp discriminant function boundaries of classical decision trees become smoothed, yielding partially overlapping basis functions.

There are tradeoffs associated with the continuum of degree-of-overlap; in particular, nonoverlapping basis functions are generally viewed as being easier to interpret and better able to reject noisy input variables that carry little information about the output. Overlapping basis functions often are viewed as yielding lower variance predictions and as being more robust.

66.2.5 General Mixture Models

The use of mixture models is not restricted to density estimation; rather, the mixture approach can be used quite generally to build complex models out of simple parts. To illustrate, let us consider using mixture models to model a conditional density in the context of a regression or classification problem. A mixture model in this setting is referred to as a “mixtures of experts” model [Jacobs et al. 1991].

Suppose that we have at our disposal an elemental conditional model $p(\mathbf{t} | \mathbf{x}, \mathbf{w})$. Consider a situation in which the conditional mean or discriminant exhibits variation on a local scale that is a good match to our elemental model, but the variation differs in different regions of the input space. We could use a more complex network to try to capture this global variation; alternatively, we might wish to combine local variants of our elemental models in some manner. This can be achieved by defining the following probabilistic mixture:

$$p(\mathbf{t} | \mathbf{x}, \mathbf{w}) = \sum_{i=1}^M p(i | \mathbf{x}, \mathbf{v}) p(\mathbf{t} | \mathbf{x}, i, \mathbf{w}_i) \quad (66.11)$$

Comparing this mixture to the unconditional mixture defined earlier Equation 66.2, we see that both the mixing proportions and the component densities are now conditional densities dependent on the input

vector \mathbf{x} . The former dependence is particularly important: we now view the mixing proportion $p(i | \mathbf{x}, \mathbf{v})$ as providing a probabilistic device for choosing different elemental models (“experts”) in different regions of the input space. A learning algorithm that chooses values for the parameters \mathbf{v} as well as the values for the parameters \mathbf{w}_i can be viewed as attempting to find both a good partition of the input space and a good fit to the local models within that partition.

This approach can be extended recursively by considering mixtures of models where each model may itself be a mixture model [Jordan and Jacobs 1994]. Such a recursion can be viewed as providing a probabilistic interpretation for the decision trees discussed in the previous section. We view the decisions in the decision tree as forming a recursive set of probabilistic selections among a set of models. The total probability of target t given input \mathbf{x} is the sum across all paths down the tree,

$$p(t | \mathbf{x}, \mathbf{w}) = \sum_{i=1}^M p(i | \mathbf{x}, \mathbf{u}) \sum_{j=1}^M p(j | \mathbf{x}, i, \mathbf{v}_i) \cdots p(t | \mathbf{x}, i, j, \dots, \mathbf{w}_{ij} \cdots) \quad (66.12)$$

where i and j are the decisions made at the first level and second level of the tree, respectively, and $p(t | \mathbf{x}, i, j, \dots, \mathbf{w}_{ij} \cdots)$ is the elemental model at the leaf of the tree defined by the sequence of decisions. This probabilistic model is a conditional hierarchical mixture. Finding parameter values \mathbf{u} , \mathbf{v}_i , etc., to fit this model to data can be viewed as finding a nested set of partitions of the input space and fitting a set of local models within the partition.

The mixture model approach can be viewed as a special case of a general methodology known as *learning by committee*. Bishop [1995] provides a discussion of committees; we will also meet them in the section on Bayesian methods later in the chapter.

66.3 Learning from Data

The previous section has provided a selection of models to choose from; we now face the problem of matching these models to data. In principle, the problem is straightforward: given a family of models of interest we attempt to find out how probable each of these models is in the light of the data. We can then select the most probable model [a selection rule known as *maximum a posteriori* (MAP) estimation], or we can select some highly probable subset of models, weighted by their probability (an approach that we discuss in the section on Bayesian methods). In practice, there are a number of problems to solve, beginning with the specification of the family of models of interest. In the simplest case, in which the family can be described as a fixed structure with varying parameters (e.g., the class of feedforward MLPs with a fixed number of hidden units), the learning problem is essentially one of *parameter estimation*. If, on the other hand, the family is not easily viewed as a fixed parametric family (e.g., feedforward MLPs with a variable number of hidden units), then we must solve the *model selection* problem.

In this section we discuss the parameter estimation problem. The goal will be to find MAP estimates of the parameters by maximizing the probability of the parameters given the data \mathcal{D} . We compute this probability using Bayes rule,

$$p(\mathbf{w} | \mathcal{D}) = \frac{p(\mathcal{D} | \mathbf{w})p(\mathbf{w})}{p(\mathcal{D})} \quad (66.13)$$

where we see that to calculate MAP estimates we must maximize the expression in the numerator (the denominator does not depend on \mathbf{w}). Equivalently we can minimize the negative logarithm of the numerator. We thus define the following **cost function** $J(\mathbf{w})$:

$$J(\mathbf{w}) = -\ln p(\mathcal{D} | \mathbf{w}) - \ln p(\mathbf{w}) \quad (66.14)$$

which we wish to minimize with respect to the parameters \mathbf{w} . The first term in this cost function is a (negative) log **likelihood**. If we assume that the elements in the training set \mathcal{D} are conditionally

independent of each other given the parameters, then the likelihood factorizes into a product form. For density estimation we have

$$p(\mathcal{D} | \mathbf{w}) = \prod_{n=1}^N p(\mathbf{x}_n | \mathbf{w}) \quad (66.15)$$

and for classification and regression we have

$$p(\mathcal{D} | \mathbf{w}) = \prod_{n=1}^N p(\mathbf{t}_n | \mathbf{x}_n, \mathbf{w}) \quad (66.16)$$

In both cases this yields a log likelihood which is the sum of the log probabilities for each individual data point. For the remainder of this section we will assume this additive form; moreover, we will assume that the log prior probability of the parameters is uniform across the parameters and drop the second term. Thus, we focus on *maximum likelihood* (ML) estimation, where we choose parameter values \mathbf{w}_{ML} that maximize $\ln p(\mathcal{D} | \mathbf{w})$.

66.3.1 Likelihood-Based Cost Functions

Regression, classification, and density estimation make different probabilistic assumptions about the form of the data and therefore require different cost functions.

Equation 66.3 defines a probabilistic model for regression. The model is a conditional density for the targets \mathbf{t} in which the targets are distributed as Gaussian random variables (assuming Gaussian errors ϵ) with mean values $f(\mathbf{x})$. We now write the conditional mean as $f(\mathbf{x}, \mathbf{w})$ to make explicit the dependence on the parameters \mathbf{w} . Given the training set $\mathcal{D} = \{\mathbf{x}_n, \mathbf{t}_n\}_{n=1}^N$, and given our assumption that the targets \mathbf{t}_n are sampled independently (given the inputs \mathbf{x}_n and the parameters \mathbf{w}), we obtain

$$J(\mathbf{w}) = \frac{1}{2} \sum_n \|\mathbf{t}_n - f(\mathbf{x}_n, \mathbf{w})\|^2 \quad (66.17)$$

where we have assumed an identity covariance matrix and dropped those terms that do not depend on the parameters. This cost function is the standard least-squares cost function, which is traditionally used in neural network training for real-valued targets. Minimization of this cost function is typically achieved via some form of gradient optimization, as we discuss in the following section.

Classification problems differ from regression problems in the use of discrete-valued targets, and the likelihood accordingly takes a different form. For binary classification the Bernoulli probability model $p(t | \mathbf{x}, \mathbf{w}) = y^t (1 - y)^{1-t}$ is natural, where we use y to denote the probability $p(t = 1 | \mathbf{x}, \mathbf{w})$. This model yields the following log likelihood:

$$J(\mathbf{w}) = - \sum_n [t_n \ln y_n + (1 - t_n) \ln(1 - y_n)] \quad (66.18)$$

which is known as the *cross-entropy* function. It can be minimized using the same generic optimization procedures as are used for least squares.

For multiway classification problems in which there are C categories, where $C > 2$, the multinomial distribution is natural. Define \mathbf{t}_n such that its elements $t_{n,i}$ are one or zero according to whether the n th data point belongs to the i th category, and define $y_{n,i}$ to be the network's estimate of the posterior probability of category i for data point n ; that is, $y_{n,i} \equiv p(t_{n,i} = 1 | \mathbf{x}_n, \mathbf{w})$. Given these definitions, we obtain the following cost function:

$$J(\mathbf{w}) = - \sum_n \sum_i t_{n,i} \ln y_{n,i} \quad (66.19)$$

which again has the form of a cross entropy.

We now turn to density estimation as exemplified by Gaussian mixture modeling. The probabilistic model in this case is that given in Equation 66.2. Assuming Gaussian component densities with arbitrary covariance matrices, we obtain the following cost function:

$$J(\mathbf{w}) = - \sum_n \ln \sum_i \pi_i \frac{1}{|\Sigma_i|^{1/2}} \exp \left\{ -\frac{1}{2} (\mathbf{x}_n - \boldsymbol{\mu}_i)^T \Sigma_i^{-1} (\mathbf{x}_n - \boldsymbol{\mu}_i) \right\} \quad (66.20)$$

where the parameters \mathbf{w} are the collection of mean vectors $\boldsymbol{\mu}_i$, the covariance matrices Σ_i , and the mixing proportions π_i . A similar cost function arises for the generalized mixture models [cf. Equation 66.12].

66.3.2 Gradients of the Cost Function

Once we have defined a probabilistic model, obtained a cost function, and found an efficient procedure for calculating the gradient of the cost function, the problem can be handed off to an optimization routine. Before discussing optimization procedures, however, it is useful to examine the form that the gradient takes for the examples that we have discussed in the previous two sections.

The i th output unit in a layered network is endowed with a rule for combining the activations of units in earlier layers, yielding a quantity that we denote by z_i and a function that converts z_i into the output y_i . For regression problems, we assume linear output units such that $y_i = z_i$. For binary classification problems, our earlier discussion showed that a natural output function is the logistic: $y_i = 1/(1 + e^{-z_i})$. For multiway classification, it is possible to generalize the derivation of the logistic function to obtain an analogous representation for the multiway posterior probabilities known as the *softmax function* [cf. Bishop 1995]:

$$y_i = \frac{e^{z_i}}{\sum_k e^{z_k}} \quad (66.21)$$

where y_i represents the posterior probability of category i .

If we now consider the gradient of $J(\mathbf{w})$ with respect to z_i , it turns out that we obtain a single canonical expression of the following form:

$$\frac{\partial J}{\partial \mathbf{w}} = \sum_i (t_i - y_i) \frac{\partial z_i}{\partial \mathbf{w}} \quad (66.22)$$

As discussed by Rumelhart et al. [1995], this form for the gradient is predicted from the theory of generalized linear models [McCullagh and Nelder 1983], where it is shown that the linear, logistic, and softmax functions are (inverse) *canonical links* for the Gaussian, Bernoulli, and multinomial distributions, respectively. Canonical links can be found for all of the distributions in the exponential family, thus providing a solid statistical foundation for handling a wide variety of data formats at the output layer of a network, including counts, time intervals, and rates.

The gradient of the cost function for mixture models has an interesting interpretation. Taking the partial derivative of $J(\mathbf{w})$ in Equation 66.20 with respect to $\boldsymbol{\mu}_i$, we find

$$\frac{\partial J}{\partial \boldsymbol{\mu}_i} = \sum_n h_{n,i} \Sigma_i (\mathbf{x}_n - \boldsymbol{\mu}_i) \quad (66.23)$$

where $h_{n,i}$ is defined as follows:

$$h_{n,i} = \frac{\pi_i |\Sigma_i|^{-1/2} \exp \left\{ -\frac{1}{2} (\mathbf{x}_n - \boldsymbol{\mu}_i)^T \Sigma_i^{-1} (\mathbf{x}_n - \boldsymbol{\mu}_i) \right\}}{\sum_k \pi_k |\Sigma_k|^{-1/2} \exp \left\{ -\frac{1}{2} (\mathbf{x}_n - \boldsymbol{\mu}_k)^T \Sigma_k^{-1} (\mathbf{x}_n - \boldsymbol{\mu}_k) \right\}} \quad (66.24)$$

When summed over i , the quantity $h_{n,i}$ sums to one and is often viewed as the “responsibility” or “credit” assigned to the i th component for the n th data point. Indeed, interpreting Equation 66.24 using Bayes rule shows that $h_{n,i}$ is the posterior probability that the n th data point is generated by the i th component

Gaussian. A learning algorithm based on this gradient will move the i th mean μ_i toward the data point \mathbf{x}_n , with the effective step size proportional to $h_{n,i}$.

The gradient for a mixture model will always take the form of a weighted sum of the gradients associated with the component models, where the weights are the posterior probabilities associated with each of the components. The key computational issue is whether these posterior weights can be computed efficiently. For Gaussian mixture models, the calculation (Equation 66.24) is clearly efficient. For decision trees there is a set of posterior weights associated with each of the nodes in the tree, and a recursion is available that computes the posterior probabilities in an upward sweep [Jordan and Jacobs 1994]. Mixture models in the form of a chain are known as **hidden Markov models**, and the calculation of the relevant posterior probabilities is performed via an efficient algorithm known as the Baum–Welch algorithm.

For general layered network structures, a generic algorithm known as backpropagation is available to calculate gradient vectors [Rumelhart et al. 1986]. Backpropagation is essentially the chain rule of calculus realized as a graphical algorithm. As applied to layered networks it provides a simple and efficient method that calculates a gradient in $O(W)$ time per training pattern, where W is the number of weights.

66.3.3 Optimization Algorithms

By introducing the principle of maximum likelihood in Section 66.1, we have expressed the problem of learning in neural networks in terms of the minimization of a cost function, $J(\mathbf{w})$, which depends on a vector, \mathbf{w} , of adaptive parameters. An important aspect of this problem is that the gradient vector $\nabla_{\mathbf{w}} J$ can be evaluated efficiently (for example, by backpropagation). Gradient-based minimization is a standard problem in unconstrained nonlinear optimization for which many powerful techniques have been developed over the years. Such algorithms generally start by making an initial guess for the parameter vector \mathbf{w} and then iteratively updating the vector in a sequence of steps,

$$\mathbf{w}^{(\tau+1)} = \mathbf{w}^{(\tau)} + \Delta \mathbf{w}^{(\tau)} \quad (66.25)$$

where τ denotes the step number. The initial parameter vector $\mathbf{w}^{(0)}$ is often chosen at random, and the final vector represents a minimum of the cost function at which the gradient vanishes. Because of the nonlinear nature of neural network models, the cost function is generally a highly complicated function of the parameters and may possess many such minima. Different algorithms differ in how the update $\Delta \mathbf{w}^{(\tau)}$ is computed.

The simplest such algorithm is called *gradient descent* and involves a parameter update which is proportional to the negative of the cost function gradient $\Delta = -\eta \nabla E$ where η is a fixed constant called the learning rate. It should be stressed that gradient descent is a particularly inefficient optimization algorithm. Various modifications have been proposed, such as the inclusion of a *momentum* term, to try to improve its performance. In fact, much more powerful algorithms are readily available, as described in standard textbooks such as Fletcher [1987]. Two of the best known are called *conjugate gradients* and *quasi-Newton* (or *variable metric*) methods. For the particular case of a sum-of-squares cost function, the *Levenberg–Marquardt* algorithm can also be very effective. Software implementations of these algorithms are widely available.

The algorithms discussed so far are called *batch* since they involve using the whole dataset for each evaluation of the cost function or its gradient. There is also a *stochastic* or *on-line* version of gradient descent in which, for each parameter update, the cost function gradient is evaluated using just one of the training vectors at a time (which are then cycled either in order or in a random sequence). Although this approach fails to make use of the power of sophisticated methods such as conjugate gradients, it can prove effective for very large datasets, particularly if there is significant redundancy in the data.

66.3.4 Hessian Matrices, Error Bars, and Pruning

After a set of weights have been found for a neural network using an optimization procedure, it is often useful to examine second-order properties of the fitted network as captured in the Hessian matrix $H = \partial^2 J / \partial \mathbf{w} \partial \mathbf{w}^T$. Efficient algorithms have been developed to compute the Hessian matrix in time $O(W^2)$

[Bishop 1995]. As in the case of the calculation of the gradient by backpropagation, these algorithms are based on recursive message passing in the network.

One important use of the Hessian matrix lies in the calculation of error bars on the outputs of a network. If we approximate the cost function locally as a quadratic function of the weights (an approximation which is equivalent to making a Gaussian approximation for the log likelihood), then the estimated variance of the i th output y_i can be shown to be

$$\hat{\sigma}_{y_i}^2 = \left(\frac{\partial y_i}{\partial \mathbf{w}} \right)^T H^{-1} \left(\frac{\partial y_i}{\partial \mathbf{w}} \right) \quad (66.26)$$

where the gradient vector $\partial y_i / \partial \mathbf{w}$ can be calculated via backpropagation.

The Hessian matrix also is useful in pruning algorithms. A pruning algorithm deletes weights from a fitted network to yield a simpler network that may outperform a more complex, **overfitted** network (discussed subsequently) and may be easier to interpret. In this setting, the Hessian is used to approximate the increase in the cost function due to the deletion of a weight. A variety of such pruning algorithms is available [cf. Bishop 1995].

66.3.5 Complexity Control

In previous sections we have introduced a variety of models for representing probability distributions, we have shown how the parameters of the models can be optimized by maximizing the likelihood function, and we have outlined a number of powerful algorithms for performing this minimization. Before we can apply this framework in practice there is one more issue we need to address, which is that of model complexity. Consider the case of a mixture model given by Equation 66.2. The number of input variables will be determined by the particular problem at hand. However, the number M of component densities has yet to be specified. Clearly if M is too small the model will be insufficiently flexible and we will obtain a poor representation of the true density. What is not so obvious is that if M is too large we can also obtain poor results. This effect is known as *overfitting* and arises because we have a dataset of finite size. It is illustrated using the simple example of mixture density estimation in Figure 66.4. Here a set of 100 data points in one dimension has been generated from a distribution consisting of a mixture of two Gaussians (shown by the dashed curves). This dataset has then been fitted by a mixture of M Gaussians by use of the expectation-maximization (EM) algorithm. We see that a model with 1 component ($M = 1$) gives a poor representation of the true distribution from which the data were generated, and in particular is unable to capture the

FIGURE 66.4 Effects of model complexity illustrated by modeling a mixture of two Gaussians (shown by the dashed curves) using a mixture of M Gaussians (shown by the solid curves). The results are obtained for 20 cycles of EM.

bimodal aspect. For $M = 2$ the model gives a good fit, as we expect since the data were themselves generated from a two-component Gaussian mixture. However, increasing the number of components to $M = 10$ gives a poorer fit, even though this model contains the simpler models as special cases.

The problem is a very fundamental one and is associated with the fact that we are trying to infer an entire distribution function from a finite number of data points, which is necessarily an ill-posed problem. In regression, for example, there are infinitely many functions which will give a perfect fit to the finite number of data points. If the data are noisy, however, the best generalization will be obtained for a function which does not fit the data perfectly but which captures the underlying function from which the data were generated. By increasing the flexibility of the model, we are able to obtain ever better fits to the training data, and this is reflected in a steadily increasing value for the likelihood function at its maximum. Our goal is to model the true underlying density function from which the data were generated since this allows us to make the best predictions for new data. We see that the best approximation to this density occurs for an intermediate value of M .

The same issue arises in connection with nonlinear regression and classification problems. For example, the number M of hidden units in an MLP network controls the model complexity and must be optimized to give the best generalization. In a practical application, we can train a variety of different models having different complexities, compare their generalization performance using an independent validation set, and then select the model with the best generalization. In fact, the process of optimizing the complexity using a validation set can lead to some partial overfitting to the validation data itself, and so the final performance of the selected model should be confirmed using a third independent data set called a *test set*.

Some theoretical insight into the problem of overfitting can be obtained by decomposing the error into the sum of bias and variance terms [Geman et al. 1992]. A model which is too inflexible is unable to represent the true structure in the underlying density function, and this gives rise to a high bias. Conversely, a model which is too flexible becomes tuned to the specific details of the particular data set and gives a high variance. The best generalization is obtained from the optimum tradeoff of bias against variance.

As we have already remarked, the problem of inferring an entire distribution function from a finite data set is fundamentally ill posed since there are infinitely many solutions. The problem becomes well posed only when some additional constraint is imposed. This constraint might be that we model the data using a network having a limited number of hidden units. Within the range of functions which this model can represent there is then a unique function which best fits the data. Implicitly, we are assuming that the underlying density function from which the data were drawn is relatively smooth. Instead of limiting the number of parameters in the model, we can encourage smoothness more directly using the technique of **regularization**. This involves adding penalty term Ω to the original cost function J to give the total cost function \tilde{J} of the form

$$\tilde{J} = J + \nu\Omega \quad (66.27)$$

where ν is called a regularization coefficient. The network parameters are determined by minimizing \tilde{J} , and the value of ν controls the degree of influence of the penalty term Ω . In practice, Ω is typically chosen to encourage smooth functions. The simplest example is called *weight decay* and consists of the sum of the squares of all of the adaptive parameters in the model,

$$\Omega = \sum_i w_i^2 \quad (66.28)$$

Consider the effect of such a term on the MLP function (Equation 66.9). If the weights take very small values then the network outputs become approximately linear functions of the inputs (since the sigmoidal function is approximately linear for small values of its argument). The value of ν in Equation 66.27 controls the effective complexity of the model, so that for large ν the model is oversmoothed (corresponding to high bias), whereas for small ν the model can overfit (corresponding to high variance). We can therefore consider a network with a relatively large number of hidden units and control the effective complexity by changing ν . In practice, a suitable value for ν can be found by seeking the value which gives the best performance on a validation set.

The weight decay regularizer (Equation 66.28) is simple to implement but suffers from a number of limitations. Regularizers used in practice may be more sophisticated and may contain multiple regularization coefficients [Neal 1994].

Regularization methods can be justified within a general theoretical framework known as *structural risk minimization* [Vapnik 1995]. Structural risk minimization provides a quantitative measure of complexity known as the **VC dimension**. The theory shows that the VC dimension predicts the difference between performance on a training set and performance on a test set; thus, the sum of log likelihood and (some function of) VC dimension provides a measure of generalization performance. This motivates regularization methods (Equation 66.27) and provides some insight into possible forms for the regularizer Ω .

66.3.6 Bayesian Viewpoint

In earlier sections we discussed network training in terms of the minimization of a cost function derived from the principle of maximum a posteriori or maximum likelihood estimation. This approach can be seen as a particular approximation to a more fundamental, and more powerful, framework based on Bayesian statistics. In the maximum likelihood approach, the weights \mathbf{w} are set to a specific value, \mathbf{w}_{ML} , determined by minimization of a cost function. However, we know that there will typically be other minima of the cost function which might give equally good results. Also, weight values close to \mathbf{w}_{ML} should give results which are not too different from those of the maximum likelihood weights themselves.

These effects are handled in a natural way in the Bayesian viewpoint, which describes the weights not in terms of a specific set of values but in terms of a probability distribution over all possible values. As discussed earlier (cf. Equation 66.13), once we observe the training dataset \mathcal{D} we can compute the corresponding *posterior* distribution using Bayes' theorem, based on a *prior* distribution function $p(\mathbf{w})$ (which will typically be very broad), and a *likelihood* function $p(\mathcal{D} | \mathbf{w})$,

$$p(\mathbf{w} | \mathcal{D}) = \frac{p(\mathcal{D} | \mathbf{w})p(\mathbf{w})}{p(\mathcal{D})} \quad (66.29)$$

The likelihood function will typically be very small except for values of \mathbf{w} for which the network function is reasonably consistent with the data. Thus, the posterior distribution $p(\mathbf{w} | \mathcal{D})$ will be much more sharply peaked than the prior distribution $p(\mathbf{w})$ (and will typically have multiple maxima). The quantity we are interested in is the predicted distribution of target values \mathbf{t} for a new input vector \mathbf{x} once we have observed the data set \mathcal{D} . This can be expressed as an integration over the posterior distribution of weights of the form

$$p(\mathbf{t} | \mathbf{x}, \mathcal{D}) = \int p(\mathbf{t} | \mathbf{x}, \mathbf{w})p(\mathbf{w} | \mathcal{D})d\mathbf{w} \quad (66.30)$$

where $p(\mathbf{t} | \mathbf{x}, \mathbf{w})$ is the conditional probability model discussed in the Introduction.

If we suppose that the posterior distribution $p(\mathbf{w} | \mathcal{D})$ is sharply peaked around a single most-probable value \mathbf{w}_{MP} , then we can write Equation 66.30 in the form:

$$p(\mathbf{t} | \mathbf{x}, \mathcal{D}) \simeq p(\mathbf{t} | \mathbf{x}, \mathbf{w}_{MP}) \int p(\mathbf{w} | \mathcal{D})d\mathbf{w} \quad (66.31)$$

$$= p(\mathbf{t} | \mathbf{x}, \mathbf{w}_{MP}) \quad (66.32)$$

and so predictions can be made by fixing the weights to their most probable values. We can find the most probable weights by maximizing the posterior distribution or equivalently by minimizing its negative logarithm. Using Equation 66.29, we see that \mathbf{w}_{MP} is determined by minimizing a regularized cost function of the form in Equation 66.27 in which the negative log of the prior $-\ln p(\mathbf{w})$ represents the regularizer $\nu\Omega$. For example, if the prior consists of a zero-mean Gaussian with variance ν^{-1} , then we obtain the weight-decay regularizer of Equation 66.28.

The posterior distribution will become sharply peaked when the size of the dataset is large compared to the number of parameters in the network. For datasets of limited size, however, the posterior distribution has a finite width and this adds to the uncertainty in the predictions for \mathbf{t} , which can be expressed in

terms of error bars. Bayesian error bars can be evaluated using a local Gaussian approximation to the posterior distribution [MacKay 1992]. The presence of multiple maxima in the posterior distribution also contributes to the uncertainties in predictions. The capability to assess these uncertainties can play a crucial role in practical applications.

The Bayesian approach can also deal with more general problems in complexity control. This can be done by considering the probabilities of a set of alternative models, given the dataset

$$p(\mathcal{H}_i | \mathcal{D}) = \frac{p(\mathcal{D} | \mathcal{H}_i)p(\mathcal{H}_i)}{p(\mathcal{D})} \quad (66.33)$$

Here different models can also be interpreted as different values of regularization parameters as these too control model complexity. If the models are given the same prior probabilities $p(\mathcal{H}_i)$ then they can be ranked by considering the *evidence* $p(\mathcal{D} | \mathcal{H}_i)$, which itself can be evaluated by integration over the model parameters \mathbf{w} . We can simply select the model with the greatest probability. However, a full Bayesian treatment requires that we form a linear combination of the predictions of the models in which the weighting coefficients are given by the model probabilities.

In general, the required integrations, such as that in Equation 66.30, are analytically intractable. One approach is to approximate the posterior distribution by a Gaussian centered on \mathbf{w}_{MP} and then to linearize $p(\mathbf{t} | \mathbf{x}, \mathbf{w})$ about \mathbf{w}_{MP} so that the integration can be performed analytically [MacKay 1992]. Alternatively, sophisticated Monte Carlo methods can be employed to evaluate the integrals numerically [Neal 1994]. An important aspect of the Bayesian approach is that there is no need to keep data aside in a validation set as is required when using maximum likelihood. In practical applications for which the quantity of available data is limited, it is found that a Bayesian treatment generally outperforms other approaches.

66.3.7 Preprocessing, Invariances, and Prior Knowledge

We have already seen that neural networks can approximate essentially arbitrary nonlinear functional mappings between sets of variables. In principle, we could therefore use a single network to transform the raw input variables into the required final outputs. However, in practice for all but the simplest problems the results of such an approach can be improved upon considerably by incorporating various forms of preprocessing, for reasons we shall outline in the following.

One of the simplest and most common forms of preprocessing consists of a simple normalization of the input, and possibly also target, variables. This may take the form of a linear rescaling of each input variable independently to give it zero mean and unit variance over the training set. For some applications, the original input variables may span widely different ranges. Although a linear rescaling of the inputs is equivalent to a different choice of first-layer weights, in practice the optimization algorithm may have considerable difficulty in finding a satisfactory solution when typical input values are substantially different. Similar rescaling can be applied to the output values, in which case the inverse of the transformation needs to be applied to the network outputs when the network is presented with new inputs. Preprocessing is also used to encode data in a suitable form. For example, if we have categorical variables such as red, green, and blue, these may be encoded using a 1-of-3 binary representation.

Another widely used form of preprocessing involves reducing the dimensionality of the input space. Such transformations may result in loss of information in the data, but the overall effect can be a significant improvement in performance as a consequence of the curse of dimensionality discussed in the complexity control section. The finite dataset is better able to specify the required mapping in the lower dimensional space. Dimensionality reduction may be accomplished by simply selecting a subset of the original variables but more typically involves the construction of new variables consisting of linear or nonlinear combinations of the original variables called *features*. A standard technique for dimensionality reduction is principal component analysis [Anderson 1984]. Such methods, however, make use only of the input data and ignore the target values and can sometimes be significantly suboptimal.

Yet another form of preprocessing involves correcting deficiencies in the original data. A common occurrence is that some of the input variables are missing for some of the data points. Correction

of this problem in a principled way requires that the probability distribution $p(\mathbf{x})$ of input data be modeled.

One of the most important factors determining the performance of real-world applications of neural networks is the use of *prior knowledge*, which is information additional to that present in the data. As an example, consider the problem of classifying handwritten digits discussed in [Section 66.1](#). The most direct approach would be to collect a large training set of digits and to train a feedforward network to map from the input image to a set of 10 output values representing posterior probabilities for the 10 classes. However, we know that the classification of a digit should be independent of its position within the input image. One way of achieving such *translation invariance* is to make use of the technique of *shared weights*. This involves a network architecture having many hidden layers in which each unit takes inputs only from a small patch, called a *receptive field*, of units in the previous layer. By a process of constraining neighboring units to have common weights, it can be arranged that the output of the network is insensitive to translations of the input image. A further benefit of weight sharing is that the number of independent parameters is much smaller than the number of weights, which assists with the problem of model complexity. This approach is the basis for the highly successful U.S. postal code recognition system of LeCun et al. [1989]. An alternative to shared weights is to enlarge the training set artificially by generating virtual examples based on applying translations and other transformations to the original training set [Poggio and Vetter 1992].

66.4 Graphical Models

Neural networks express relationships between variables by utilizing the representational language of graph theory. Variables are associated with nodes in a graph and transformations of variables are based on algorithms that propagate numerical messages along the links of the graph. Moreover, the graphs are often accompanied by probabilistic interpretations of the variables and their interrelationships. As we have seen, such probabilistic interpretations allow a neural network to be understood as a form of a probabilistic model and reduce the problem of learning the weights of a network to a problem in statistics.

Related graphical models have been studied throughout statistics, engineering, and AI in recent years. Hidden Markov models, Kalman filters, and path analysis models are all examples of graphical probabilistic models that can be fitted to data and used to make inferences. The relationship between these models and neural networks is rather strong; indeed, it is often possible to reduce one kind of model to the other. In this section, we examine these relationships in some detail and provide a broader characterization of neural networks as members of a general family of graphical probabilistic models.

Many interesting relationships have been discovered between graphs and probability distributions [Spiegelhalter et al. 1993, Pearl 1988]. These relationships derive from the use of graphs to represent conditional independencies among random variables. In an undirected graph, there is a direct correspondence between conditional independence and graph separation: random variables X_i and X_k are conditionally independent given X_j if nodes X_i and X_k are separated by node X_j (we use the symbol X_j to represent both a random variable and a node in a graph). This statement remains true for sets of nodes. [See [Figure 66.5\(a\)](#).] Directed graphs have a somewhat different semantics due to the ability of directed graphs to represent induced dependencies. An induced dependency is a situation in which two nodes which are marginally independent become conditionally dependent given the value of a third node. [See [Figure 66.5\(b\)](#).] Suppose, for example, that X_i and X_k represent independent coin tosses, and X_j represents the sum of X_i and X_k . Then X_i and X_k are marginally independent but are conditionally dependent given X_j . The semantics of independence in directed graphs is captured by a graphical criterion known as *d-separation* [Pearl 1988], which differs from undirected separation only in those cases in which paths have two arrows arriving at the same node [as in [Figure 66.5\(b\)](#)].

Although the neural network architectures that we have discussed until now all have been based on directed graphs, undirected graphs also play an important role in neural network research. Constraint satisfaction architectures, including the Hopfield network [Hopfield 1982] and the **Boltzmann machine** [Hinton and Sejnowski 1986], are the most prominent examples. A Boltzmann machine is an undirected probabilistic graph that respects the conditional independency semantics previously described

FIGURE 66.5 (a) An undirected graph in which X_i is independent of X_j given X_k and X_l , and X_k is independent of X_l given X_i and X_j . (b) A directed graph in which X_i and X_k are marginally independent but are conditionally dependent given X_j .

FIGURE 66.6 (a) A directed graph representation of an HMM. Each horizontal link is associated with the transition matrix A , and each vertical link is associated with the emission matrix B . (b) An HMM as a Boltzmann machine. The parameters on the horizontal links are logarithms of the entries of the A matrix, and the parameters on the vertical links are logarithms of the entries of the B matrix. The two representations yield the same joint probability distribution.

[cf. Figure 66.5(a)]. Each node in a Boltzmann machine is a binary-valued random variable X_i (or, more generally, a discrete-valued random variable). A probability distribution on the 2^N possible configurations of such variables is defined via an *energy function* E . Let J_{ij} be the weight on the link between X_i and X_j , let $J_{ij} = J_{ji}$, let α index the configurations, and define the energy of configuration α as follows:

$$E_\alpha = - \sum_{i < j} J_{ij} X_i^\alpha X_j^\alpha \quad (66.34)$$

The probability of configuration α is then defined via the Boltzmann distribution:

$$P_\alpha = \frac{e^{-E_\alpha/T}}{\sum_\gamma e^{-E_\gamma/T}} \quad (66.35)$$

where the *temperature* T provides a scale for the energy.

An example of a directed probabilistic graph is the hidden Markov model (HMM). An HMM is defined by a set of *state variables* H_i , where i is generally a time or a space index, a set of output variables O_i , a *probability transition matrix* $A = p(H_i | H_{i-1})$, and an *emission matrix* $B = p(O_i | H_i)$. The directed graph for an HMM is shown in Figure 66.6(a). As can be seen from considering the separatory properties of the graph, the conditional independencies of the HMM are defined by the following Markov conditions:

$$H_i \perp \{H_1, O_1, \dots, H_{i-2}, O_{i-2}, O_{i-1}\} | H_{i-1}, \quad 2 \leq i \leq N \quad (66.36)$$

and

$$O_i \perp \{H_1, O_1, \dots, H_{i-1}, O_{i-1}\} | H_i, \quad 2 \leq i \leq N \quad (66.37)$$

where the symbol \perp is used to denote independence.

Figure 66.6(b) shows that it is possible to treat an HMM as a special case of a Boltzmann machine [Luttrell 1989, Saul and Jordan 1995]. The probabilistic structure of the HMM can be captured by defining the weights on the links as the logarithms of the corresponding transition and emission probabilities. The Boltzmann distribution (Equation 66.35) then converts the additive energy into the product form of the standard HMM probability distribution. As we will see, this reduction of a directed graph to an undirected graph is a recurring theme in the graphical model formalism.

General mixture models are readily viewed as graphical models [Buntine 1994]. For example, the unconditional mixture model of Equation 66.2 can be represented as a graphical model with two nodes — a multinomial hidden node, which represents the selected component, a visible node representing \mathbf{x} , with a directed link from the hidden node to the visible node (hidden/visible distinction discussed subsequently). Conditional mixture models [Jacobs et al. 1991] simply require another visible node with directed links to the hidden node and the visible nodes. Hierarchical conditional mixture models [Jordan and Jacobs 1994] require a chain of hidden nodes, one hidden node for each level of the tree.

Within the general framework of probabilistic graphical models, it is possible to tackle general problems of inference and learning. The key problem that arises in this setting is the problem of computing the probabilities of certain nodes, which we will refer to as *hidden nodes*, given the observed values of other nodes, which we will refer to as *visible nodes*. For example, in an HMM, the variables O_i are generally treated as visible, and it is desired to calculate a probability distribution on the hidden states H_i . A similar inferential calculation is required in the mixture models and the Boltzmann machine.

Generic algorithms have been developed to solve the inferential problem of the calculation of posterior probabilities in graphs. Although a variety of inference algorithms have been developed, they can all be viewed as essentially the same underlying algorithm [Shachter et al. 1994]. Let us consider undirected graphs. A special case of an undirected graph is a *triangulated graph* [Spiegelhalter et al. 1993], in which any cycle having four or more nodes has a chord. For example, the graph in Figure 66.5(a) is not triangulated but becomes triangulated when a link is added between nodes X_i and X_j . In a triangulated graph, the cliques of the graph can be arranged in the form of a *junction tree*, which is a tree having the property that any node that appears in two different cliques in the tree also appears in every clique on the path that links the two cliques (the “running intersection property”). This cannot be achieved in nontriangulated graphs. For example, the cliques in Figure 66.5(a) are $\{X_i, X_k\}$, $\{X_k, X_j\}$, $\{X_j, X_l\}$, and it is not possible to arrange these cliques into a tree that obeys the running intersection property. If a chord is added, the resulting cliques are $\{X_i, X_j, X_k\}$ and $\{X_i, X_j, X_l\}$, and these cliques can be arranged as a simple chain that trivially obeys the running intersection property. In general, it turns out that the probability distributions corresponding to triangulated graphs can be characterized as *decomposable*, which implies that they can be factorized into a product of local functions (potentials) associated with the cliques in the triangulated graph.* The calculation of posterior probabilities in decomposable distributions is straightforward and can be achieved via a local message-passing algorithm on the junction tree [Spiegelhalter et al. 1993].

Graphs that are not triangulated can be turned into triangulated graphs by the addition of links. If the potentials on the new graph are defined suitably as products of potentials on the original graph, then the independencies in the original graph are preserved. This implies that the algorithms for triangulated graphs can be used for *all* undirected graphs; an untriangulated graph is first triangulated. (See Figure 66.7.) Moreover, it is possible to convert *directed* graphs to undirected graphs in a manner that preserves the probabilistic structure of the original graph [Spiegelhalter et al. 1993]. This implies that the junction tree algorithm is indeed generic; it can be applied to any graphical model.

The problem of calculating posterior probabilities on graphs is NP-hard; thus, a major issue in the use of the inference algorithms is the identification of cases in which they are efficient. Chain structures such as HMMs yield efficient algorithms, and indeed the classical forward-backward algorithm for HMMs is

*An interesting example is a Boltzmann machine on a triangulated graph. The potentials are products of $\exp(J_{ij})$ factors, where the product is taken over all (i, j) pairs in a particular clique. Given that the product across potentials must be the joint probability, this implies that the partition function (the denominator of Equation 66.35) must be unity in this case.

FIGURE 66.7 The basic structure of the junction tree algorithm for undirected graphs. The graph in (a) is first triangulated (b), then the cliques are identified (c), and arranged into a tree (d). Products of potential functions on the nodes in (d) yield probability distributions on the nodes in (a).

a special, efficient case of the junction tree algorithm [Smyth et al. 1996]. Decision tree structures such as the hierarchical mixture of experts yield efficient algorithms, and the recursive posterior probability calculation of Jordan and Jacobs [1994] described earlier is also a special case of the junction tree algorithm. All of the simpler mixture model calculations described earlier are therefore also special cases. Another interesting special case is the state estimation algorithm of the Kalman filter [Shachter and Kenley 1989]. Finally, there are a variety of special cases of the Boltzmann machine which are amenable to the exact calculations of the junction tree algorithm [Saul and Jordan 1995].

For graphs that are outside of the tractable categories of trees and chains, the junction tree algorithm often performs surprisingly well, but for highly connected graphs the algorithm can be too slow. In such cases, approximate algorithms such as Gibbs sampling are utilized. A virtue of the graphical framework is that Gibbs sampling has a generic form, which is based on the notion of a *Markov boundary* [Pearl 1988]. A special case of this generic form is the stochastic update rule for general Boltzmann machines.

Our discussion has emphasized the unifying framework of graphical models both for expressing probabilistic dependencies in graphs and for describing algorithms that perform the inferential step of calculating posterior probabilities on these graphs. The unification goes further, however, when we consider learning. A generic methodology known as the expectation-maximization algorithm is available for MAP and Bayesian estimation in graphical models [Dempster et al. 1977]. EM is an iterative method, based on two alternating steps: an *E step*, in which the values of hidden variables are estimated, based on the current values of the parameters and the values of visible variables, and an *M step*, in which the parameters are updated, based on the estimated values obtained from the E step. Within the framework of the EM algorithm, the junction tree algorithm can readily be viewed as providing a generic E step. Moreover, once the estimated values of the hidden nodes are obtained from the E step, the graph can be viewed as fully observed, and the M step is a standard MAP or ML problem. The standard algorithms for all of the tractable architectures described (mixtures, trees, and chains) are, in fact, instances of this general graphical EM algorithm, and the learning algorithm for general Boltzmann machines is a special case of a generalization of EM known as GEM [Dempster et al. 1977].

What about the case of feedforward neural networks such as the multilayer perceptron? It is, in fact, possible to associate binary hidden values with the hidden units of such a network (cf. our earlier discussion of the logistic function; see also Amari [1995]) and apply the EM algorithm directly. For N hidden units, however, there are 2^N patterns whose probabilities must be calculated in the E step. For large N , this is an intractable computation, and recent research has therefore begun to focus on fast methods for approximating these distributions [Hinton et al. 1995, Saul et al. 1996].

Defining Terms

Boltzmann machine: An undirected network of discrete valued random variables, where an energy function is associated with each of the links, and for which a probability distribution is defined by the Boltzmann distribution.

- Classification:** A learning problem in which the goal is to assign input vectors to one of a number of (usually mutually exclusive) classes.
- Cost function:** A function of the adaptive parameters of a model whose minimum is used to define suitable values for those parameters. It may consist of a likelihood function and additional terms.
- Decision tree:** A network that performs a sequence of classificatory decisions on an input vector and produces an output vector that is conditional on the outcome of the decision sequence.
- Density estimation:** The problem of modeling a probability distribution from a finite set of examples drawn from that distribution.
- Discriminant function:** A function of the input vector that can be used to assign inputs to classes in a classification problem.
- Hidden Markov model:** A graphical probabilistic model characterized by a state vector, an output vector, a state transition matrix, an emission matrix, and an initial state distribution.
- Likelihood function:** The probability of observing a particular data set under the assumption of a given parametrized model, expressed as a function of the adaptive parameters of the model.
- Mixture model:** A probability model that consists of a linear combination of simpler component probability models.
- Multilayer perceptron:** The most common form of neural network model, consisting of successive linear transformations followed by processing with nonlinear activation functions.
- Overfitting:** The problem in which a model which is too complex captures too much of the noise in the data, leading to poor generalization.
- Radial basis function network:** A common network model consisting of a linear combination of basis functions, each of which is a function of the difference between the input vector and a center vector.
- Regression:** A learning problem in which the goal is to map each input vector to a real-valued output vector.
- Regularization:** A technique for controlling model complexity and improving generalization by the addition of a penalty term to the cost function.
- VC dimension:** A measure of the complexity of a model. Knowledge of the VC dimension permits an estimate to be made of the difference between performance on the training set and performance on a test set.

Further Information

In this chapter we have emphasized the links between neural networks and statistical pattern recognition. A more extensive treatment from the same perspective can be found in Bishop [1995]. For a view of recent research in the field, the proceedings of the annual Neural Information Processing Systems (NIPS), MIT Press, conferences are highly recommended.

Neural computing is now a very broad field, and there are many topics which have not been discussed for lack of space. Here we aim to provide a brief overview of some of the more significant omissions, and to give pointers to the literature.

The resurgence of interest in neural networks during the 1980s was due in large part to work on the statistical mechanics of fully connected networks having symmetric connections (i.e., if unit i sends a connection to unit j then there is also a connection from unit j back to unit i with the same weight value). We have briefly discussed such systems; a more extensive introduction to this area can be found in Hertz et al. [1991].

The implementation of neural networks in specialist very large-scale integrated (VLSI) hardware has been the focus of much research, although by far the majority of work in neural computing is undertaken using software implementations running on standard platforms.

An implicit assumption throughout most of this chapter is that the processes which give rise to the data are stationary in time. The techniques discussed here can readily be applied to problems such as time series forecasting, provided this stationarity assumption is valid. If, however, the generator of the data is itself evolving with time, then more sophisticated techniques must be used, and these are the focus of much current research (see Bengio [1996]).

One of the original motivations for neural networks was as models of information processing in biological systems such as the human brain. This remains the subject of considerable research activity, and there is a continuing flow of ideas between the fields of neurobiology and of artificial neural networks. Another historical springboard for neural network concepts was that of adaptive control, and again this remains a subject of great interest.

67.1 Introduction

In this chapter, we use the generic term **planning** to encompass both planning and scheduling problems, and the terms *planner* or *planning system* to refer to software for planning or scheduling. Planning is concerned with reasoning about the consequences of acting in order to choose from among a set of possible courses of action. In the simplest case, a planner might enumerate a set of possible courses of action, consider their consequences in turn, and choose one particular course of action that satisfies a given set of requirements.

Algorithmically, a planning problem has as input a set of possible courses of actions, a predictive model for the underlying dynamics, and a performance measure for evaluating courses of action. The output or solution to a planning problem is one or more courses of action that satisfy the specified requirements for performance. Most planning problems are combinatorial in the sense that the number of possible courses of actions or the time required to evaluate a given course of action is exponential in the description of the problem.

Just because there is an exponential number of possible courses of action does not imply that a planner has to enumerate them all in order to find a solution. However, many planning problems can be shown to be NP-hard, and, for these problems, all known exact algorithms take exponential time in the worst case. The computational complexity of planning problems often leads practitioners to consider approximations, computation time vs. solution quality tradeoffs, and heuristic methods.

67.1.1 Planning and Scheduling Problems

We use the travel planning problem as our canonical example of planning (distinct from scheduling). A *travel planning problem* consists of a set of travel options (airline flights, cabs, subways, rental cars,

and shuttle services), travel dynamics (information concerning travel times and costs and how time and cost are affected by weather or other factors), and a set of requirements. The requirements for a travel planning problem include an itinerary (be in Providence on Monday and Tuesday, and in Phoenix from Wednesday morning until noon on Friday) and constraints on solutions (leave home no earlier than the Sunday before, arrive back no later than the Saturday after, and spend no more than \$1000 in travel-related costs). Planning can be cast either in terms of **satisficing** (find some solution satisfying the constraints) or **optimizing** (find the least cost solution satisfying the constraints).

We use the job-shop scheduling problem as our canonical example of scheduling (distinct from planning). The specification of a *job-shop scheduling problem* includes a set of jobs, where each job is a partially ordered set of tasks of specified duration, and a set of machines, where each machine is capable of carrying out a subset of the set of all tasks. A *feasible solution* to a job-shop scheduling problem is a mapping from tasks to machines over specific intervals of time, so that no machine has assigned to it more than one task at a time and each task is completed before starting any other task that follows it in the specified partial order. Scheduling can also be cast in terms of either satisficing (find a feasible solution) or optimizing (find a solution that minimizes the total time required to complete all jobs).

67.1.2 Distinctions and Disciplines

To distinguish between planning and scheduling, we note that scheduling is primarily concerned with figuring out *when* to carry out actions whereas planning is concerned with *what* actions need to be carried out. In practice, this distinction often blurs and many real-world problems involve figuring out both what and when.

In real job shops, each task need not specify a rigid sequence of steps (the what). For example, drilling a hole in a casting may be accomplished more quickly if a positioning device, called a fixture, is installed on the machine used for drilling. However, the fixture takes time to install and may interfere with subsequent machining operations for other tasks. Installing a fixture for one task may either expedite (the next job needs the same fixture) or retard (the fixture is in the way in the next job) subsequent jobs. In this version of our canonical scheduling problem, planning can take on considerable importance.

We can, however, design a problem so as to emphasize either planning or scheduling. For example, it may be reasonable to let a human decide the what (e.g., the type of machine and specific sequence of machining steps for each task) and a computer program decide the when (e.g., the time and machine for each task). This division of labor has allowed the field of operations research to focus effort on solving problems that stress scheduling and finesse planning, as we previously distinguished the two. Restricting attention to scheduling has the effect of limiting the options available to the planner, thereby limiting the possible interactions among actions and simplifying the combinatorics. In addition, some scheduling problems do not allow for the possibility of events outside the direct control of the planner, so-called *exogenous* events. Planning researchers in artificial intelligence generally allow a wide range of options (specifying both what and when) resulting in a very rich set of interactions among the individual actions in a given course of action and between actions and exogenous events.

The travel planning problem includes as a special case the classic traveling salesperson problem, a problem of considerable interest in operations research. In the traveling salesperson problem, there is a completely connected graph with L vertices corresponding to L distinct cities, an $L \times L$ matrix whose entries encode the distance between each pair of cities, and the objective is to find a minimal-length tour of a specified subset of the cities. The classic traveling salesperson problem involves a very limited set of possible interactions (e.g., you must finish one leg of a tour before beginning the next, and the next leg of a tour must begin at the city in which the previous leg ended). In contrast, variants of the travel planning problem studied in artificial intelligence generally consider a much richer set of possible interactions (e.g., if you start on a multileg air trip it is generally more cost effective to continue with the same airline; travel that extends over a Saturday is less expensive than travel that does not).

Planning of the sort studied in artificial intelligence is similar in some respects to problems studied in a variety of other disciplines. We have already mentioned operations research; planning is also similar to the

problem of synthesizing controllers in control theory or the problem of constructing decision procedures in various decision sciences. Planning problems of the sort considered in this chapter differ from those studied in other disciplines mainly in the details of their formulation. Planning problems studied in artificial intelligence typically involve very complex dynamics, requiring expressive languages for their representation, and encoding a wide range of knowledge, often symbolic, but invariably rich and multifaceted.

67.2 Classifying Planning Problems

In this section, we categorize different planning problems according to their inputs: the set of basic courses of action, the underlying dynamics, and the performance measure. We begin by considering models used to predict the consequences of action.

67.2.1 Representing Dynamical Systems

We refer to the environment in which actions are carried out as a **dynamical system**. A description of the environment at an instant of time is called the *state* of the system. We assume that there is a finite, but large set of states \mathcal{S} , and a finite set of actions \mathcal{A} , that can be executed.

States are described by a vector of *state variables*, where each state variable represents some aspect of the environment that can change over time (e.g., the location or color of an object). The resulting dynamical system can be described as a deterministic, nondeterministic, or stochastic finite-state machine, and time is isomorphic to the integers. In the case of a deterministic finite-state machine, the dynamical system is defined by a **state-transition function** f that takes a state $s_t \in \mathcal{S}$ and an action $a_t \in \mathcal{A}$ and returns the next state $f(s_t, a_t) = s_{t+1} \in \mathcal{S}$.

If there are N state variables each of which can take on two or more possible values, then there are as many as 2^N states and the state-transition function is N dimensional. We generally assume each state variable at t depends on only a small number (at most M) of state variables at $t - 1$. This assumption enables us to *factor* the state-transition function f into N functions, each of dimension at most M , so that $f(s, a) = \langle g_1(s, a), \dots, g_N(s, a) \rangle$ where $g_i(s, a)$ represents the i th state variable.

In most planning problems, a plan is constructed at one time and executed at a later time. The state-transition function models the evolution of the state of the dynamical system as a consequence of actions carried out by a *plan executor*. We also want to model the information available to the plan executor. The plan executor may be able to observe the state of the dynamical system, partial state information corrupted by noise, or only the current time. We assume that there is a set of possible observations \mathcal{O} and the information available to the plan executor at time t is determined by the current state and the *output function* $h: \mathcal{S} \rightarrow \mathcal{O}$, so that $h(s_t) = o_t$. We also assume that the plan executor has a clock and can determine the current time t .

Figure 67.1 depicts the general planning problem. The planner is notated as Γ ; it takes as input the current observation o_t and has as output the current **plan** π_t . The planner need not issue a new plan on

FIGURE 67.1 A block diagram for the general planning problem with state-transition function f , output function h , planner Γ , and plan executor Ψ .

every state transition and can keep a history of past observations if required. The plan executor is notated as Ψ ; it takes as input the current observation o_t and the current plan π_t and has as output the current action a_t .

In the classic formulation of the problem, all planning is done prior to any execution. This formulation is inappropriate in cases where new information becomes available in the midst of execution and replanning is called for. The idea of the planner and plan executor being part of the specification of a planning problem is relatively new in artificial intelligence. The theory that relates to accounting for computations performed during execution is still in its infancy and is only touched upon briefly in this chapter.

Some physical processes modeled as dynamical systems evolve deterministically; the next state of the system is completely determined by the current state and action. Other processes, said to be *stochastic*, are subject to random changes or are so complex that it is often convenient to model their behavior in statistical terms; the next state of such a system is summarized by a distribution over the set of states.

If the state transitions are governed by a stochastic process, then the state-transition and output functions are random functions and we define the state-transition and output conditional probability distributions as follows:

$$\begin{aligned} Pr(f(s_t, a_t) | s_t, a_t) \\ Pr(h(s_t) | s_t) \end{aligned}$$

In the general case, it requires $O(2^N)$ storage to encode these distributions for Boolean state variables. However, in many practical cases, these probability distributions can be factored by taking advantage of independence among state variables.

As mentioned earlier, we assume that the i th state variable at time t depends on a small subset (of size at most M) of the state variables at time $t - 1$. Let $Parents(i, s)$ denote the subset of state variables that the i th state variable depends on in s . We can represent the conditional probability distribution governing state transitions as the following product:

$$Pr(\langle g_1(s_t, a_t), \dots, g_N(s_t, a_t) \rangle | s_t, a_t) = \prod_{i=1}^N Pr(g_i(s_t, a_t) | Parents(i, s_t), a_t)$$

This factored representation requires only $O(N2^M)$ storage for Boolean state variables, which is reasonable assuming that M is relatively small.

The preceding descriptions of dynamical systems provide the semantics for a planning system embedded in a dynamic environment. There remains the question of syntax, specifically: how do you represent the dynamical system? In artificial intelligence, the answer varies widely. Researchers have used first-order logic [Allen et al. 1991], dynamic logic [Rosenschein 1981], **state-space operators** [Fikes and Nilsson 1971], and factored probabilistic state-transition functions [Dean and Kanazawa 1989]. In the later sections, we examine some of these representations in more detail.

In some variants of job-shop scheduling the dynamics are relatively simple. We might assume, for example, that if a job is started on a given machine, it will successfully complete in a fixed, predetermined amount of time known to the planner. Everything is under the control of the planner, and evaluating the consequences of a given plan (schedule) is almost trivial from a computational standpoint.

We can easily imagine variants of the travel planning problems in which the dynamics are quite complicated. For example, we might wish to model flight cancellations and delays due to weather and mechanical failure in terms of a stochastic process. The planner cannot control the weather but it can plan to avoid the deleterious effects of the weather (e.g., take a Southern route if a chance of snow threatens to close Northern airports). In this case, there are factors not under control of the planner and evaluating a given travel plan may require significant computational overhead.

67.2.2 Representing Plans of Action

We have already introduced a set of actions \mathcal{A} . We assume that these actions are *primitive* in that they can be carried out by the hardware responsible for executing plans. Semantically, a plan π is a mapping from what is known at the time of execution to the set of actions. The set of all plans for a given planning problem is notated Π .

For example, a plan might map the current observation o_t to the action a_t to take in the current state s_t . Such a plan would be independent of time. Alternatively, a plan might ignore observations altogether and map the current time t to the action to take in state s_t . Such a plan is independent of the current state, or at least the observable aspects of the current state.

If the action specified by a plan is dependent on observations of the current state, then we say that the plan is *conditional*. If the action specified by a plan is dependent on the current time, then we say that the plan is *time variant*, otherwise we say it is *stationary*. If the mapping is one-to-one, then we say that the plan is deterministic, otherwise it is nondeterministic and possibly stochastic if the mapping specifies a distribution over possible actions.

Conditional plans are said to run in a **closed loop**, since they enable the executor to react to the consequences of prior actions. Unconditional plans are said to run in an **open loop**, since they take no account of exogenous events or the consequences of prior actions that were not predicted using the dynamical model.

Now that we have the semantics for plans, we can think about how to represent them. If the mapping is a function, we can use any convenient representation for functions, including decision trees, tabular formats, hash tables, or artificial neural networks. In some problems, an unconditional, time-variant, deterministic plan is represented as a simple sequence of actions. Alternatively, we might use a set of possible sequences of actions perhaps specified by a partially ordered set of actions to represent a nondeterministic plan [i.e., the plan allows any total order (sequence) consistent with the given partial order].

67.2.3 Measuring Performance

For a deterministic dynamical system in initial state s_0 , a plan π determines a (possibly infinite) sequence of states $h_\pi = \langle s_0, s_1, \dots \rangle$, called a **history or state-space trajectory**. More generally, a dynamical system together with a plan induces a probability distribution over histories, and h_π is a random variable governed by this distribution. A value function V assigns to each history a real value. In the deterministic case, the performance J of a plan π is the value of the resulting history, $J(\pi) = V(h_\pi)$. In the general case, the performance J of a plan is the expected value according to V over all possible histories, $J(\pi) = E[V(h_\pi)]$, where E denotes taking an expectation.

In artificial intelligence planning (distinct from scheduling), much of the research has focused on goal-based performance measures. A **goal** \mathcal{G} is a subset of the set of states \mathcal{S} .

$$V(\langle s_0, s_1, \dots \rangle) = \begin{cases} 1 & \text{if } \exists i, s_i \in \mathcal{G} \\ 0 & \text{otherwise} \end{cases}$$

Alternatively, we can consider the number of transitions until we reach a goal state as a measure of performance.

$$V(\langle s_0, s_1, \dots \rangle) = \begin{cases} -\min_i s_i \in \mathcal{G} & \text{if } \exists i, s_i \in \mathcal{G} \\ -\infty & \text{otherwise} \end{cases}$$

In the stochastic case, the corresponding measure of performance is called *expected time to target*, and the objective in planning is to minimize this measure.

Generalizing on the expected-time-to-target performance measure, we can assign to each state a cost using the cost function C . This cost function yields the following value function on histories:

$$V((s_0, s_1, \dots)) = - \sum_{i=0}^{\infty} C(s_i)$$

In some problems, we may wish to discount future costs using a discounting factor $0 \leq \gamma < 1$,

$$V((s_0, s_1, \dots)) = - \sum_{i=0}^{\infty} \gamma^i C(s_i)$$

This performance measure is called *discounted cumulative cost*. These value functions are said to be *separable* since the total value of a history is a simple sum or weighted sum (in the discounted case) of the costs of each state in the history.

It should be noted that we can use any of the preceding methods for measuring the performance of a plan to define either a satisficing criterion (e.g., find a plan whose performance is above some fixed threshold) or an optimizing criterion (e.g., find a plan maximizing a given measure of performance).

67.2.4 Categories of Planning Problems

Now we are in a position to describe some basic classes of planning problems. A planning problem can be described in terms of its dynamics, either deterministic or stochastic. We might also consider whether the actions of the planner completely or only partially determine the state of the environment.

A planning problem can be described in terms of the knowledge available to the planner or executor. In the problems considered in this chapter, we assume that the planner has an accurate model of the underlying dynamics, but this need not be the case in general. Even if the planner has an accurate predictive model, the executor may not have the necessary knowledge to make use of that model. In particular, the executor may have only partial knowledge of the system state and that knowledge may be subject to errors in observation (e.g., noisy, error-prone sensors).

We can assume that all computations performed by the planner are carried out prior to any execution, in which case the planning problem is said to be **off-line**. Alternatively, the planner may periodically compute a new plan and hand it off to the executor; this sort of planning problem is said to be **on-line**. Given space limitations, we are concerned primarily with off-line planning problems in this chapter.

Now that we have some familiarity with the various classes of planning problems, we consider some specific techniques for solving them. Our emphasis is on the design, analysis, and application of planning algorithms.

67.3 Algorithms, Complexity, and Search

Once we are given a set of possible plans and a *performance function* implementing a given performance measure, we can cast any planning or scheduling problem as a search problem. If we assume that evaluating a plan (applying the performance function) is computationally simple, then the most important issue concerns how we search the space of possible plans. Specifically, given one or more plans currently under consideration, how do we extend the search to consider other, hopefully better, performing plans? We focus on two methods for extending search: *refinement* methods and *repair* methods.

A refinement method takes an existing partially specified plan (schedule) and refines it by adding detail. In job-shop scheduling, for example, we might take a (partial) plan that assigns machines and times to k of the jobs, and extend it so that it accounts for $k + 1$ jobs. Alternatively, we might build a plan in chronological order by assigning the earliest interval with a free machine on each iteration.

A repair method takes a completely specified plan and attempts to transform it into another completely specified plan with better performance. In travel planning, we might take a plan that makes use of one airline's flights and modify it to use the flights of another, possibly less expensive or more reliable airline. Repair methods often work by first analyzing a plan to identify unwanted interactions or bottlenecks and then attempting to eliminate the identified problems.

The rest of this section is organized as follows. In "Complexity Results," we briefly survey what is known about the complexity of planning and scheduling problems, irrespective of what methods are used to solve them. In "Planning with Deterministic Dynamics," we focus on traditional search methods for generating plans of actions given deterministic dynamics. We begin with open-loop planning problems with complete knowledge of the initial state, progressing to closed-loop planning problems with incomplete knowledge of the initial state. In "Scheduling with Deterministic Dynamics," we focus on methods for generating schedules given deterministic dynamics. In both of the last two sections just mentioned we discuss refinement- and repair-based methods. In "Improving Efficiency," we mention related work in machine learning concerned with learning search rules and adapting previously generated solutions to planning and scheduling problems. In "Approximation in Stochastic Domains," we consider a class of planning problems involving stochastic dynamics and address some issues that arise in trying to approximate the value of conditional plans in stochastic domains. Our discussion begins with a quick survey of what is known about the complexity of planning and scheduling problems.

67.3.1 Complexity Results

Garey and Johnson [1979] provide an extensive listing of NP-hard problems, including a great many scheduling problems. They also provide numerous examples of how a hard problem can be rendered easy by relaxing certain assumptions. For example, most variants of job-shop scheduling are NP-hard. Suppose, however, that you can suspend work on one job in order to carry out a rush job, resuming the suspended job on completion of the rush job so that there is no time lost in suspending and resuming. With this assumption, some hard problems become easy. Unfortunately, most real scheduling problems are NP-hard. Graham et al. [1977] provide a somewhat more comprehensive survey of scheduling problems with a similarly dismal conclusion. Lawler et al. [1985] survey results for the traveling salesperson problem, a special case of our travel planning problem. Here again the prospects for optimal, exact algorithms are not good, but there is some hope for approximate algorithms.

With regard to open-loop, deterministic planning, Chapman [1987], Bylander [1991], and Gupta and Nau [1991] have shown that most problems in this general class are hard. Dean and Boddy [1988] show that the problem of evaluating plans represented as sets of partially ordered actions is NP-hard in all but the simplest cases. Bäckström and Klein [1991] provide some examples of easy (polynomial time) planning problems, but these problems are of marginal practical interest.

Regarding closed-loop, deterministic planning, Papadimitriou and Tsitsiklis [1987] discuss polynomial-time algorithms for finding an optimal conditional plan for a variety of performance functions. Unfortunately, the polynomial is in the size of the state space. As mentioned earlier, we assume that the size of the state space is exponential in the number of state variables. Papadimitriou and Tsitsiklis also list algorithms for the case of stochastic dynamics that are polynomial in the size of the state space.

From the perspective of worst-case, asymptotic time and space complexity, most practical planning and scheduling problems are computationally very difficult. The literature on planning and scheduling in artificial intelligence generally takes it on faith that any interesting problem is at least NP-hard. The research emphasis is on finding powerful heuristics and clever search algorithms. In the remainder of this section, we explore some of the highlights of this literature.

67.3.2 Planning with Deterministic Dynamics

In the following section, we consider a special case of planning in which each action deterministically transforms one state into another. Nothing changes without the executor performing some action. We assume that the planner has an accurate model of the dynamics. If we also assume that we are given

complete information about the initial state, it will be sufficient to produce unconditional plans that are produced off-line and run in an open loop.

Recall that a state is described in terms of a set of state variables. Each state assigns to each state variable a value. To simplify the notation, we restrict our attention to Boolean variables. In the case of Boolean variables, each state variable is assigned either true or false. Suppose that we have three Boolean state variables: P , Q , and R . We represent the particular state s in which P and Q are true and R is false by the *state-variable assignment*, $s = \{P = \text{true}, Q = \text{true}, R = \text{false}\}$, or, somewhat more compactly, by $s = \{P, Q, \neg R\}$, where $X \in s$ indicates that X is assigned true in s and $\neg X \in s$ indicates that X is assigned false in s .

An action is represented as a *state-space operator* α defined in terms of *preconditions* ($\text{Pre}(\alpha)$) and *postconditions* (also called effects) ($\text{Post}(\alpha)$). Preconditions and postconditions are represented as state-variable assignments that assign values to subsets of the set of all state variables. Here is an example operator α_{eg} :

Operator α_{eg}

Preconditions: $P, \neg R$

Postconditions: $\neg P, \neg Q$

If an operator (action) is applied (executed) in a state in which the preconditions are satisfied, then the variables mentioned in the postconditions are assigned their respective values in the resulting state. If the preconditions are not satisfied, then there is no change in state.

In order to describe the state-transition function, we introduce a notion of consistency and define two operators \oplus and \ominus on state-variable assignments. Let φ and ϑ denote state-variable assignments. We say that φ and ϑ are *inconsistent* if there is a variable X such that φ and ϑ assign X different values; otherwise, we say that φ and ϑ are *consistent*. The operator \ominus behaves like set difference with respect to the variables in assignments. The expression $\varphi \ominus \vartheta$ denotes a new assignment consisting of the assignments to variables in φ that have no assignment in ϑ (e.g., $\{P, Q\} \ominus \{P\} = \{P, Q\} \ominus \{\neg P\} = \{Q\} \ominus \{\} = \{Q\}$). The operator \oplus takes two consistent assignments and returns their union (e.g., $\{Q\} \oplus \{P\} = \{P, Q\}$, but $\{P\} \oplus \{\neg P\}$ is undefined).

The state-transition function is defined as follows:

$$f(s, \alpha) = \begin{cases} s & \text{if } s \text{ and } \text{Pre}(\alpha) \text{ are inconsistent} \\ \text{Post}(\alpha) \oplus (s \ominus \text{Post}(\alpha)) & \text{otherwise} \end{cases}$$

If we apply the operator α_{eg} to a state where the variables P and Q are true, and R is false, we have

$$f(\{P, Q, \neg R\}, \alpha_{eg}) = \{\neg P, \neg Q, \neg R\}$$

We extend the state-transition function to handle sequences of operators in the obvious way,

$$\begin{aligned} f(s, \langle \alpha_1, \alpha_2, \dots, \alpha_n \rangle) &= f(f(s, \alpha_1), \langle \alpha_2, \dots, \alpha_n \rangle) \\ f(s, \langle \rangle) &= s \end{aligned}$$

Our performance measure for this problem is goal based. Goals are represented as state-variable assignments that assign values to subsets of the set of all state variables. By assigning values to one or more state variables, we designate a set of states as the goal. We say that a state s *satisfies* a goal ϕ , notated $s \models \phi$, just in case the assignment ϕ is a subset of the assignment s . Given an initial state s_0 , a goal ϕ , and a library of operators, the objective of the planning problem is to find a sequence of state-space operators $\langle \alpha_1, \dots, \alpha_n \rangle$ such that $f(s_0, \langle \alpha_1, \dots, \alpha_n \rangle) \models \phi$.

Using a state-space operator to transform one state into the next state is called **progression**. We can also use an operator to transform one goal into another, namely, the goal that the planner would have prior to carrying out the action corresponding to the operator. This use of an operator to transform goals is called **regression**. In defining regression, we introduce the notion of an impossible assignment, denoted \perp .

We assume that if you regress a goal using an operator with postconditions that are inconsistent with the goal, then the resulting regressed goal is impossible to achieve. Here is the definition of regression:

$$b(\phi, \alpha) = \begin{cases} \perp & \text{if } \phi \text{ and } Post(\alpha) \text{ are inconsistent} \\ Pre(\alpha) \oplus (\phi \ominus Post(\alpha)) & \text{otherwise} \end{cases}$$

67.3.2.1 Conditional Postconditions and Quantification

Within the general operator-based state-transition framework previously described, a variety of syntactic abbreviations can be used to facilitate compact action representation. For example, the postconditions of an action may be *conditional*. A conditional postcondition of the form $P \Rightarrow Q$ means that the action changes the value of the variable Q to true only if the value of P is true in the state where the operator is applied. It is easy to see that an action with such a conditional effect corresponds to two simpler actions, one which has a precondition P and the postcondition Q , and the other which has a precondition $\neg P$ and does not mention Q in its postconditions.

Similarly, when state variables can be typed in terms of objects in the domain to which they are related, it is possible to express preconditions and postconditions of an operator as quantified formulas. As an example, suppose in the travel domain, we have one state variable $loc(c)$ which is true if the agent is in city c and false otherwise. The action of flying from city c to city c' has the effect that the agent is now at city c' , and the agent is not in any other city. If there are n cities, c_1, \dots, c_n , the latter effect can be expressed either as a set of propositional postconditions $\neg loc(c_1), \dots, \neg loc(c_{j-1}), \neg loc(c_{j+1}), \dots, \neg loc(c_n)$ where $c' = c_j$, or, more compactly, as the quantified effect $\forall_{z:city(z)} z \neq c' \Rightarrow \neg loc(z)$. Since operators with conditional postconditions and quantified preconditions and postconditions are just shorthand notations for finitely many propositional operators, the transition function, as well as the progression and regression operations, can be modified in straightforward ways to accommodate them. For example, if a goal formula $\{W, S\}$ is regressed through an operator having preconditions $\{P, Q\}$ and postconditions $\{R \Rightarrow \neg W\}$, we get $\{\neg R, S, P, Q\}$. Note that by making $\neg R$ a part of the regressed formula, we ensure that $\neg W$ will not be a postcondition of the operator, thereby averting the inconsistency with the goals.

67.3.2.2 Representing Partial Plans

Although solutions to the planning problems can be represented by operator sequences, to facilitate efficient methods of plan synthesis, it is useful to have a more flexible representation for partial plans. A *partial plan* consists of a set of *steps*, a set of *ordering constraints* that restrict the order in which steps are to be executed, and a set of *auxiliary constraints* that restrict the value of state variables over particular intervals of time. Each step is associated with a state-space operator. To distinguish between multiple instances of the same operator appearing in a plan, we assign each step a unique integer i and represent the i th step as the pair (i, α_i) where α_i is the operator associated with the i th step.

Figure 67.2 shows a partial plan π_{eg} consisting of seven steps. The plan π_{eg} is represented as follows:

$$\langle \{ (0, \alpha_0), (1, \alpha_1), (2, \alpha_2), (3, \alpha_3), (4, \alpha_4), (5, \alpha_5), (\infty, \alpha_\infty) \}, \\ \{ (0 \succ 1), (1 \prec 2), (1 \prec 4), (2 \prec 3), (3 \prec 5), (4 \prec 5), (5 \succ \infty) \}, \\ \{ (1 \stackrel{Q}{\prec} 2), (3 \stackrel{R}{\prec} \infty) \} \rangle$$

An ordering constraint of the form $(i \prec j)$ indicates that step i precedes step j . An ordering constraint of the form $(i \succ j)$ indicates that step i is contiguous with step j , that is, step i precedes step j and no other steps intervene. The steps are *partially ordered* in that step 2 can occur either before or after step 4. An auxiliary constraint of the form $(i \stackrel{P}{\prec} j)$ is called an *interval preservation constraint* and indicates that P is to be preserved in the range between steps i and j (and therefore no operator with postcondition $\neg P$ should occur between steps i and j). In particular, according to the constraint $(3 \stackrel{R}{\prec} \infty)$, step 4 should not occur between steps 3 and ∞ .

FIGURE 67.2 This figure depicts the partial plan π_{eg} . The postconditions (effects) of the steps are shown above the steps, whereas the preconditions are shown below the steps in parentheses. The ordering constraints between steps are shown by arrows. The interval preservation constraints are shown by arcs, whereas the contiguity constraints are shown by dashed lines.

The set of steps $\{\sigma_1, \sigma_2, \dots, \sigma_n\}$ with contiguity constraints

$$\{(\sigma_0 \preceq \sigma_1), (\sigma_1 \preceq \sigma_2), \dots, (\sigma_{n-1} \preceq \sigma_n)\}$$

is called the *header* of the plan π . The last element of the header σ_n is called the *head step*. The state defined by $f(s_0, \langle \alpha_{\sigma_1}, \dots, \alpha_{\sigma_n} \rangle)$, where α_{σ_i} is the operator associated with σ_i , is called the *head state*. In a similar manner, we can define the *tail*, *tail step*, and *tail state*.

As an example, the partial plan π_{eg} shown in Figure 67.2 has the steps 0 and 1 in its header, with step 1 being the head step. The head state (which is the state resulting from applying α_1 to the initial state) is $\{P, Q\}$. Similarly, the tail consists of steps 5 and ∞ , with step 5 being the tail step. The tail state (which is the result of regressing the goal conditions through the operator α_5) is $\{R, U\}$.

67.3.2.3 Refinement Search

A large part of the work on plan synthesis in artificial intelligence falls under the rubric of refinement search. Refinement search can be seen as search in the space of partial plans. The search starts with the empty partial plan, and adds details to that plan until a complete plan results. Semantically, a partial plan can be seen as a shorthand notation for the set of complete plans (action sequences) that are consistent with the constraints. A refinement strategy converts a partial plan π into a set of new plans $\{\pi_1, \dots, \pi_n\}$ such that all of the potential solutions represented by π are represented by at least one of π_1, \dots, π_n . Syntactically, this is accomplished by generating each of the children plans (refinements) by adding additional constraints to π .

The following is a general template for refinement search. The search starts with the null plan $\{(0, \alpha_0), (\infty, \alpha_\infty), \{(0 < \infty)\}, \{\}\}$, where α_0 is a dummy operator with no preconditions and postconditions corresponding to the initial state, and α_∞ is a dummy operator with no postconditions and preconditions corresponding to the goal. For example, if we were trying to find a sequence of actions to transform the initial state $\{P, Q, \neg R\}$ into a state satisfying the goal $\{R\}$, then we would have $\text{Pre}(\alpha_0) = \{\}$, $\text{Post}(\alpha_0) = \{P, Q, \neg R\}$, $\text{Pre}(\alpha_\infty) = \{R\}$, and $\text{Post}(\alpha_\infty) = \{\}$.

We define a generic refinement procedure, $\text{Refine}(\pi)$, as follows [Kambhampati et al. 1995]:

1. If an action sequence $\langle \alpha_1, \alpha_2, \dots, \alpha_n \rangle$ corresponds to a total order consistent with both ordering constraints and the auxiliary constraints of π , and is a solution to the planning problem, then terminate and return $\langle \alpha_1, \alpha_2, \dots, \alpha_n \rangle$
2. If the constraints in π are inconsistent, then eliminate π from future consideration
3. Select a refinement strategy, and apply the strategy to π and add the resulting refinements to the set of plans under consideration
4. Select a plan π' from those under consideration and call $\text{Refine}(\pi')$

In step 3, the search selects a refinement strategy to be applied to the partial plan. There are several possible choices here, corresponding intuitively to different ways of splitting the set of potential solutions

represented by the plan. In the following sections, we outline four popular refinement strategies employed in the planning literature.

67.3.2.4 State-Space Refinements

The most straightforward way of refining partial plans involves using progression to convert the initial state into a state satisfying the goal conditions, or using regression to convert a set of goal conditions into a set of conditions that are satisfied in the initial state. From the point of view of partial plans, this corresponds to growing the plan from either the beginning or the end.

Progression (or forward state-space) refinement involves advancing the head state by adding a step σ , such that the preconditions of α_σ are satisfied in the current head state, to the header of the plan. The step σ may be newly added to the plan or currently present in the plan. In either case, it is made contiguous to the current head step and becomes the new head step.

As an example, one way of refining the plan π_{eg} in Figure 67.2 using progression refinement would be to apply an instance of the operator α_2 (either the instance that is currently in the plan $(2, \alpha_2)$ or a new instance) to the head state (recall that it is $\{P, Q\}$). This is accomplished by putting a contiguity constraint between $(2, \alpha_2)$ and the current head step $(1, \alpha_1)$ (thereby making the former the new head step).

We can also define a refinement strategy based on regression, which involves regressing the tail state of a plan through an operator. For example, the operator α_3 is applicable (in the backward direction) through this tail state (which is $\{R, U\}$), whereas the operator α_4 is not (since its postconditions are inconsistent with the tail state). Thus, one way of refining π_{eg} using regression refinement would be to apply an instance of the operator α_3 (either the existing instance in step 3 or a new one) to the tail state in the backward direction. This is accomplished by putting a contiguity constraint between $(3, \alpha_3)$ and the current tail step.

From a search control point of view, one of the important questions is deciding which of the many refinements generated by progression and regression refinements are most likely to lead to a solution. It is possible to gain some focus by using *state difference heuristics*, which prefer the refinements where the set difference between the tail state and the head state is the smallest.

Although the state difference heuristic works well enough for regression refinements, it does not provide sufficient focus to progression refinements. The problem is that in a realistic planning problem, there potentially may be many operators that are applicable in the current head state, and only a few of them may be relevant to the goals of the problem. Thus, the strategy of generating all of the refinements and ranking them with respect to the state difference heuristic can be prohibitively expensive. We need a method of automatically zeroing on those operators which are possibly relevant to the goals.

One popular way of generating the list of relevant operators is to use *means-ends analysis*. The general idea is the following. Suppose we have an operator α whose postconditions match a goal of the problem. Clearly, α is a relevant operator. If the preconditions of α are satisfied in the head state of the current partial plan, we can apply it directly. Suppose they are not all satisfied. In such a case, we can consider the preconditions of α as subgoals, look for an operator α' whose postconditions match one of these subgoals, and check if it is applicable to the head state. This type of recursive analysis can be continued to find the set of relevant operators, and focus progression refinement.

67.3.2.5 Plan-Space Refinements

As we have seen previously in state-space refinements, partial plans are extended by adding new steps and new contiguity constraints. The contiguity constraints are required since without them the head state and tail state are not well defined. State-space refinements have the disadvantage that they completely determine the order and position of every step introduced into the plan. Although it is easy to see whether or not a given step is relevant to a plan, often the precise position at which a step must occur in the final plan is not apparent until all of the steps have been added. In such situations, state-space refinement can lead to premature commitment to the order of steps, causing extensive backtracking.

Plan-space refinement attempts to avoid this premature commitment. The main idea in plan-space refinement is to shift the attention from advancing the world state to establishing goals. A precondition P of a step (i, α_i) in a plan is said to be *established* if there is some step (j, α_j) in the plan that precedes i and

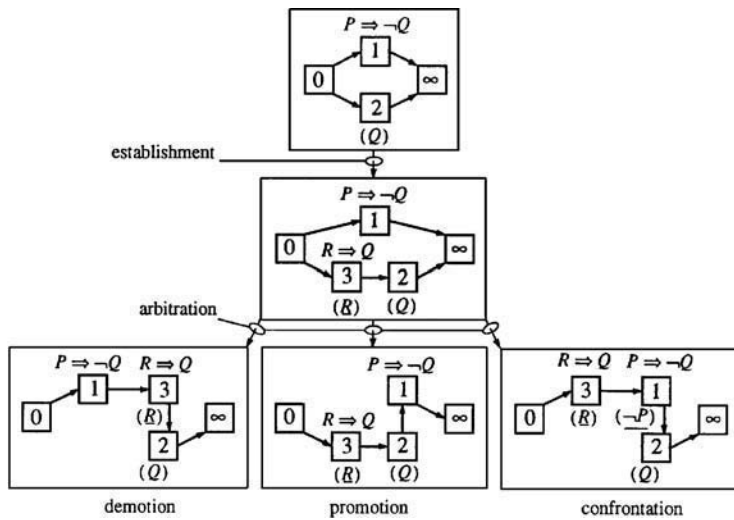

FIGURE 67.3 An example of precondition establishment. This diagram illustrates an attempt to establish Q for step 2. Establishing a postcondition can result in a potential conflict, which requires arbitration to avert the conflict. Underlined preconditions correspond to secondary preconditions.

causes P to be true, and no step that can possibly intervene between j and i has postconditions that are inconsistent with P . It is easy to see that if every precondition of every step in the plan is established, then that plan will be a solution plan. Plan-space refinement involves picking a precondition P of a step (i, α_i) in the partial plan, and adding enough additional step, ordering, and auxiliary constraints to ensure the establishment of P .

We illustrate the main ideas in precondition establishment through an example. Consider the partial plan at the top in Figure 67.3. Step 2 in this plan requires a precondition Q . To establish this precondition, we need a step which has Q as its postcondition. None of the existing steps have such a postcondition. Suppose an operator α_3 in the library has a postcondition $R \Rightarrow Q$. We introduce an instance of α_3 as step 3 into the plan. Step 3 is ordered to come before step 2 (and after step 0). Since α_3 makes Q true only when R is true before it, to make sure that Q will be true following step 3, we need to ensure that R is true before it. This can be done by posting R as a precondition of step 3. Since R is not a normal precondition of α_3 , and is being posted only to guarantee one of its conditional effects, it is called a *secondary precondition* [Pednault 1988].

Now that we have introduced step 3 and ensured that it produces Q as a postcondition, we need to make sure that Q is not violated by any steps possibly intervening between steps 3 and 2. This phase of plan-space refinement is called *arbitration*. In our example, step 1, which can possibly intervene between steps 3 and 2, has a postcondition $P \Rightarrow \neg Q$ that is potentially inconsistent with Q . To avert this inconsistency, we can either order step 1 to come before step 3 (demotion), or order step 1 to come after step 2 (promotion), or ensure that the offending conditional effect will not occur. This last option, called *confrontation*, can be carried out by posting $\neg P$ as a (secondary) precondition of step 1. All these partial plans, corresponding to different ways of establishing the precondition Q at step 2 are returned as the refinements of the original plan.

One problem with this precondition-by-precondition establishment approach is that the steps added in establishing a precondition might unwittingly violate a previously established precondition. Although this does not affect the completeness of the refinement search, it can lead to wasted planning effort, and necessitate repeated establishments of the same precondition within the same search branch. Many variants of plan-space refinements avoid this inefficiency by *protecting* their establishments. Whenever a condition P of a step σ is established with the help of the effects of a step σ' , an interval preservation

constraint ($\sigma' \perp \sigma$) is added to remember this establishment. If the steps introduced by later refinements violate this preservation constraint, those conflicts are handled much the same way as in the arbitration phase previously discussed. In the example shown in Figure 67.3, we can protect the establishment of precondition Q by adding the constraint $3 \perp 2$.

Although the order in which preconditions are selected for establishment does not have any effect on the completeness of a planner using plan-space refinement, it can have a significant impact on the size of the search space explored by the planner (and thereby its efficiency). Thus, any available domain specific information regarding the relative importance of the various types of preconditions can be gainfully exploited. As an example, in the travel domain, the action of taking a flight to go from one place to another may have as its preconditions having a reservation and being at the airport. To the extent that having a reservation is considered more critical than being at the airport, we would want to work on establishing the former first.

67.3.2.6 Task-Reduction Refinements

In both the state-space and plan-space refinements, the only knowledge that is available about the planning task is in terms of primitive actions (that can be executed by the underlying hardware), and their preconditions and postconditions. Often, one has more structured planning knowledge available in a domain. For example, in a travel planning domain, we might have the knowledge that one can reach a destination by either taking a flight or by taking a train. We may also know that taking a flight in turn involves making a reservation, buying a ticket, taking a cab to the airport, getting on the plane, etc. In such a situation, we can consider taking a flight as an abstract task (which cannot be directly executed by the hardware). This abstract task can then be reduced to a plan fragment consisting of other abstract or primitive tasks (in this case making a reservation, buying a ticket, going to the airport, getting on the plane). This way, if there are some high-level problems with the taking flight action and other goals (e.g., there is not going to be enough money to take a flight as well paying the rent), we can resolve them *before* we work on low-level details such as getting to the airport.

This idea forms the basis for task reduction refinement. Specifically, we assume that in addition to the knowledge about primitive actions, we also have some abstract actions, and a set of schemas (plan fragments) that can replace any given abstract action. Task reduction refinement takes a partial plan π containing abstract and primitive tasks, picks an abstract task σ , and for each reduction schema (plan fragment) that can be used to reduce σ , a refinement of π is generated with σ replaced by the reduction schema (plan fragment). As an example, consider the partial plan on the left in Figure 67.4. Suppose the operator α_2 is an abstract operator. The central box in Figure 67.4 shows a reduction schema for step 2, and the partial plan shown on the right of the figure shows the result of refining the original plan with this reduction schema. At this point any interactions between the newly introduced plan fragment and the previously existing plan steps can be resolved using techniques such as promotion, demotion, and confrontation discussed in the context of plan-space refinement. This type of reduction is carried out until all of the tasks are primitive.

FIGURE 67.4 Step 2 in the partial plan shown on the left is reduced to obtain a new partial plan shown on the right. In the new plan, step 2 is replaced with the (renamed) steps and constraints specified in the reduction shown in the center box.

In some ways, task reduction refinements can be seen as macrorefinements that package together a series of state-space and plan-space refinements, thereby reducing a considerable amount of search. This, and the fact that in most planning domains, canned reduction schemas are readily available, have made task reduction refinement a very popular refinement choice for many applications.

67.3.2.7 Hybrid Refinements

Although early refinement planning systems tended to subscribe exclusively to a single refinement strategy, it is possible and often effective to use multiple refinement strategies. As an example, the partial plan π_{eg} shown in Figure 67.2 can be refined with progression refinement (e.g., by putting a contiguity constraint between step 1 and step 2), with regression refinement (e.g., by putting a contiguity constraint between step 3 and step 5), or plan-space refinement (e.g., by establishing the precondition S of step 3 with the help of the effect step 2). Finally, if the operator α_4 is a nonprimitive operator, we can also use task reduction refinement to replace α_4 with its reduction schema. There is some evidence that planners using multiple refinement strategies intelligently can outperform those using single refinement strategies [Kambhampati 1995]. However, the question as to which refinement strategy should be preferred when is still largely open.

67.3.2.8 Handling Incomplete Information

Although the refinement methods just described were developed in the context of planning problems where the initial state is completely specified, they can be extended to handle incompletely specified initial states. Incomplete specification of the initial state means that the values of some of the state variables in the initial state are not specified. Such incomplete specification can be handled as long as the state variables are observable (i.e., the correct value of the variable can be obtained at execution time).

Suppose the initial state is incomplete with respect to the value of the state variable ϕ . If ϕ has only a small number of values, K , then we can consider this planning problem to be a collection of K problems, each with the same goal and a complete initial state in which ϕ takes on a specific value. Once the K problems are solved, we can make a K -way conditional plan that gives the correct plan conditional given the observed value of the state variable ϕ . There exist methods for extending refinement strategies so that instead of working on K unconditional plans with significant overlap, a single, multithreaded conditional plan is generated [Peot and Shachter 1991].

Conditional planning can be very expensive in situations in which the unspecified variable ϕ has a large set of possible values or there are several unspecified variables. If there are U unspecified variables each with K possible values, then a conditional plan that covers all possible contingencies has to account for U^K possible initial states. In some cases, we can avoid a combinatorial explosion by performing some amount of on-line planning; first plan to obtain the necessary information, then, after obtaining this information, plan what to do next. Unfortunately, this on-line approach has potential problems.

In travel planning, for example, you could wait until you arrive in Boston's Logan Airport to check on the weather in Chicago in order to plan whether to take a Southern or Northern route to San Francisco. But, if you do wait and it is snowing in Chicago, you may find out that all of the flights taking Southern routes are already sold out. In this case, it would have been better to anticipate the possibility of snow in Chicago and reserve a flight to San Francisco taking a Southern route. Additional complications arise concerning the time when you observe the value of a given variable, the time when you need to know the value of a variable, and whether or not the value of a variable changes between when you observe it and when you need to know a value.

Uncertainty arises not only with respect to initial conditions, but also as a consequence of the actions of the planner (e.g., you get stuck in traffic and miss your flight) or the actions of others (e.g., the airline cancels your flight). In general, uncertainty is handled by introducing *sensing* or *information gathering* actions (operators). These operators have preconditions and postconditions similar to other operators, but some of the postconditions, those corresponding to the consequences of information gathering, are nondeterministic; we will not know the actual value of these postconditions until after we have executed the action [Etzioni et al. 1992].

The approach to conditional planning just sketched theoretically extends to arbitrary sources of uncertainty, but in practice search has to be limited to consider only outcomes that are likely to have a significant impact on performance. Subsequently we briefly consider planning using stochastic models that quantify uncertainty involving outcomes.

67.3.2.9 Repair Methods in Planning

The refinement methods for plan synthesis described in this section assume access to the complete dynamics of the system. Sometimes, the system dynamics are complex enough that using the full model during plan synthesis can be inefficient. In many such domains, it is often possible to come up with a simplified model of the dynamics that is approximately correct. As an example, in the travel domain, the action of taking a flight from one city to another has potentially many preconditions, including ones such as: having enough money to buy tickets and enough clean clothes to take on the travel. Often, most of these preconditions are trivially satisfied, and we are justified in approximating the set of preconditions to simply ensure that we have a reservation and are at the airport on time. In such problems, a simplified model can be used to drive plan generation using refinement methods, and the resulting plan can then be *tested* with respect to the complete dynamical model of the system. If the testing shows the plan to be correct, we are done. If not, the plan needs to be *repaired* or *debugged*. This repair process involves both adding and deleting constraints from the plan.

If the complete dynamical model is declarative (instead of being a black box), it is possible to extract from the testing phase an *explanation* of why the plan is incorrect (for example, in terms of some of the preconditions that are not satisfied, or are violated by some of the indirect effects of actions). This explanation can then be used to focus the repair activity [Simmons and Davis 1987, Hammond 1989]. Similar repair methods can also be useful in situations where we have probably approximately correct *canned* plans for generic types of goals, and we would like to solve planning problems involving collections of these goals by putting the relevant canned plans together and modifying them.

67.3.3 Scheduling with Deterministic Dynamics

As we mentioned earlier, scheduling is typically concerned with deciding when to carry out a given set of actions so as to satisfy various types of constraints on the order in which the actions need to be performed, and the ways in which different resources are consumed. Artificial intelligence approaches to scheduling typically declaratively represent and reason with the constraints.

Constraint-based schedulers used in a real applications generally employ sophisticated programming languages to represent a range of constraints. For example, many schedulers require temporal constraints that specify precedence, contiguity, duration, and earliest and latest start and completion times for tasks.

In some schedulers, temporal constraints are enforced rigidly, so that they never need to be checked during search. Many scheduling problems also manage a variety of resources. In the job-shop scheduling problem, machines are resources; only one task can be performed on a machine at a time. Other resources encountered in scheduling problems include fuel, storage space, human operators and crew, vehicles, and assorted other equipment. Tasks have constraints that specify their resource requirements and resources have capacity constraints that ensure that a schedule does not over allocate resources.

In addition to constraints on the time of occurrence and resources used by tasks, there are also constraints on the state of the world that are imposed by physics: the dynamics governing the environment. For example, a switch can be in the on or off position but not both at the same time. In some scheduling problems, the dynamical system is represented as a large set of state constraints.

67.3.3.1 Scheduling and Constraint Satisfaction

Scheduling problems are typically represented in terms of a set of variables and constraints on their values. A schedule is then represented as an assignment of values to all of the variables that satisfies all of the constraints. The resulting formulation of scheduling problems is called a *constraint satisfaction problem* [Tsang 1993].

Formally, a constraint satisfaction problem is specified by a set of n variables $\{x_1, \dots, x_n\}$, their respective value domains $\Omega_1, \dots, \Omega_n$, and a set of m constraints $\{C_1, \dots, C_m\}$. A constraint C_i involves a subset $\{x_{i_1}, \dots, x_{i_k}\}$ of the set of all variables $\{x_1, \dots, x_n\}$ and is defined by a subset of the Cartesian product $\Omega_{i_1} \times \dots \times \Omega_{i_k}$. A constraint C_i is *satisfied* by a particular assignment in which $x_{i_1} \leftarrow v_{i_1}, \dots, x_{i_k} \leftarrow v_{i_k}$ just in case $(v_{i_1}, \dots, v_{i_k})$ is in the subset of $\Omega_{i_1} \times \dots \times \Omega_{i_k}$ that defines C_i . A solution is an assignment of values to all of the variables such that all of the constraints are satisfied. There is a performance function that maps every complete assignment to a numerical value representing the cost of the assignment. An optimal solution is a solution that has the lowest cost.

As an example, consider the following formulation of a simplified version of the job-shop scheduling problem as a constraint satisfaction problem. Suppose we have N jobs, $1, 2, \dots, N$, each consisting of a single task, and M machines, $1, 2, \dots, M$. Since there is exactly one task for each job, we just refer to jobs. Assume that each job takes one unit of time and there are T time units, $1, 2, \dots, T$. Let $z_{ij} = 1$ if the j th machine can handle the i th job and $z_{ij} = 0$ otherwise. The z_{ij} are specified in the description of the problem. Let x_i for $1 \leq i \leq N$ take on values from $\{j \mid z_{ij} = 1\} \times \{1, 2, \dots, T\}$, where $x_i = (j, k)$ indicates that the i th job is assigned to the j th machine during the k th time unit. The x_i are assigned values in the process of planning. There are $N(N - 1)$ constraints of the form $x_i \neq x_j$, where $1 \leq i, j \leq N$, and $i \neq j$. We are searching for an assignment to the x_i that satisfies these constraints.

67.3.3.2 Refinement-Based Methods

A refinement-based method for solving a constraint satisfaction problem progresses by incrementally assigning values to each of the variables. A partial plan (schedule) π is represented as partial assignment of values to variables $\{x_{\pi_1} \leftarrow v_{\pi_1}, \dots, x_{\pi_k} \leftarrow v_{\pi_k}\}$, where $\{x_{\pi_1}, \dots, x_{\pi_k}\}$ is a subset of the set of all variables $\{x_1, \dots, x_n\}$. The partial assignment π can be seen as a shorthand notation for all of the complete assignments that agree on the assignment of values to the variables in $\{x_{\pi_1}, \dots, x_{\pi_k}\}$. A partial assignment π is said to be inconsistent if the assignment of values to variables in π already violates one or more constraints. If the partial assignment π is consistent, it can be refined by selecting a variable x_j that is not yet assigned a value in π and extending π to produce a set of refinements each of which assigns x_j one of the possible values from its domain Ω_j . Thus, the set of refinements of π is $\{\pi \cup \{x_j \leftarrow v\} \mid v \in \Omega_j\}$. In the case of satisficing scheduling, search terminates when a complete and consistent assignment is produced. In the case of optimizing scheduling, search is continued with *branch-and-bound* techniques until an optimal solution is found.

From the point of view of efficiency, it is known that the order in which the variables are considered and the order in which the values of the variables are considered during refinement have a significant impact on the efficiency of search. Considering variables with the least number of possible values first is known to provide good performance in many domains. Other ways of improving search efficiency include using *lookahead* techniques to prune inconsistent partial assignments ahead of time, to process the domains of the remaining variables so that any infeasible values are removed, or using dependency directed backtracking techniques to recover from inconsistent partial assignments intelligently. See Tsang [1993] for a description of these techniques and their tradeoffs.

67.3.3.3 Repair-Based Methods

A repair-based method for solving constraint satisfaction problems is to start with an assignment to all of the variables in which not all of the constraints are satisfied and reassign a subset of the variables so that more of the constraints are satisfied. Reassigning a subset of the variables is referred to as repairing an assignment. Consider the following repair method for solving the simplified job-shop scheduling problem.

We say that two variables x_i and x_j ($i \neq j$) *conflict* if their values violate a constraint; in the simplified job-shop scheduling problem considered here, a constraint is violated if $x_i = x_j$. *Min-conflicts* is a heuristic for repairing an existing assignment that violates some of the constraints to obtain a new assignment that violates fewer constraints. The hope is that by performing a short sequence of repairs as determined by the min-conflicts heuristic we obtain an assignment that satisfies all of the constraints. The min-conflicts heuristic counsels us to select a variable that is in conflict and assign it a new value that minimizes the

number of conflicts. See the Johnston and Minton article in [Zweben and Fox 1994] for more on the min-conflicts heuristic.

Min-conflicts is a special case of a more general strategy that proceeds by making *local* repairs. In the job-shop scheduling problem, a local repair corresponds to a change in the assignment of a single variable.

For the traveling salesperson problem, there is a very effective local repair method that works quite well in practice. Suppose that there are five cities A, B, C, D, E , and an existing tour (a path consisting of a sequence of edges beginning and ending in the same city) $(A, B), (B, C), (C, D), (D, E), (E, A)$. Take two edges in the tour, say (A, B) and (C, D) , and consider the length of the tour $(A, C), (C, B), (B, D), (D, E), (E, A)$ that results from replacing (A, B) and (C, D) with (A, C) and (B, D) . Try all possible pairs of edges [there are $O(L^2)$ such edges where L is the number of cities], and make the replacement (repair) that results in the shortest tour. Continue to make repairs in this manner until no improvement (reduction in the length of the resulting tour) is possible. Lin and Kernighan's algorithm, which is based on this local repair method, generates solutions that are within 10% of the length of the optimal tour on a large class of practical problems [Lin and Kernighan 1973].

67.3.3.4 Rescheduling and Iterative Repair Methods

Repair methods are typically implemented with iterative search methods; at any point during the scheduling process, there is a complete schedule available for use. This ready-when-you-are property of repair methods is important in applications that require frequent rescheduling, such as job shops in which change orders and new rush jobs are a common occurrence.

Most repair methods employ greedy strategies that attempt to improve the current schedule on every iteration by making local repairs. Such greedy strategies often have a problem familiar to researchers in combinatorial optimization. The problem is that many repair methods, especially those that perform only local repairs, are liable to converge to local extrema of the performance function and thereby miss an optimal solution. In many cases, these local extrema correspond to very poor solutions.

To improve performance and reduce the risk of becoming stuck in local extrema corresponding to badly suboptimal solutions, some schedulers employ stochastic techniques that occasionally choose to make repairs other than those suggested by their heuristics. Simulated annealing [Kirkpatrick et al. 1983] is one example of a stochastic search method used to escape local extrema in scheduling. In simulated annealing, there is a certain probability that the scheduler will choose a repair other than the one suggested by the scheduler's heuristics. These random repairs force the scheduler to consider repairs that at first may not look promising but in the long term lead to better solutions. Over the course of scheduling this probability is gradually reduced to zero. See the article by Zweben et al. in Zweben and Fox [1994] for more on iterative repair methods using simulated annealing.

Another way of reducing the risk of getting stuck in local extrema involves making the underlying search systematic (so that it eventually visits all potential solutions). However, traditional systematic search methods tend to be too rigid to exploit local repair methods such as the min-conflicts heuristic. In general, local repair methods attempt to direct the search by exploiting the local gradients in the search space. This guidance can sometimes be at odds with the commitments that have already been made in the current search branch. Iterative methods do not have this problem since they do not do any bookkeeping about the current state of the search. Recent work on partial-order dynamic backtracking algorithms [Ginsberg and McAllester 1994] provides an elegant way of keeping both systematicity and freedom of movement.

67.3.4 Improving Efficiency

Whereas the previous sections surveyed the methods used to organize the search for plans and discussed their relative advantages, as observed in the section on complexity results most planning problems are computationally hard. The only way we can expect efficient performance is to exploit the structure and idiosyncrasies of the specific applications. One attractive possibility involves dynamically customizing the performance of a general-purpose search algorithm to the structure and distribution of the application

problems. A variety of machine learning methods have been developed and used for this purpose. We briefly survey some of these methods.

One of the simplest ways of improving performance over time involves caching plans for frequently occurring problems and subproblems, and reusing them in subsequent planning scenarios. This approach is called *case-based planning (scheduling)* [Hammond 1989, Kambhampati and Hendler 1992] and is motivated by similar considerations to those motivating task-reduction refinements. In storing a previous planning experience, we have two choices: store the final plan or store the plan along with the search decisions that lead to the plan. In the latter case, we exploit the previous experience by *replaying* the previous decisions in the new situation.

Caching typically involves only storing the information about the successful plan and the decisions leading to it. Often, there is valuable information in the search failures encountered in coming up with the successful plan. By analyzing the search failures and using *explanation-based learning* techniques, it is possible to learn *search control rules* that, for example, can be used to advise a planner as to which refinement or repair to pursue under what circumstances. For more about the connections between planning and learning see Minton [1992].

67.3.5 Approximation in Stochastic Domains

In this section, we consider a planning problem involving stochastic dynamics. We are interested in generating conditional plans for the case in which the state is completely observable [the output function is the identity $h(x_t) = x_t$] and the performance measure is expected discounted cumulative cost with discount γ . This constitutes an extreme case of closed-loop planning in which the executor is able to observe the current state at any time without error and without cost.

In this case, a plan is just a mapping from (observable) states to actions $\pi : \mathcal{S} \rightarrow \mathcal{A}$. To simplify the presentation, we notate states with the integers $0, 1, \dots, |\mathcal{S}|$, where $s_0 = 0$ is the initial state. We refer to the performance of a plan π starting in state i as $J(\pi | i)$. We can compute the performance of a plan by solving the following set of $|\mathcal{S}| + 1$ equations in $|\mathcal{S}| + 1$ unknowns,

$$J(\pi | i) = C(i) + \gamma \sum_{j=0}^{|\mathcal{S}|} \Pr(f(i, \pi(i)) = j | i, \pi(i)) J(\pi | j)$$

The objective in planning is to find a plan π from the set of all possible plans Π s such that for all $\pi' \in \Pi$, $J(\pi | i) \geq J(\pi' | i)$ for $0 \leq i \leq |\mathcal{S}|$.

As an aside, we note that the conditional probability distribution governing state transitions, $\Pr(f(i, \pi(i)) = j | i, \pi(i))$, can be specified in terms of *probabilistic state space operators*, allowing us to apply the techniques of the section on planning with deterministic dynamics. A probabilistic state-space operator α is a set of triples of the form $\langle \phi, \rho, \omega \rangle$ where ϕ is a set of preconditions, ρ is a probability, and ω is a set of postconditions. Semantically, if ϕ is satisfied just prior to α , then with probability ρ the postconditions in ω are satisfied immediately following α . If a proposition is not included in ϕ , then it is assumed not to affect the outcome of α ; if a proposition is not included in ω , then it is assumed to be unchanged by α . For example, given the following representation for α :

$$\alpha = \{ \langle \{P\}, 1, \emptyset \rangle, \langle \{\neg P\}, 0.2, \{P\} \rangle, \langle \{\neg P\}, 0.8, \{\neg P\} \rangle \}$$

if P is true prior to α , nothing is changed following α ; but if P is false, then 20% of the time P becomes true and 80% of the time P remains false. For more on planning in stochastic domains using probabilistic state-space operators, see Kushmerick et al. [1994].

There are well-known methods for computing an optimal plan for the problem previously described [Puterman 1994]. Most of these methods proceed using iterative repair-based methods that work by improving an existing plan π using the computed function $J(\pi | i)$. On each iteration, we end up with a new plan π' and must calculate $J(\pi' | i)$ for all i . If, as we assumed earlier, $|\mathcal{S}|$ is exponential in the

number of state variables, then we are going to have some trouble solving a system of $|\mathcal{S}| + 1$ equations. In the rest of this section, we consider one possible way to avoid incurring an exponential amount of work in evaluating the performance of a given plan.

Suppose that we know the initial state s_0 and a bound C_{\max} ($C_{\max} \geq \max_i C(i)$) on the maximum cost incurred in any state. Let π be any plan, $J_{\infty}(\pi) = J(\pi | 0)$ be the performance of π accounting for an infinite sequence of state transitions, and $J_K(\pi)$ the performance of π accounting for only K state transitions. We can bound the difference between these two measures of performance as follows (see Fiechter [1994] for a proof):

$$|J_{\infty}(\pi) - J_K(\pi)| \leq \gamma^K C_{\max} / (1 - \gamma)$$

These result implies that if we are willing to sacrifice a (maximum) error of $\gamma^K C_{\max} / (1 - \gamma)$ in measuring the performance of plans, we need only concern ourselves with histories of length K . So how do we calculate $J_K(\pi)$? The answer is a familiar one in statistics; namely, we estimate $J_K(\pi)$ by sampling the space of K -length histories.

Using a factored representation of the conditional probability distribution governing state transitions, we can compute a random K -length history in time polynomial in K and N (the number of state variables), assuming that M (the maximum dimensionality of a state-variable function) is constant. The algorithm is simply, given s_0 , for $t = 0$ to $K - 1$, determine s_{t+1} according to the distribution $Pr(s_{t+1} | s_t, \pi(s_t))$. For each history $\langle s_0, \dots, s_K \rangle$ so determined, we compute the quantity $V(\langle s_0, \dots, s_K \rangle) = \sum_{j=0}^K \gamma^j C(s_j)$ and refer to this as one *sample*.

If we compute enough samples and take their average, we will have an accurate estimate of $J_K(\pi)$. The following algorithm takes two parameters, ϵ and δ , and computes an estimate $\hat{J}_K(\pi)$ of $J_K(\pi)$ such that

$$Pr[J_K(\pi)(1 - \epsilon) \leq \hat{J}_K(\pi) \leq J_K(\pi)(1 + \epsilon)] > 1 - \delta$$

1. $T \leftarrow 0; Y \leftarrow 0$
2. $S \leftarrow 4 \log(2/\delta)(1 + \epsilon)/\epsilon^2$
3. *While* $Y < S$ *do*
 - a. $T \leftarrow T + 1$
 - b. *Generate a random history* $\langle s_0, \dots, s_K \rangle$
 - c. $Y \leftarrow Y + V(\langle s_0, \dots, s_K \rangle)$
4. *Return* $J_K(\pi) = S/T$

This algorithm terminates after generating $E[T]$ samples, where

$$E[T] \leq 4 \log(2/\delta)(1 + \epsilon) (J_K(\pi)\epsilon^2)^{-1}$$

so that the entire algorithm for approximating $J_{\infty}(\pi)$ runs in expected time polynomial in $1/\delta$, $1/\epsilon$, $1/(1 - \gamma)$ (see Dagum et al. [1995] for a detailed analysis).

Approximating $J_{\infty}(\pi)$ is only one possible step in an algorithm for computing an optimal or near-optimal plan. In most iterative repair-based algorithms, the algorithm evaluates the current policy and then tries to improve it on each iteration. In order to have a polynomial time algorithm, we not only have to establish a polynomial bound on the time required for evaluation but also a polynomial bound on the total number of iterations. The point of this exercise is that when faced with combinatorial complexity, we need not give up but we may have to compromise. In practice, making reasonable tradeoffs is critical in solving planning and scheduling problems. The simple analysis demonstrates that we can trade time (the expected number of samples required) against the accuracy (determined by the ϵ factor) and reliability (determined by the δ factor) of our answers.

67.3.6 Practical Planning

There currently are no off-the-shelf software packages available for solving real-world planning problems. Of course, there do exist general-purpose planning systems. The SIPE [Wilkins 1988] and O-Plan [Currie and Tate 1991] systems are examples that have been around for some time and have been applied to a range of problems from spacecraft scheduling to fermentation planning for commercial breweries. In scheduling, several companies have sprung up to apply artificial intelligence scheduling techniques to commercial applications, but their software is proprietary and by no means turn-key. Moreover, these systems are rather large; they are really programming environments meant to support design and not necessarily to provide the basis for stand-alone products.

Why, you might ask, are there not convenient libraries in C, Pascal, and Lisp for solving planning problems much as there are libraries for solving linear programs? The answer to this question is complicated, but we can provide some explanation for why this state of affairs is to be expected. Before you can solve a planning problem you have to understand it and translate it into an appropriate language for expressing operators, goals, and initial conditions. Although it is true, at least in some academic sense, that most planning problems can be expressed in the language of propositional operators that we introduced earlier in this chapter, there are significant practical difficulties to realizing such a problem encoding. This is especially true in problems that require reasoning about geometry, physics, and continuous change.

In most problems, operators have to be encoded in terms of schemas and somehow generated on demand; such schema-based encodings require additional machinery for dealing with variables that draw upon work in automated theorem proving and logic programming. Dealing with quantification and disjunction, although possible in finite domains using propositional schemas, can be quite complex. Finally, in addition to just encoding the problem, it is also necessary to cope with the inevitable combinatorics that arise by encoding expert heuristic knowledge to guide search. Designing heuristic evaluation functions is more an art than a science and, to make matters worse, an art that requires deep knowledge of the particular domain.

The point is that the problem-dependent aspects of building planning systems are monumental in comparison with the problem-independent aspects that we have concentrated upon in this chapter. Building planning systems for real-world problems is further complicated by the fact that most people are uncomfortable turning over control to a completely automated system. As a consequence, the interface between humans and machines is a critical component in planning systems that we have not even touched upon in this brief overview.

To be fair, the existence of systems for solving linear programs does not imply off-the-shelf solutions to any real-world problems either. And, once you enter the realm of mixed integer and linear programs, the existence of systems for solving such programs is only of marginal comfort to those trying to solve real problems given that the combinatorics severely limit the effective use of such systems. The bottom line is that if you have a planning problem in which discrete-time, finite-state changes can be modeled as operators, then you can look for advice in books such as Wilkins's account of applying SIPE to real problems [Wilkins 1988] and look to the literature on heuristic search to implement the basic engine for guiding search given a heuristic evaluation function. But you should be suspicious of anyone offering a completely general-purpose system for solving planning problems. The general planning problem is just too hard to admit to quick off-the-shelf technological solutions.

67.4 Research Issues and Summary

In this chapter, we provide a framework for characterizing planning and scheduling problems that focuses on properties of the underlying dynamical system and the capabilities of the planning system to observe its surroundings. The presentation of specific techniques distinguishes between refinement-based methods that construct plans and schedules piece by piece, and repair-based methods that modify complete plans and schedules. Both refinement- and repair-based methods are generally applied in the context of heuristic search.

Most planning and scheduling problems are computationally complex. As a consequence of this complexity, most practical approaches rely on heuristics that exploit knowledge of the planning domain. Current research focuses on improving the efficiency of algorithms based on existing representations and on developing new representations for the underlying dynamics that account for important features of the domain (e.g., uncertainty) and allow for the encoding of appropriate heuristic knowledge. Given the complexity of most planning and scheduling problems, an important area for future research concerns identifying and quantifying tradeoffs, such as those involving solution quality and algorithmic complexity.

Planning and scheduling in artificial intelligence cover a wide range of techniques and issues. We have not attempted to be comprehensive in this relatively short chapter. Citations in the main text provide attribution for specifically mentioned techniques. These citations are not meant to be exhaustive by any means. General references are provided in the Further Information section at the end of this chapter.

Defining Terms

Closed-loop planner: A planning system that periodically makes observations of the current state of its environment and adjusts its plan in accord with these observations.

Dynamical system: A description of the environment in which plans are to be executed that account for the consequences of actions and the evolution of the state over time.

Goal: A subset of the set of all states such that a plan is judged successful if it results in the system ending up in one of these states.

History or state-space trajectory: A (possibly infinite) sequence of states generated by a dynamical system.

Off-line planning algorithm: A planning algorithm that performs all of its computations prior to executing any actions.

On-line planning algorithm: A planning algorithm in which planning computations and the execution of actions are carried out concurrently.

Open-loop planner: A planning system that executes its plans with no feedback from the environment, relying exclusively on its ability to accurately predict the evolution of the underlying dynamical system.

Optimizing: A performance criterion that requires maximizing or minimizing a specified measure of performance.

Plan: A specification for acting that maps from what is known at the time of execution to the set of actions.

Planning: A process that involves reasoning about the consequences of acting in order to choose from among a set of possible courses of action.

Progression: The operation of determining the resulting state of a dynamical system given some initial state and specified action.

Regression: The operation of transforming a given (target) goal into a prior (regressed) goal so that if a specified action is carried out in a state in which the regressed goal is satisfied, then the target goal will be satisfied in the resulting state.

Satisficing: A performance criterion in which some level of satisfactory performance is specified in terms of a goal or fixed performance threshold.

State-space operator: A representation for an individual action that maps each state into the state resulting from executing the action in the (initial) state.

State-transition function: A function that maps each state and action deterministically to a resulting state. In the stochastic case, this function is replaced by a conditional probability distribution.

Further Information

Research on planning and scheduling in artificial intelligence is published in the journals *Artificial Intelligence*, *Computational Intelligence*, and the *Journal of Artificial Intelligence Research*. Planning and scheduling work is also published in the proceedings of the International Joint Conference on Artificial Intelligence and the National Conference on Artificial Intelligence. Specialty conferences such as the International Conference on Artificial Intelligence Planning Systems and the European Workshop on Planning cover planning and scheduling exclusively.

Georgeff [1987] and Hendler et al. [1990] provide useful summaries of the state of the art. Allen et al. [1990] is a collection of readings that covers many important innovations in automated planning. Dean et al. [1995] and Penberthy and Weld [1992] provide somewhat more detailed accounts of the basic algorithms covered in this chapter. Zweben and Fox [1994] is a collection of readings that summarizes many of the basic techniques in knowledge-based scheduling. Allen et al. [1991] describe an approach to planning based on first-order logic. Dean and Wellman [1991] tie together techniques from planning in artificial intelligence, operations research, control theory, and the decision sciences.

68.1 Introduction

A machine learning system is one that automatically improves with experience, adapts to an external environment, or detects and extrapolates patterns. An appropriate machine learning technology could relieve the current economically dictated one-size-fits-all approach to application design. Help systems might specialize themselves to their users to choose an appropriate level of response-sophistication; portables might automatically prefer the most context-appropriate method to minimize power consumption; compilers may learn to optimize code to best exploit the processor, memory, and network resources of the machine on which they find themselves installed; and multimedia delivery systems might learn reliable time-varying patterns of available network bandwidth to optimize delivery decisions. The potential benefits to computer science of such abilities are immense and the opportunities ubiquitous. Machine learning promises to become the fractional horsepower motor of the information age.

Unfortunately, to date many formal results in machine learning and computational learning theory have been negative; they indicate that intractable numbers of training examples can be required for desirable real-world learning tasks. Such results are based upon statistical and information theoretic arguments and therefore apply to any algorithm. The reasoning can be paraphrased roughly along the following lines. When the desired concept is subtle and complex, a suitably flexible and expressive concept vocabulary must be employed to avoid cheating (i.e., directly encoding illegitimate preferences for the desired learning outcome). It follows that a great deal of evidence is required to tease apart the subtly different hypotheses. Each training example carries relatively little information and, thus, an inordinately large **training set** is required before we can be reasonably sure that an adequate concept has emerged. In fact, the numbers can be staggering: confidently acquiring good approximations to apparently simple everyday human-level

concepts can require more training examples than there are molecules in the universe. We take this as an indication that current inductive approaches, which focus on empirical learning with an *a priori* bias, are missing some important aspects.

Explanation-based learning (EBL) offers an alternative. In it, the information embodied in the training examples is augmented through interaction with declarative prior knowledge. This prior knowledge (or **domain theory**) describes an expert's understanding of the relevant conceptual structure of the world. Interaction is managed by an inference engine that uses the prior domain knowledge to conjecture possible causal patterns underlying the training examples. That is, it suggests *explanations* for why a particular training example is assigned its training classification and actively looks for evidence to confirm or refute these conjectures. EBL represents one way to combine deductive inference with inductive inference. Traditionally, the deductive and inductive approaches are quite disparate but they have complementary strengths. In deductive logic, nonlinear interactions are easily specified and can be efficient to infer. Unfortunately, in many AI research systems, logic has proved too brittle to adequately model real-world phenomena. On the other hand, inductive or statistical inference has been found in many disciplines to be sufficiently robust to model real-world phenomena. However, nonlinear interactions can be exponentially expensive to infer from data. EBL uses the strengths of each to overcome the weaknesses of the other.

The deductive component of EBL embodies significant departures from conventional logic. Unlike the axiom set of conventional logic, the EBL domain theory need not perfectly capture world interactions. There is no micro-world or intended model on which to base a conventional possible-worlds semantics. Instead, we assume that the formal representations only approximately capture world interactions. As a result, an expression derivable from the domain theory, even using a sound inferencer, counts only as *evidence* for believing the expression. In conventional logic, any sound derivation is a theorem and, *ipso facto*, can be fully believed. Thus, the syntactic procedure of constructing explanations is deductive, but semantically it is more in line with Peirce's abduction.

Compared to conventional empirical learning, an EBL system needs to rely much less on the examples for selecting a concept to describe the underlying phenomenon. This greatly reduces the risk of **overfitting**.

To illustrate, consider learning a **classifier** or **concept descriptor** intended to predict cities where John would like to live. For training examples, John says that acceptable cities include San Francisco, Paris, Boston, and Toronto, and that he would not like to live in Peoria, Boise, Topeka, or El Paso. We might guess that he wants to live in a large city. Or perhaps John enjoys an active night life. As we discover John's opinion on additional training cities, the set of possible classification rules narrows.

Clearly, a plethora of reasonable classifiers are consistent with this set of city assignments. Interestingly, many other rules that are just as accurate on the training set seem far less reasonable. The positive examples all have poorer air quality than the negative ones. Perhaps John wants to live in a place with unhealthy air pollution levels. Perhaps John wishes to avoid cities with the letter "e" in their names. We as humans have a natural predisposition toward certain descriptors and away from others. This common-sense ability to avoid silly hypotheses is central to the computational tractability of human concept acquisition.

Common sense is intuitively compelling to humans but elusive to computers. The only mechanism in the framework of conventional inductive learning is to supply an *a priori* preference against such concepts. The problem is that such preferences should often not be *a priori* and absolute but contingent on our understanding, which can change with training. If we come to believe that John is an opera buff or a professor or that he may suffer from 'E'-phobia, then we should amend our prior preferences accordingly. The set of "reasonable" concepts changes with our beliefs about John.

An alternative analysis suggests that existing beliefs influence our interpretation of the training examples. If John is a human like us, we can infer a great deal about his desires and priorities. We cannot know exactly what kind of person John is, but knowing he is a person allows us to interpret training examples as direct evidence about his own individualistic traits. Once estimated, these human attributes can help us to prefer more reasonable concept descriptors. We can think of the domain theory as a mechanism by which input training examples can be embellished to magnify their information content. EBL offers a systematic way to incorporate approximate declarative and general prior world knowledge into an automated inductive concept learning system.

68.2 Background

The conventional formalization of induction requires two spaces: an **example space** and a **hypothesis space**. The example space is the set of all items of interest in the world. In the example, this is the set of all possible cities. Note that the example space is a mathematical construct and we need not explicitly represent all of its elements. It is sufficient to specify set membership rules and be able to assert properties about some small number of explicitly represented elements. What city properties need to be represented for individual examples? For this example, we might include the city's population, whether or not it has a prestigious university, number of parks, and so on. The example space must represent enough properties to support the distinctions required by the concept descriptor. The set of all expressible concept descriptors forms the hypothesis space.

Most often, each example is represented as a vector of conjoined feature values. The values themselves are ground predicate logic expressions. Thus, we might represent one city, CITY381, as

$$\text{name=Toronto} \wedge \text{population=697,000} \wedge \text{area=221.77} \wedge \dots$$

An equal sign separates each feature name from its value. The symbol \wedge indicates the logical AND connective. We interpret the expression as saying that CITY381 is equivalent to something whose name is Toronto, whose population is 697,000, and \dots . Thus, CITY381 is now defined by its features. As in other logical formalisms, the actual symbol used to denote this city is arbitrary. If CITY381 were replaced everywhere by CITY382, nothing would change. One can imagine including many additional features such as the city's crime rate or the average housing price.

Toronto is a city in which John would be happy. Thus, its classification is positive. For John, city classification is binary (each city is preferred by John or it is not). In other applications (e.g., identifying aircraft types from visual cues or diagnosing tree diseases from symptoms), many different classes can exist.

Figure 68.1 is a schematic depiction of the example space for John's city preference. San Francisco, Paris, Boston, and Toronto (the four positive examples in the training set) are represented by the symbol $+$; Peoria, Boise, Topeka, and El Paso are marked as $-$. For pedagogical purposes we will simply use two dimensions. In general, there may be many dimensions and they need not be ordered or metric. Importantly, distinct cities correspond to distinct points in the space.

A classifier or concept descriptor is any function that partitions the example space. Figure 68.2 depicts three sample concept descriptors for John's city preference. Each concept classifies some examples as positive (those within its boundary) and the others as negative. Concept C1 misclassifies four cities; one undesirable city is included and three desirable cities are excluded. Concepts C2 and C3 both correctly classify all eight cities of the training set but embody quite different partitionings of the example space. Thus, they venture different labelings for unseen cities. C2 might classify all large cities as desirable, whereas C3 might classify any city without the letter "e" in its name as desirable.

FIGURE 68.1 The training set.

FIGURE 68.2 Three concept descriptors.

A concept descriptor can be represented using the same features employed to represent examples. Constrained variables augment ground expressions as feature values. Thus, a concept descriptor for large safe cities might be

$$\text{population}=?x \wedge \text{crime-index}=?y$$

with constraints $?x > 500,000$ and $?y < .03$

We might choose to allow disjunctions or other connectives. We might also allow more complex relations to serve as constraints among descriptor variables. By increasing the expressive power of the concept vocabulary, we allow more varied partitioning of the example space. The set of all expressible concept descriptors is the hypothesis space. Just as looking for the same needle is more challenging in a larger haystack, increasing the size of the hypothesis space by allowing a more expressive concept vocabulary can make the learning problem more difficult.

The unknown but objectively correct partitioning of the example space for the task at hand is called the **target concept**. In this example the target concept is embodied by John himself, who is the unimpeachable final authority on where he would like to live. Often, as in this example, the target concept is fundamentally unknowable. Most likely, we cannot fully capture John's city preferences. He might, for example, like large cities in general but have an unnatural fear of suspension bridges, a fondness for large groves of maple trees, or other subtle or peculiar personality quirks requiring distinctions not representable within our concept vocabulary. In machine learning, selecting a good approximate concept when the target concept is known not to be contained in the hypothesis space is known as agnostic learning. In the real world, it is the rule rather than the exception.

Even in those applications where we can be certain that within the hypothesis space lurks the true target concept, we may prefer an approximation. The target concept itself may be very complex, difficult to learn, or expensive to use, whereas a simpler approximation might be almost as accurate and much more efficient. Additionally, in most applications there is the possibility of noise. Some elements of the training set may be accidentally misclassified, or the values of some features may be incorrect, resulting in questionable training labels assigned or impossible or unlikely examples. These situations can often be treated in the agnostic regime.

Thus, the concept acquisition task is to find an element of the hypothesis space that is a good approximation of the target concept. We have reduced the slippery problem of inventing a new concept to the problem of finding a descriptor from a preexisting space of possible answers. Have we trivialized the concept formation task? No, this restriction is quite mild. In fact, we have only committed to a representational vocabulary. This is nothing more than a syntactic well-formedness criterion. Defining a hypothesis space is a bit like a publisher commissioning a novel with the stipulation that the manuscript be in English or requiring that it be typed with roman characters. Such restrictions are severe in the sense that they rule out far more items in our universe than they permit, but the author's creative latitude is not significantly diminished. So it is with properly defined hypothesis spaces. The commitment to a particular representation

vocabulary for concept descriptors defines a space. It rules out far more things than it permits. But properly done, the hypothesis space still supports a sufficiently rich variety of concept descriptors so as not to trivialize the learning problem.

An empirical or conventional inductive learning algorithm searches the hypothesis space guided only by the training data. It entertains hypotheses from the hypothesis set until sufficient training evidence confirms one or indicates that no acceptable one is likely to be found. The search is seldom uniquely determined by the training set elements. The concept found is often a function of the learning algorithm's characteristics. Such concept preferences that go beyond the training data, including representational limitations, are collectively termed the **inductive bias** of the learning algorithm. It has been well established that inductive bias is inescapable in concept learning. Incidentally, among the important implications of this result is the impossibility of any form of Lockean *tabula rasa* learning.

Discipline is necessary in formulating the inductive bias. A concept vocabulary that is overly expressive can dilute the hypothesis space and greatly increase the complexity of the concept acquisition task. On the other hand, a vocabulary that is not expressive enough may preclude finding an adequate concept or (more often) may trivialize the search so that the algorithm is condemned to find a desired concept without relying on the training data as it should. Essentially, hypothesis design then functions as arcane programming to predispose the learner to do what the implementor knows to be the right thing for the learning problem.

68.3 Explanation-Based and Empirical Learning

Explanation-based learning is best viewed as a principled method for extracting the maximum information from the training examples. It works by constructing explanations for the training examples and using the explanations to guide the selection of a concept descriptor. The explanations interpret the examples, bringing into focus alternative coherent sets of features that might be important for correct classification. The explanations also augment the examples by inference, adding features deemed relevant to the classification task.

We now explore a brief and intuitive example illustrating the difference between the explanation-based and the conventional inductive approaches.

Suppose we are lost in the jungle with our pet gerbil. We have only enough food to keep ourselves alive and decide that bugs, which are plentiful and easy to catch, will have to suffice for the gerbil. Unfortunately, a significant number of insect-like jungle creatures are poisonous. To save our pet we must quickly acquire a descriptor that identifies nonpoisonous bugs.

Again, we represent examples as feature/value pairs. Features might include a bug's number of legs, the number of body parts, the average size, the bug's coloring, how many wings it has, what it seems to like to eat, what seems to like to eat it, where it lives, a measure of how social it is, etc. One insect we see might be represented as

$$\begin{aligned} \text{legs}=6 \wedge \text{body-parts}=3 \wedge \text{size}=2\text{cm} \wedge \text{color}=\text{bright-purple} \\ \wedge \text{wings}=4 \wedge \text{wing-type}=\text{folding} \wedge \dots \end{aligned}$$

Let us call this bug X7 for the 7th example of a bug that we catch. The bug representation vocabulary can also serve as the concept descriptor vocabulary as long as we allow constrained variables to be feature values. A concept descriptor for nonpoisonous bugs might be something like

$$\text{legs}=?\times 1 \wedge \text{body-parts}=?\times 1 * 2 \wedge \text{size} > 1.5\text{cm} \wedge \text{color}=\text{purple}$$

which says that anything that has twice as many legs as body parts, is over 1.5 cm, and is purple will be considered nonpoisonous. This descriptor includes insects like X7 and long dark purple centipedes but excludes spiders (because they do not have enough body parts for their eight legs) and yellow butterflies (because they are the wrong color).

FIGURE 68.3 Training examples for an empirical learning approach: (a) hypothesized and (b) confirmed.

Empirical learning uncovers emergent patterns in the example space by viewing the training data as representative of all examples of interest. Patterns found within the training set are likely to be found in the world, provided the training set is a statistically adequate sample. In this example, we feed sample bugs to our gerbil to view the effect. An empirical system searches for an adequate concept descriptor by sampling broadly over the available bugs, revising estimates of the likelihood of various descriptors as evidence mounts. We may observe that the gerbil becomes nauseous and lethargic after eating X7, so we label it as poisonous. Next, X8, a reddish-brown many-legged worm that we find hidden on the jungle floor, is consumed with no apparent ill effects. It is labeled nonpoisonous. This process continues for several dozen bugs. A pattern begins to emerge. Figure 68.3a illustrates three of the potential concepts consistent with the first eight training examples. Assuming a reasonably expressive hypothesis space, there would be many such consistent concepts, and perhaps even an unboundedly large number.

We can be confident of the descriptor only after testing it on a statistically significant sample of bugs. This number can be quite large and depends on the expressivity of the hypothesis space. This can be quantified in a number of ways, the most popular being the Vapnik-Chervonenkis (or V-C) dimension. Perhaps after sampling several hundred or several thousand, we can statistically defend adopting the pattern that bugs that are either not bright purple or have more than ten legs and whose size is less than 3 cm are sufficiently plentiful and nonpoisonous to sustain our gerbil. This is illustrated in Figure 68.3b.

$$(\text{legs} > 10 \wedge \text{size} < 3\text{cm}) \vee \neg \text{color} = \text{PURPLE}$$

By contrast, the EBL approach searches for explanations of how gerbil poisoning/nonpoisoning can be connected to the observed bug's features using our background knowledge of the world. After observing that X7 makes our gerbil ill, we might recall the fact that poisonousness is a characteristic evolved to protect individuals of a species from being eaten. Furthermore, it is an effective deterrent only if the poisonous species itself is easily identifiable by its would-be predator. Thus, the bug should have a unique appearance, sharp patterns, bright colors, great regularity among individuals, etc. This explains the poisonousness of X7: the bright purple coloring is relevant, and the number of legs, the fact that it feeds on hemlock blossoms, etc. are irrelevant. The explanation also indicates that bugs that are plain-looking, camouflaged, or change their color to blend into their surroundings, are probably not poisonous. The palatability of X8 is justified by its plainness. Such an explanation provides evidence for and against the nonpoisonousness of many untested bugs. Figure 68.4a illustrates several possible positive and one negative explanation boundary. For a reasonable domain theory, there will be relatively few alternative ways of explaining positive or negative examples. Thus, if a few more test examples all turn out to be consistent with plainness, we can be quite confident that the rule of eating only plain-looking bugs will suffice for our gerbil. A confirmed EBL boundary is shown in Figure 68.4b. With EBL, the pattern emerges from the training data and explanation combined. Far fewer examples are required, which is fortunate for our gerbil.

Figures 68.3b and 68.4b show EBL and empirical approaches converging to the same concept boundaries in example space. This need not be the case. The particular concept selected may depend on many things,

FIGURE 68.4 Training examples for an EBL concept: (a) hypothesized and (b) confirmed.

including the order of presentation of the training examples, and in EBL, aspects of the domain theory. For example, suppose the background knowledge supported this explanation of X7: bugs are very simple organisms; they are more likely to collect and concentrate poison from elsewhere than to manufacture it within their bodies. If we also know a good deal about which plants are poisonous, we might choose only those bugs that, like X8, are seen to prefer feeding on nonpoisonous plants. Alternatively or additionally, we might know that gerbils are similar to jungle mice. We notice that jungle mice feed almost exclusively on grubs of the mound-building beetles that construct colonies in jungle clearings. We might reason that mound-building beetle grubs are, therefore, likely to be edible for our gerbil. After a few sample grubs are successfully devoured, we might acquire a concept descriptor that fits only these grubs. Although quite different boundaries result, each concept descriptor is adequate for nourishing the gerbil. Any one or the disjunction of all can be used to keep our pet alive.

68.4 Explanation-Based Learning

As we have seen, by getting the most out of each training example, EBL can acquire a concept descriptor using relatively few training examples. The price of example efficiency is a domain theory. Acquiring a concept descriptor with EBL consists of three steps:

1. Constructing one or more explanations from training examples
2. Using the the explanation(s) and examples together to construct a set of hypothesized EBL concept descriptors
3. Selecting one or more of the descriptors to apply to the task at hand

The first step, constructing explanations, employs an inference mechanism over the domain theory. For our purposes, a domain theory is any set of prior beliefs about the world, and an inference mechanism is any procedure that suggests new beliefs by combining existing beliefs. Any such procedure is quite acceptable; inference by analogy and other unsound methods are perfectly consistent with explanation-based learning. However, the inference mechanism will usually be some sound logical procedure such as first-order resolution. If the domain theory is imperfect, the inferencer must not be of the refutational or indirect variety. This is because a flawed domain theory may already contain contradictions, and so discovering a contradiction after adding the negated goal may have nothing whatever to do with explaining it.

An **explanation** for a training example is any tree-structured graph with the following properties:

- Each leaf node is either a prior belief or a property of the example being explained.
- Each nonleaf node is the result of applying the inference procedure to prior nodes.
- The root node is the training classification assigned to the example.

A sample explanation is shown in Figure 68.7. It has a characteristic triangular structure with the inference of the example's classification at the apex (root node). This explanation shows how the training example (OBJ1) can be classified to be a cup. We examine this explanation in greater detail in a moment. For now, note that the explanation justifies the classification of the example; an explanation conjectures an answer to *why* the example should be labeled with the classification given.

Once the explanations are constructed, they are used to conjecture one or more concept descriptors. An explanation, by its very nature, is narrowly focused. It applies to the training example but to little else. To yield a useful descriptor, the range of applicability must be broadened. *Generalization* involves removing constraints: eliminating some characteristics, replacing constants with variables, transforming some characteristics into more abstract ones, etc.

68.5 Constructing Explanations

We now examine these steps in greater detail by way of an example. We consider learning a concept descriptor for a simplified drinking cup. A suitable domain theory for this task is given in Figure 68.5. The domain knowledge is represented as a collection of first-order Horn clauses. Horn theories are a popular formalism for knowledge representation in artificial intelligence (AI). They embody an effective compromise between expressiveness and computational tractability, but there is nothing particularly special about first-order Horn theories as far as EBL is concerned. The knowledge representation language must simply support the construction of an explanation that carries evidence for its conclusion.

This illustrates the difference in semantics of an EBL domain theory. Treated as a logical expression, R3 provides sufficient conditions to entail an object is “lifiable.” As a plausible domain theory expression, R3 suggests that “lifiable” may be an important derived feature and that it might be adequately estimated from an object both being light and having a handle.

The domain theory: In our example, we provide the single training object, OBJ1, which is a known positive example of a cup. OBJ1 names the particular collection of properties shown in Figure 68.6a and Figure 68.6b. Two different representation schemes are presented. The first is a predicate calculus representation. It specifies a separate logical sentence for each of the relevant relations. The second is a semantic net representation. Here, each arrow or directed arc points from an object to a feature value that

- R1: $\forall x \text{ drinkable-from}(x) \Rightarrow \text{cup}(x)$
- R2: $\forall x \text{ liftable}(x) \wedge \text{open}(x) \Rightarrow \text{drinkable-from}(x)$
- R3: $\forall x \forall y \text{ weight}(x, \text{LIGHT}) \wedge \text{has-part}(x, y) \wedge \text{isa}(y, \text{HANDLE}) \Rightarrow \text{liftable}(x)$
- R4: $\forall x \forall y \text{ has-part}(x, y) \wedge \text{isa}(y, \text{CONCAVITY}) \Rightarrow \text{open}(x)$
- R5: $\forall x \forall y \text{ has-part}(x, y) \wedge \text{isa}(y, \text{CONCAVITY}) \wedge \text{orientation}(x, \text{UPWARD}) \Rightarrow \text{liquid-container}(x)$
- R6: $\forall x \forall y \text{ has-part}(x, y) \wedge \text{isa}(y, \text{FLAT-BOTTOM}) \Rightarrow \text{stable}(x)$

FIGURE 68.5 The CUP domain theory.

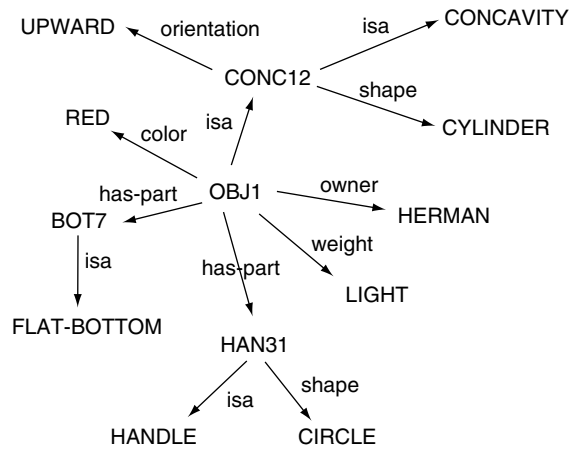

FIGURE 68.6b OBJ1 in semantic net notation.

the object possesses. The arrow is labeled with the name of the feature. Both representations specify that OBJ1 has three parts, called CONC12, HAN31, and BOT7. OBJ1 is colored RED, is owned by HERMAN, and so on.

Given OBJ1 as a positive example, an EBL system attempts to construct an explanation for why OBJ1 is indeed a cup. Figure 68.7 shows such an explanation. Arrows denote the contribution of each background knowledge rule to the explanation. For clarity, the quantification variables (each rule's formal parameters) have been renamed to be unique. Arrows point from a rule's antecedents to its consequent. For example, rule R3 allows the consequent property *liftable* to be concluded from the antecedents *weight*, *has-part*, and *isa*. The three arrows on the lower left, which are labeled as R3, constitute an instantiation of this domain theory rule. Double lines show expressions across rules that must match for the explanation to hold. These are enforced by unifying the connected expressions. Thus, the first antecedent of R3,

$$\text{weight}(x_3, \text{LIGHT})$$

is unified with the known property from the training example

$$\text{weight}(\text{OBJ1}, \text{LIGHT})$$

This match is contingent upon the variable x_3 , being bound to OBJ1 and variable y_3 being bound to HAN31. From the consequent we can infer that OBJ1 is *liftable*. This conclusion, along with others, supports the inference that OBJ1 has the property *drinkable-from*. By R1, we plausibly infer that OBJ1 is a cup, completing the explanation.

68.6 Generalizing

The next step produces a generalized EBL concept descriptor. There are several distinct kinds of generalization performed. But before describing them, it is important to be clear on the meaning of "generalization." In EBL, an explanation counts as derivational evidence for the classification label assigned to the training example. Generalizing means finding a larger set of examples where the same classification evidence applies. In the inductive learning literature, generalization can mean finding *any* larger set of examples that contains the example of interest. Simply removing a conjunct or adding a disjunct without regard for its effect on the explanation is not a well-formed EBL generalization.

The semantics of conventional first-order logic dictate that the sentences of the theory be consistent and correct (with respect to the intended interpretation) with a sound logical inference engine. Thus, if the

BINDINGS

- x_1 OBJ1
- x_2 OBJ1
- x_3 OBJ1
- x_4 OBJ1
- x_5 OBJ1
- x_6 OBJ1
- y_3 HAN31
- y_4 CONC12
- y_5 CONC12
- y_6 BOT7

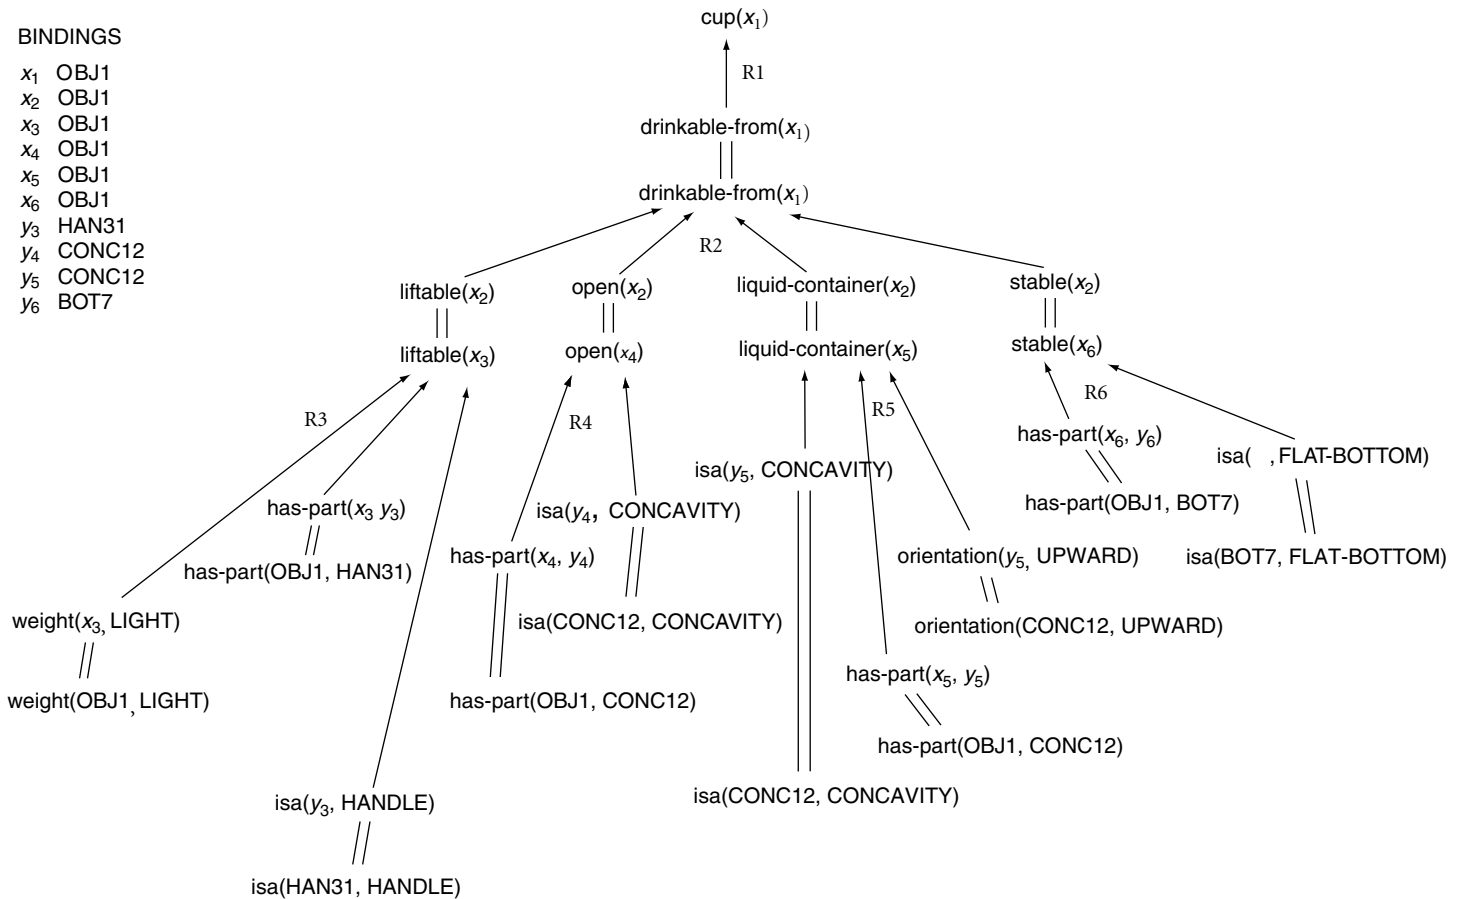

FIGURE 68.7 Explanation for the training example OBJ1.

foundation of the EBL system is conventional first-order logic, EBL-generalized descriptors are necessarily correct. This form of EBL is often termed *speed-up* learning. It is a common misconception in the literature that an EBL domain theory must be a conventional variety of logic. This has given rise to mistakenly *equating* EBL with speed-up learning, eliminating any **knowledge level change** in the performance system. This view precludes some of the most important strengths of EBL. Next we examine some individual types of EBL generalization.

68.6.1 Irrelevant Feature Elimination

The explanation provides sufficient grounds for believing that the training example (in our case, OBJ1) satisfies the goal specification (cupness). Clearly, any feature of OBJ1 not mentioned in the explanation could have a different value without affecting the explanation's veracity. The owner could have been George instead of Herman; the cup could be blue instead of red, etc. In general, most of an object's properties will not participate in the explanation. This is particularly true for more realistic representations. These might include many additional properties: its current location in the room, distances to other objects, what it is resting upon, how full it is, what it contains, the temperature of the contained liquid, whether it is clean or used and who drank from it last, where it was purchased, how valuable it is, etc.

Empirical learning systems can become overwhelmed in such situations. Coincidences abound when objects have many features, training data is limited, or the space of well-formed concepts is large. This is often the case in the real world. Coincidences, by their very nature, are not predictive of future examples. Empirical learners are vulnerable to such coincidences. The phenomenon of overfitting is related to this issue. Recall our first informal example of John's city preference. It is most likely a mere coincidence that testing for the letter "e" correctly classifies the training data. An empirical approach would have no legitimate mechanism to choose among descriptors that are equally complex and behave similarly on the training data. An EBL system, on the other hand, is unlikely to be sidetracked by such coincidences.

By irrelevant feature elimination, the example explanation of [Figure 68.7](#) gives rise to the concept descriptor C1:

$$\begin{aligned}
 &[\text{weight}(\text{OBJ1}, \text{LIGHT}) \wedge \text{has-part}(\text{OBJ1}, \text{HAN31}) \wedge \text{isa}(\text{HAN31}, \text{HANDLE}) \\
 &\quad \wedge \text{has-part}(\text{OBJ1}, \text{CONC12}) \wedge \text{isa}(\text{CONC12}, \text{CONCAVITY}) \\
 &\quad \wedge \text{orientation}(\text{CONC12}, \text{UPWARD}) \wedge \text{has-part}(\text{OBJ1}, \text{BOT7}) \\
 &\quad \wedge \text{isa}(\text{BOT7}, \text{FLAT-BOTTOM})] \Rightarrow \text{cup}(\text{OBJ1})
 \end{aligned}$$

This descriptor is not very general. Importantly, however, it is in the same form as the original background knowledge. That is, it provides an alternative method to infer the cupness of an object, and it states that weight, orientation, and the various isa and has-part relations are sufficient for this inference. No other features of the object are needed if these are present.

68.6.2 Identity Elimination

The second generalization type removes unnecessary mention of example characteristics. According to the explanation, OBJ1 is liftable by virtue of its having handle HAN31. Without a handle, the explanation's veracity is compromised. But the training example need not have had this particular handle. If it had some other handle (e.g., HAN32 or HAN4597), the conclusion of cupness would still be justified. Thus, HAN31 can be generalized into a predicate calculus variable. Likewise, OBJ1 can be generalized to a different predicate calculus variable. But we must ensure that required relations hold among these variables. The variable that replaces HAN31 must still be a handle; it must be a part of the variable that replaces OBJ1, and so on.

We can find the minimal general conditions required to conclude cupness by pruning the lowest portions of the explanation. Pruning involves breaking unification links within the explanation and keeping only the central structure (the subgraph that includes the goal justification). After this generalization step, we

can obtain the descriptor C2:

$$\forall x_1, y_3, y_4, y_6 [\text{weight}(x_1, \text{LIGHT}) \wedge \text{has-part}(x_1, y_3) \wedge \text{isa}(y_3, \text{HANDLE}) \\ \wedge \text{has-part}(x_1, y_4) \wedge \text{isa}(y_4, \text{CONCAVITY}) \wedge \text{orientation}(y_4, \text{UPWARD}) \\ \wedge \text{has-part}(x_1, y_6) \wedge \text{isa}(y_6, \text{FLAT-BOTTOM})] \Rightarrow \text{cup}(x_1)$$

This says that anything that has a handle, an upward pointing concavity, a flat bottom, and is light is a cup. This rule applies to many objects in addition to OBJ1 and can be used as a concept descriptor for cup classification. We can be confident of this descriptor's correctness although only one example has been seen. Identity elimination works because of generalities already built into the domain theory. These preexisting domain theory generalities are essential to EBL. If the domain theory were changed to include an alternate rule R3:

$$\text{R3a: } \forall x [\text{weight}(x, \text{LIGHT}) \wedge \text{has-part}(x, \text{HAN31}) \wedge \text{isa}(\text{HAN31}, \text{HANDLE})] \Rightarrow \text{liftable}(x)$$

then EBL generalization of HAN31 would not be possible although the conclusion of OBJ1's cupness would still be supported. For the sake of EBL, we would prefer to avoid domain rules such as R3a. Ideally, the role that an object plays in the domain theory is entirely determined by its properties, never by its identity. Philosophically, this has some interesting ramifications but it is uncontroversial so far as EBL is concerned. This has been termed the principle of *no function in form*. It is often adhered to in AI and usually results in a theory with fewer rules. This property is also important in the next generalization type.

68.6.3 Operationality Pruning

Easily reconstructable subexplanations of the original explanation can also be eliminated. For example, we could prune the substructure added by rule R6 by breaking the unification at the stable predicate. This results in a slightly different concept, C3:

$$\forall x_1, y_3, y_4, y_6 [\text{weight}(x_1, \text{LIGHT}) \wedge \text{has-part}(x_1, y_3) \wedge \text{isa}(y_3, \text{HANDLE}) \wedge \text{has-part}(x_1, y_4) \\ \wedge \text{isa}(y_4, \text{CONCAVITY}) \wedge \text{orientation}(y_4, \text{UPWARD}) \wedge \text{stable}(x_1)] \Rightarrow \text{cup}(x_1)$$

This descriptor is syntactically simpler than the previous one. It has one fewer antecedent conjuncts. However, to determine that a new object is a cup, that object's stability must now be justified at the time the concept is applied. The previous descriptor only consults properties expressed directly in the definition of the test object. In that rule, the test object's stability is never an issue. Sufficient ancillary properties are tested to justify that the object is stable. In particular, all objects are required to have flat bottoms. In point of fact, many objects are stable although they do not have flat bottoms. Indeed, many cups do not possess flat bottoms. The zarf (Figure 68.8) is often used in Middle Eastern countries to support hot coffee

FIGURE 68.8 The zarf.

FIGURE 68.9 Generality–operationality trade-off: (a) explanation and (b) operationality boundaries.

cups that have rounded bottoms. The zarf is a cylindrical chalice-like holder into which the rounded cup bottom is nestled. There are other common and not so common ways to achieve stability. While C3 is a more general concept descriptor, the price of this generality is that an inferencer must conclude stability when the concept descriptor is evaluated on an object. Thus, it is more expensive to use. We say it is less *operational*. Constructing a subexplanation on demand is typically a harder task than the straightforward lookup of several object properties.

Likewise, we could entertain concept descriptors that sever other of the explanation’s unifications. Cups could be allowed to be liftable by other means than having a handle, which include Styrofoam cups and the like. Liquid containment could be other than by an open concavity, giving rise to covered travel mugs. The higher in the explanation that unifications are broken, the more general is the resulting concept descriptor but the more expensive it is to evaluate.

Thus, there is a trade-off between concept descriptor generality and operationality. The minimal generalization is the result of applying identity elimination. The maximal generalization is an uninformative repetition of the general domain rule:

$$\forall x_1 \text{ drinkable-from}(x_1) \Rightarrow \text{cup}(x_1)$$

In between there are many alternative choices requiring progressively harder subexplanations to be constructed at the time of concept use.

Figure 68.9a shows a schematic explanation tree. An explanation’s **operationality boundary** is any coherent choice of unification pruning traversing the explanation structure. Figure 68.9b shows several schematic choices for the operationality boundary.

In the following section on selecting a concept descriptor, we discuss different approaches that have been advanced for deciding how to choose the operationality boundary. For now it is sufficient to realize that even once a particular explanation has been constructed, there are many potential concept descriptors from which to choose.

68.6.4 Disjunctive Augmentation

Pruning requires a subexplanation to be constructed from scratch at the time the concept is used. This can be expensive. Disjunctive augmentation supports similar flexibility at a greatly reduced cost. Instead of simply pruning a subexplanation, we add one or more alternative subexplanations, any one of which can be used to support the requisite property. At the time the concept is used, the system need only choose among several pruned subexplanations.

Suppose we give the learning system a second positive example of a cup. This cup’s stability is achieved by a zarf as in Figure 68.8. We also suppose that the system has sufficient background theory to conclude that this cup is indeed stable. The explanation of this example’s cupness will be similar to the explanation of Figure 68.7 except that stability is achieved by the zarf instead of the conventional flat bottom. Generalizing

both explained examples results in a disjunct supporting the stable predicate. Note that this is quite different from operationality pruning. No operationality boundary severs the stable predicate from its support. In this case, two distinct methods of achieving stability are determined. Satisfying either qualifies the object as a cup.

Disjunctive augmentation opens the door to potential inefficiencies. It is well established that disjunction is a primary source of computational complexity in automated inference. It is possible, indeed likely, that in any interesting explanation there are many augmentations possible which make subtle distinctions and result in only marginal improvements in a descriptor's generality. Discovering alternative subexplanations is expensive. Similarly, use of the concept descriptor can be made more complex.

68.7 The Utility Problem: Selecting a Concept Descriptor

In the final step, EBL ensures that the acquired concept is useful. Concepts are typically acquired for some purpose. There is little point in acquiring a new concept unless an AI application program (a scheduling system, diagnosis system, database retrieval agent, etc.) works better with it. It is important to appreciate that performance improvement in an application system is the ultimate goal of any machine learning system. Ensuring that acquired concepts help rather than hurt performance is the **utility problem**.

Concept accuracy is no guarantee of concept utility. In the performance system there is some cost associated with possessing concepts. A newly acquired concept may be accurate so that it indeed saves work by simplifying the task. The benefit of applying that concept may not outweigh the overhead of including it in the system. To illustrate, consider a commuter who drives home every workday. The standard well-traveled route, Avenue A, takes 15 min. Suppose a learning system discovers two additional routes home. One follows Avenue B and takes only 10 min, whereas the other follows Avenue C and takes 11 min. Because they are poorer roads, they are often closed for repair; but because there is but one road crew, they are never simultaneously closed. The newly learned concept chooses between these routes, both of which are quicker than Avenue A. The concept must include an antecedent to ensure that the selected road be open because each route only works when there is no construction. The acquired concept might say something like, "if there is no maintenance on Avenue B, then take it and save 5 min, else take Avenue C and save 4 min." The overhead cost of a piece of knowledge in the performance system includes three components: (1) the cost of locating the knowledge in memory, (2) the cost of evaluating precondition antecedents in the situation, and (3) the slowdown of locating other knowledge for other purposes caused by the presence of this knowledge. Consider cost 2 in the context of our example. Suppose the only reliable way to determine whether or not there is maintenance is by placing a call to the Public Works department. If it happens that such calls are completed within, say, 2 min, then the newly acquired concept is a useful one: with the concept, the performance system saves 2 to 3 min over solving the problem without the concept. However, if the Public Works office is typically busy or inefficient so that the average call takes 6 min, then the performance system incurs a penalty of 1 to 2 min with each application. In either case, the concept is accurate; it adequately captures the relevant world knowledge, shortens driving time, and never causes a solvable problem to become unsolvable. However, its inclusion may result in poorer system performance.

The decision on what concepts to adopt can be quite subtle. A concept's utility can be strongly influenced by attributes far removed from it. Here the crucial feature in determining positive or negative concept utility (the efficiency of the Public Works telephone operator) would at first seem quite distant from the process of driving home. A concept's utility can also depend on the particular distribution of problems to which the performance system will be applied. It can be influenced by other concepts that have been previously adopted. Thus, a utility judgment may be difficult to make reliably.

The fact that correct knowledge can harm the performance system is particularly troublesome for EBL. Because EBL is more example efficient, a particular training set may yield many more concepts using an EBL approach. The performance system can quickly become swamped even if the average concept utility is only slightly negative. Each concept's utility must be evaluated before it can be given to the performance system. Only concepts with positive utilities should be added.

FIGURE 68.10 Empirical utility analysis.

FIGURE 68.11 Analytic utility analysis.

There are two broad approaches to judging a concept's utility for a performance system. In the first or *empirical* approach, a hypothesized concept is temporarily added to the performance system to measure its effect, which is then taken as an estimate of its future utility. In the second or *analytic* approach, the decision to retain a new concept is inferred directly from the concept's definition.

Figure 68.10 illustrates the empirical approach. Newly hypothesized concepts from the generalizer are represented by the oval labeled Trial Concepts. The performance system, composed of the Native Performance System together with the Concept Library, processes problems from the world. The Empirical Utility Evaluation monitors the efficiency of the performance system augmented with individual trial concepts. As statistics are gathered and compared to baseline performance, evidence mounts for or against the utility of the currently conjectured concept. When there is sufficient evidence to warrant a confident judgment about the concept's utility, it is permanently added to the system's concept library or discarded.

The analytic approach is illustrated in Figure 68.11. The native performance system is not directly involved in the utility judgment. Rather, information on what constitutes efficient processing is represented in a theory of utility. Trial concepts are evaluated with respect to this *a priori* utility theory. Concepts that are judged likely to improve the performance system are added to the system's concept library; others are discarded.

In an empirical procedure, the definitions of the concept are not directly examined. The performance system simply continues its normal processing although it can now draw upon the conjectured concept. The empirical method quite naturally incorporates information implicit in the distribution of problems. The expected utility of a concept can vary even though the concept itself is static. The knowledge of how to control a high-speed car with a flat tire is of little use to a Bedouin who travels only by camel, but is crucial to a race car driver. Such phenomena do not preclude an analytic approach. The theory of utility may itself include information on estimated problem distributions, or the effect of problem distribution on utility may be insignificant in the face of other considerations. Hybrid approaches have also been examined.

Finally, we return to the issue of incorrect knowledge. One advantage of EBL is that the approach is quite forgiving of approximate knowledge representations. The functional specification of our cup (R1) is such a case. It allows a drinking glass to be a functional cup. However, concepts C1 through C3 do not apply to drinking glasses. The acquired concepts insist that the item in question have a handle. This robustness

is due to the interplay between the background theory and the teacher's positive training examples. If the teacher had labeled a glass as a cup, the EBL system might quite happily have conjectured a rather different set of descriptors. Provided the teacher does not mislead the system in a way that admits explanation, the EBL system is often safe from such overgeneralizing. By the same token, it is useful to endow the EBL system with an overly powerful inferential ability, one that is able to generate or conjecture explanations that need not be true under the semantics of conventional logic. The domain theory need not be complete or correct. This is in striking contrast with conventional inference or theorem proving systems in which the presence of any contradiction in the theory can have disastrous effects. The use of *approximate*, *overly general*, or *plausible* background theories has been studied by several researchers and is the subject of ongoing research.

68.8 Annotated Summary of EBL Issues

Two early AI works served as inspirations for the development of the EBL approach. These were the notion of goal regression [Waldinger 1977] and the MACROPS learning of the STRIPS system [Fikes et al. 1972]. The modern approach to EBL began with DeJong [1981], Mitchell [1983], and Silver [1983]. It enjoyed an explosion of research interest throughout the 1980s. Mitchell et al. [1986], DeJong and Mooney [1986], and Segre and Elkan [1994] provide general frameworks for EBL. The cognitive architectures of Prodigy [Carbonell et al. 1990], Theo [Mitchell et al. 1991], SOAR [Laird et al. 1987], and ACT [Anderson 1983] employ versions of EBL. In the latter two, the EBL-like mechanism is called "chunking" and generally applies to preserving processing traces. Cohen [1994] has advanced an formalism built upon abduction.

Minton [1985] pointed out aspects of the utility problem. Tambe [1988] reported a similar phenomenon in SOAR. Minton [1988] provided a detailed empirical solution. Greiner and Jurisica [1992] and Gratch and DeJong [1992] refined the approach along decision theoretic lines. An alternative is to limit concept acquisition to those that can be shown *a priori* to be inexpensive to evaluate. This analytic approach is taken by Etzioni [1990], Subramanian and Feldman [1990], and Letovsky [1990], and SOAR [Tambe 1988].

EBL has been employed as a learning mechanism in many other AI areas. Illustrative examples include planning [Kambhampati 2000], theory revision [Hirsh 1987, Ourston and Mooney 1994], analogy understanding [Russell 1989], natural language processing [Bangalore and Joshi 1995, Neumann 1997], and reinforcement learning [Dietterich and Flann 1995, Laud and DeJong 2002].

The role of prior knowledge in human concept formation is well established [Murphy and Medin 1985]. There is ample psychological evidence that in knowledge-rich contexts adult concept learning is more in line with EBL than conventional empirical mechanisms [Ahn et al. 1987, Anderson 1987, Pazzani 1989]. Surprisingly, infants as young as 5.5 months exhibit EBL-like learning mechanisms [Kotovsky and Baillargeon 1998, Baillargeon 2003].

From its inception, integrating EBL with empirical induction was seen as an important direction [Lebowitz 1986, Danyluk 1987, Bergadano and Giordana 1988, Flann and Dietterich 1989, Kodratoff and Tecuci 1989, Pazzani 1989, Russell 1989]. Neural networks have served as a particularly effective integration substrate [Thrun and Mitchell 1993, Shavlik and Towell 1994].

Defining Terms

Classifier or concept descriptor: The declarative representation of a partitioning of the example space to reflect example classification.

Domain theory: Any information supplied to the concept acquisition system about the application task, the application system, the nature of expected inputs, etc. This is also known as background knowledge.

Example space: The set of all classifiable objects.

Explanation: A tree-structured graph such that each leaf node is either a prior belief or a property of the example being explained, each nonleaf node is the result of applying an inference procedure to prior nodes, the root node is the training classification assigned to the example.

Hypothesis space: The set of all well-formed concept descriptors.

- Inductive bias:** Any preference not due to the training set which is exhibited by a concept acquisition algorithm for one concept descriptor over another.
- Knowledge level change:** Any change to an AI system's representation that goes beyond the inferential closure of its previously represented knowledge.
- Operationality boundary:** In a generalized explanation, any division between the root subtree and the peripheral subtrees such that the root subtree yields a useful concept.
- Overfitting:** The selection of a concept descriptor that captures a pattern exhibited by the training set but not exhibited by the target concept. In [Section 68.1](#), the concept that avoids cities with the letter "e" overfits the training data.
- Target concept:** The correct or desired partitioning of the example space.
- Training set:** A collection of examples whose classification is known. This is an input to a concept acquisition system from which a concept descriptor is induced.
- Utility problem:** The difficulty in ensuring that an acquired concept enhances the performance of the application system.

69.1 Introduction

An important goal of cognitive science is to understand human cognition. Good models of cognition can be *predictive* — describing how people are likely to react in different scenarios — as well as *prescriptive* — describing limitations in cognition and potentially ways in which the limitations might be overcome. In a sense, the benefits of having cognitive models are similar to the benefits individuals accrue in building their own internal model. To quote Craik [1943]:

If the organism carries a ‘small-scale model’ of external reality and of its own possible actions within its head, it is able to try out various alternatives, conclude which is the best of them, react to future situations before they arise, utilize the knowledge of past events in dealing with the present and future, and in every way to react in a much fuller, safer, and more competent manner to the emergencies which face it. (p. 61)

Among the important questions facing cognitive scientists are how such models are created and how they are represented internally. Craik emphasizes the importance of the predictive power of models, and it is the model’s ability to make accurate predictions that is the ultimate measure of the model’s value. One important value of computers in cognitive science is that computer simulations provide a means to instantiate theories and to concretely test their predictive power. Further, implementation of a theory in a computer model forces theoreticians to face practical issues that they may never have otherwise considered.

The role of computer science in cognitive modeling is not strictly limited to implementation and testing, however. A core belief of most cognitive scientists is that cognition is a form of computation (otherwise, computer modeling is a doomed enterprise) and the study of computation has long been a source of ideas (and material for debates) for building cognitive models. Computers themselves once served as the dominant metaphor for cognition. In more recent years, the influence of computers has been more in the area of computational paradigms, such as rule-based systems, neural network models, etc.

69.2 Underlying Principles

One of the dangers of cognitive modeling is falling under the spell of trying to apply computational models directly to cognition. A good example of this is the “mind as computer” metaphor that was once popular but has fallen into disfavor. Computer science offers a range of computational tools designed to solve problems, and it is tempting to apply these tools to psychological data and call the result a cognitive model. As McCloskey [1991] has pointed out, this falls far short of the criteria that could reasonably be used to define a theory of cognition. One replacement for the “mind as computer” metaphor makes this point well. Neurally inspired models of cognition fell out of favor following Minsky and Papert’s 1969 book *Perceptrons* that showed that the dominant neural models at the time were unable to model nonlinear functions (notably exclusive-or). The extension of these models by the PDP (Parallel Distributed Processing) group in 1986 [Rumelhart and McClelland, 1986] is largely responsible for the **connectionist** revolution of the past 25 years. The excitement generated by these models was twofold: (1) they were computationally powerful and simple to use, and (2) as neural-level models they appeared to be physiologically plausible.

A major difficulty for connectionist theory of the past 20 years has been that, despite the fact that the early PDP-style models (particularly models built upon **feed-forward back-propagation** networks) were proven to be implausible for both physiological and theoretical reasons (e.g., see [Lachter and Bever, 1988; Newell, 1990]), many cognitive models are still built using such discredited computational engines. The reason for this appears to be simple convenience. Back-propagation networks, for example, can approximate virtually any function and are simple to train. Because any set of psychological data can be viewed as a function that maps an input to a behavior, and because feed-forward back-propagation networks can approximate virtually any function, it is hardly surprising that such networks can “model” an extraordinary range of psychological phenomena. To put this another way, many cognitive models are written in computer languages like C. Although such models may accurately characterize a huge range of data on human cognition, no one would argue that the C programming language is a realistic model of human cognition. Feed-forward neural networks seem to be a better candidate for a cognitive model because of some of their features: they intrinsically learn, they process information in a manner reminiscent of neurons, etc. In any regard, this suggests that the criteria for judging the merits of a cognitive model must include many more constraints than whether or not the model is capable of accounting for a given data set. While issues such as how information is processed are useful for judging models, they are also crucial for constructing models.

There are a number of sources and types of constraints used in cognitive modeling. These break down relatively well by the disciplines that comprise the field. In practice most cognitive models draw constraints from some, but not all, of these disciplines. In broad terms, the data for cognitive models comes from psychology. “Hardware” constraints come from neuroscience. “Software” constraints come from computer science, which also provides methodologies for validation and testing. Two related fields that are relatively new, and therefore tend to provide softer constraints are evolutionary psychology and environmental psychology. The root idea of each of these fields is that the evolution process, and especially the environmental conditions that took place during evolution, are crucially important to the kind of brain that we now have. We will examine the impact of each field on cognitive modeling in turn.

69.2.1 Psychology

The ultimate test of any theory is whether or not it can account for, or correctly predict, human behavior. Psychology as a field is responsible for the vast majority of data on human behavior. Over the last century the source of this data has evolved from mere introspection on the part of theorists to rigorous laboratory experimentation. Normally the goal of psychological experiments is to isolate a particular cognitive factor; for example, the number of items a person can hold in short term memory. In general this isolation is used as a means of reducing complexity. In principle this means that cognitive theories can be constructed piecemeal instead of out of whole cloth. It would be fair to say that the majority of work in cognitive science proceeds on this principle. A fairly typical paper in a cognitive science conference proceeding, for example,

will present a set of psychological experiments on some specific area of cognition, a model to account for the data, and computer simulations of the model.

69.2.2 Neuroscience

The impact of neuroscience on cognitive science has grown dramatically in conjunction with the influence of neural models in the last 20 years. Unfortunately, terms such as “neurally plausible” have been applied fairly haphazardly in order to lend an air of credibility to models. In response, some critics have argued that neurons are not well understood enough to be productively used as part of cognitive theory. Nevertheless, though the low level details are still being studied, neuroscience can provide a rich source of constraints and information for cognitive modelers. Within the field there are several different types of architectural constraint available. These include:

1) *Information flow.* We have learned from neuroscientists, for example, that the visual system is divided into two distinct parts, a “what” system for object identification, and a “where” system for determining spatial locations. This suggests computational models of vision should have similar properties. Further, these constraints can be used to drive cognitive theory as with the PLAN model of human cognitive mapping [Chown, et al. 1995]. In PLAN it was posited that humans navigate in two distinct ways, each corresponding to one of the visual pathways. Virtually all theories of cognitive mapping had previously included a “what” component based upon topological collections of landmarks, but none had a good theory of how more metric representations are constructed. The split in the visual system led the developers of PLAN to theorize that metric representations would have simple “where” objects as their basic units. This led directly to a representation built out of “scenes,” which are roughly akin to snapshots.

2) *Modularity.* A great deal of work in neuroscience goes towards understanding what kinds of processing is done by particular areas of the brain, such as the hippocampus. These studies can range from working with patients with brain damage to intentionally lesioning animal brains. More recently, imaging techniques such as fMRI (functional magnetic resonance imaging) have been used to gain information non-invasively. This work has provided a picture of the brain far more complex than the simple “right brain-left brain” distinction of popular psychology. The hippocampus, for example, has been implicated in the retrieval of long-term memories [Squire, 1992] as well as in the processing of spatial information [O’Keefe and Nadel, 1978]. In principle, discovering what each of the brain’s different subsystems does is akin to determining what each function that makes up a computer program does.

Modularity in the brain, however, is not as clean as modularity in computer programs. This is largely due to the way information is processed in the brain, namely by neurons passing activity to each other in a massively parallel fashion. Items processed close together in the brain, for example, tend to interfere with each other because neural cells often have a kind of inhibitory surround. This fact is useful in understanding how certain perceptual processes work. Further it means that when one is thinking about a certain kind of math problem, it may be possible to also think about something unrelated like what will be for dinner, but it will be more difficult to simultaneously think about another math problem. The increased interference between similar items (processed close together) over items processed far apart has been called “the functional distance principle” by Kinsbourne [1982]. This suggests, among other things, that there may not be a clean separation of “modules” in the brain, and further that even within a module architectural issues impact processing.

3) *Mechanisms.* Numerous data are simpler to make sense of in the context of neural processing mechanisms. A good example of this would be the **Necker cube**. From a pure information processing point of view, there is no reason that people would only be able to hold one view of the cube in their mind at a time. From a neural point of view, on the other hand, the perception of the cube can be seen as a competitive process with two mutually inhibitory outcomes. Perceptual theory is an area that has particularly benefited from a neural viewpoint.

4) *Timing.* Perhaps the most famous constraint on cognitive processing offered by neuroscience is the “100 ms rule.” This rule is based upon looking at timing data of perception and the firing rate of

neurons. From these it has been determined that no perceptual algorithm could be more than 100 steps long (though the algorithm could be massively parallel as the brain itself is).

69.2.3 Computer Science

Aside from providing the means to implement and simulate models of cognition, computer science has also provided constraints on models through limits drawn from the theory of computation, and has been a source of algorithms for modelers.

One of the biggest debates in the cognitive modeling community is whether or not computers are even capable of modeling human intelligence. Critics, normally philosophers, point to the limitations on what is computable and have gone as far as suggesting that the mind may not be computational. While some find these debates interesting, they do not actually have a significant impact on the enterprise of modeling. On the other hand, there have been theoretical results from computational theory that have had a huge impact on the development of cognitive models. Probably the best example of this is the previously mentioned work done by Minsky and Papert on Perceptrons [1969]. They showed that perceptrons, which are a simple kind of neural network, are not capable of modeling nonlinear functions (including exclusive-or). This result effectively ended the majority of neural network research for more than a decade until the PDP group developed far more powerful neural network models [Rumelhart and McClelland, 1986].

69.2.4 Evolutionary and Environmental Psychology

In recent years two branches of psychology have come to prominence as providing alternate sources of constraints based upon evolution, and in particular the kinds of environments in which humans evolved. Evolutionary psychology is most often associated with the work of Tooby and Cosmides (e.g. [Tooby and Cosmides, 1992]) while environmental psychology is often associated with the work of Steve and Rachel Kaplan (e.g. [Kaplan & Kaplan, 1989]). What both of these fields have in common is a belief that the brain should not be studied in a vacuum, that some types of context are extremely meaningful.

In the case of evolutionary psychology the context is provided by evolution. As has been noted in many places, systems that are evolved rather than designed, tend to end up looking like the work of a “tinkerer.” The eye is a well known example of a system that is poorly “designed” but is nonetheless functional and can be understood as a series of successive improvements, each adding functionality to the previous iteration [Dawkins, 1986]. This example captures the core tenets of evolutionary psychology, that evolution tends to work in piecemeal fashion with each change adding functionality to what existed previously. This does not tend to be a hard constraint on cognitive models, as it can be argued that the evolutionary story behind any particular theory simply has yet to be found. Nevertheless, the evolutionary view provides a powerful way to think about how pieces of the cognitive system came about and for what purpose.

As the name would suggest, work in environmental psychology focuses on the environment as a source of constraints. Most environmental psychologists focus their research on how people interact with different kinds of environments and how to use this knowledge to design better spaces. Another branch of the field, however, has noted that the environment adds additional meaningful context to evolutionary history. The evolutionary history of the brain is a story of information processing mechanisms that evolved to address the specific needs of our ancestors. The human ability to represent and reason about large-scale space, for example, allowed our ancestors to forage and hunt over large areas of savanna. In turn once these spatial abilities were in place they were available for the greater cognitive system and impact cognition of virtually every type [Chown, 1999]. The importance in understanding the evolutionary environments that the brain developed in is highlighted by the work of the Kaplans and their colleagues. The Kaplans have shown, for example, that people will recover more quickly in hospitals with views of nature, perform better in workplaces with views of trees, etc (for reviews see [Kaplan, 1993; Kaplan and Peterson, 1993]). This is a clear indicator that people do not treat information neutrally. As Kaplan and others [Chown, et al. 2002] have argued, the human emotional system can be understood in these terms. The argument is based upon the idea that human emotions address the need our ancestors had to make very fast decisions in encounters

with other dangerous predators. In such cases it is usually better to act quickly than to pause and consider an optimal strategy. This view of cognition undercuts rationality approaches and helps explain many of the supposed shortcomings in human reasoning.

Some of the advantages of an evolutionary/environmental perspective have been clarified by work in robotics. Early artificial intelligence and cognitive mapping focused on reasoning, for example. This led to models that were too abstract to be implemented on actual robots. The move to using robots forced researchers to come at the problem from a far more practical point of view and to consider perceptual issues more directly.

69.3 Research Issues

Since so much about cognition is still not well understood, this section will focus on two of the key debates driving research in the field. These include: 1) is the brain a symbol processor, or does it need to be modeled in neural terms? 2) Should the field be working on grand theories of cognition, or is it better to proceed on a reductionist path?

69.3.1 Are We Symbol Processors?

The connectionist revolution brought a new way of thinking to cognitive science. The critical idea is rather simple — since the “hardware” of the brain is neural, then models of the brain should be described in neural terms. Lending credence to this position was a series of neural models that had a number of attractive properties that seemed notably lacking in symbolic models of the time (e.g. **content addressable memory**, **graceful degradation**, etc. [Rumelhart and McClelland, 1986]). On the face of it, the argument for neural models seems unassailable given that the brain is a neural system. Symbolists, notably Newell [1990] and Fodor and Plyshen [1988] have attacked these models on a number of grounds, however. Their arguments are based upon the idea that the brain, like any complex system, is hierarchical. Neural models, so the argument goes, provide appropriate computational descriptions for only the lowest levels of the cognitive hierarchy. From the point of view of the symbolists, these levels of cognition are also less well understood and not as interesting from a behavioral point of view as the so-called **cognitive band** [Newell, 1990]. From this point of view the operation of the cognitive band is nothing like a neural network, but is much more like a traditional symbol system. The argument is akin to finding the appropriate level at which to study computers. It is possible, and often necessary, to look at the performance of a computer from the point of view of gates. When trying to understand the performance of a complicated piece of software, however, it is much more appropriate to study the performance at the level of a high level programming language. Further, symbolists have effectively argued that current connectionist models are not capable of the full range of behaviors needed for cognitive modeling [Newell, 1990].

The argument for symbolic models comes from computational theory. It is based upon the idea of computational equivalence. Since symbolic models are Turing-complete they are equivalent computationally to any other Turing-complete model. Along these lines a number of efforts have been made to implement symbolic models in neural hardware. The case can then be made that this is exactly what the brain does. Symbolists see this equivalence as freeing them from the need to worry about mechanisms. Even so, the impact of connectionism and the capability of neural models for pattern recognition has led even strongly symbolic models like Soar [Laird, et al., 1987] to use neural networks as pattern recognizers to obtain the symbols.

The freeing up from the constraints of mechanisms has been something of a double-edged sword for symbolic models. On the one hand, symbolic models are easily implemented on computers and relatively easy to expand, debug, etc. Further, in terms of high-level behavior, symbolic models have been shown to be capable of a much wider range of behaviors than their current connectionist counterparts. For example, Soar agents are capable of modeling the flying behaviors of combat pilots [Jones et al., 1999]. On the other hand, critics have complained that systems like Soar are little more than symbolic programming languages. As noted earlier, while a computer running C may be Turing-complete, it would be ridiculous to call

it a model of human cognition. Clark [2001] refers to this as “surface mimicry” and points out that the Soar model is far more homogeneous than the “Swiss Army Knife” model suggested by Tooby and Cosmides [1992]. The critics argue that symbolic models like Soar and ACT-R are under constrained, and therefore they cannot truly be called cognitive models. The lack of constraints goes even further than just mechanisms, symbolic models have also been attacked on evolutionary grounds. It is difficult to see how symbolic constructs like distal memory access could have evolved in any sort of piecemeal fashion.

There are several arguments that symbolists use against neural models. First is the “levels of modeling” argument. This argument posits that we simply do not understand the behavior of neurons well enough to construct credible models from them. To be fair, the majority of neural models do not model the behavior of individual neurons. Other attacks on connectionist models are based upon what current models cannot do. Popular connectionist models, such as feed-forward back-propagation networks, for example, exhibit a number of problems as memory models including “catastrophic forgetting” of old material when presented with new material [McCloskey and Cohen, 1989]. While it is certainly appropriate to attack the individual models on these grounds, it is less so to attack the entire connectionist position based on the failure of even its most notable examples. Similarly, other criticisms of connectionism have attacked the models as being nothing more than new versions of the discredited behaviorist position [Lachter and Bever, 1988]. Again, this is certainly the case with many connectionist models, and should rightfully lead to a search for better models, but it cannot undermine the general position.

A more interesting criticism focuses upon the way that connectionists have pursued cognitive modeling. The argument is the same as the one against some of the symbolic programs. As McCloskey [1991] put it, connectionists often pursue a path of “simulation in search of theory” (p. 388). McCloskey argues that many of these simulations are little better than “black boxes.” Modelers do not provide insight into what aspects of the network are crucial to its performance with regard to the task. For example, if back-propagation was used to train the network, is that a crucial step, or could another training regime have been used? If back-propagation were crucial then it would undermine the model if back-propagation were found implausible on other grounds. In other words, connectionist systems are engaged in the same sort of “surface mimicry” as symbolic systems under the guise of “neural plausibility.” McCloskey goes on to complain that connectionist models generally fall short in describing how their networks elucidate the cognitive processes they purport to model. To put it simply, connectionist networks are not well understood enough to tell us exactly how they manage to accomplish what they are trained for.

So far in discussing connectionist systems, we have avoided discussing connectionist “symbols.” While it may be the case that connectionist units represent collections of neurons, they do not normally represent what most computer scientists would think of as symbols. There are, however, connectionist models that recognize the power of symbols as a basic unit of thought. Many of these models trace their lineage to the work of D.O. Hebb’s book *The Organization of Behavior* [1949]. Hebb proposed that the “symbols” of thought were cell assemblies, tightly connected groups of neurons capable of functioning as a unit because of their strong interconnections. The problem with cell assemblies as originally formulated by Hebb was that all of the connections between neurons were positive and only became stronger through learning. Hebb omitted inhibition because there was still no hard evidence of it at the time of publication. A later simulation of the cell assembly construct [Rochester, et al., 1956] showed that without inhibition activity in the simulated brain quickly grew out of control. Unfortunately these results were sufficient to essentially stop research on cell assemblies for more than a decade even though the same paper showed that with the addition of inhibition the cell assembly construct was viable. In recent years, however, the cell assembly idea has undergone a revival as researchers from a number of domains have proposed models based upon Hebb’s original idea, but modified with modern understandings of neuroscience [Kaplan et al., 1991; Amit, 1995].

Neural models based upon cell assemblies purport to contain the best of both symbolic and connectionist models. It is difficult to study sequence learning, for example, without something approximating a symbol to serve as a unit in the sequence. Further, many connectionist systems do not address temporal issues at all. Conversely, symbolic models do not ground the symbols in any physical mechanism, nor are symbolic systems able to take advantage of the properties of neural hardware. Chown [2002], for

example, has shown that some learning results that have defied conventional modeling for nearly 40 years can be fairly easily explained when basic neural properties are accounted for in a cell assembly-based model.

69.3.2 Grand Theories?

In his book *Unified Theories of Cognition* Allen Newell [1990] called for a return to all-encompassing theories of mind called UTCs after the title of the book. Newell's reasoning echoes McCloskey's complaints about connectionism [1991], that by operating at too small a scale cognitive modelers have worked on under-constrained models. While it may be true, for example, that connectionist system X can model psychological data set Y, such models rarely address questions of how they would or could fit into a larger system. Modeling efforts such as these are sometimes attacked on the grounds that they are "doomed to succeed" in much the same way that models with too many parameters can fit all types of curves. Put another way, if a model is Turing complete, the question of whether or not it can be used to fit some data is not particularly interesting. The interesting question is whether or not there is actually evidence for it. McCloskey and others argue that for these reasons theory should drive simulation rather than the other way around.

Ironically, the two most notable examples of UTCs, Soar and ACT-R, have been attacked on virtually the same grounds — that they are under-constrained. Both systems are built on the same assumption, that at higher levels of cognition the brain is a rule-based system. At the heart of each system is a production system implementing the rule-base that serves as long-term memory. Since production systems are Turing-complete they are capable of modeling anything. To be fair, however, Soar does make some key theoretical commitments that can be used to judge its merits. First and foremost, Soar is a symbol manipulation system with all that that implies. Second, in Soar deliberative thought is equated to a search through a problem space. For example, Soar is equipped with all the basic weak search methods including breadth-first, depth-first, etc. At one time another key constraint associated with Soar was that all learning came as the result of a single mechanism called "chunking" [Laird, et al., 1984]. It is not clear, however, from recent work in Soar that this is still held as a central tenet of the system.

Soar and ACT-R have both been attacked for their commitment to production systems. This criticism actually pre-dates either system and is most famously associated with the philosopher Hubert Dreyfus [1972]. The Dreyfus position is that systems based upon rules are too brittle to account for the richness of human behavior. For example, Dreyfus discusses how knowledge about the health of a jockey's mother might influence how a bettor would make a wager. It seems unlikely that the bettor would have explicit rules dealing with such a situation, and yet humans are capable of dealing with such situations with ease. The response to this criticism has been to test it explicitly, as with Doug Lenat's CYC [Lenat and Feigenbaum, 1992] which aims to capture enough knowledge to perform common sense reasoning, or with the Soar program which builds more and more complex agents capable of difficult tasks such as flying jet airplanes in combat situations. In part, Dreyfus's criticisms can also be addressed by noting that rules need not all be specified at the same level of generality. For example, while a system for betting on horses might contain many specific rules concerning the records of horses and jockeys, a general cognitive system might reasonably be expected to include rules such as "when something traumatic happens to a person they will not perform at normal levels." Of course this raises further questions of how such rules are learned, how patterns such as "something traumatic" are recognized, etc. Dreyfus would argue that this leads to an endless cycle for any reasonably complex task.

There are also connectionist programs that work at the level of large theories of cognition. Steven Grossberg, for example, has produced a huge body of work that have never been explicitly put forth as a UTC, but which when viewed as a whole have many of the same principles. Probably the best example of this work is the ART model developed in conjunction with Gail Carpenter [1987]. The SESAME group, operating mainly out of the University of Michigan is also working on a cognitive architecture [Kaplan et al., 1991]. The SESAME architecture is based on the cell assembly and is also the only cognitive architecture to include a complete theory of spatial processing [Chown et al., 1995].

69.4 Best Practices

As the previous sections suggest, there are a number of pitfalls involved in putting together a cognitive model. History has shown that there are two problems that crop up again and again. The first is the danger of constructing a simulation without theoretically motivating the details. This is akin to the old saw that “if you have a big enough hammer everything looks like a nail.” There is a related danger that once a simulation works (or at least models the data) it is often difficult to say why. Together these dangers suggest that there should be a close relationship between theory and the simulation process. The goal of a simulation should not be simply to model a dataset, but should also be to elucidate the theory. For example, some connectionist models propose a number of mechanisms as being central to understanding a particular process. These models can be systematically “damaged” by disabling the individual mechanisms. In many cases the damage to the model can be equated to damage to individuals. This provides a second dataset to model, and provides solid evidence of what the mechanism does in the simulation. Alternatively models can be built piecemeal mechanism by mechanism. Each new piece of the simulation would correspond to a new theoretical mechanism aiming to address some shortcoming of the previous iteration. This motivates each mechanism and helps to clearly delineate its role in the overall simulation. In the SESAME group this style of simulation has been termed “the systematic exploitation of failure” by one of its members, Abraham Kaplan.

One of the earliest examples of this approach was done by Booker [1982] in an influential work that has helped shape the adaptive systems paradigm. In an adaptive systems paradigm a simple creature is placed in a microworld where the goal is survival. Creatures are successively altered (and sometimes the environments are as well) by adding and subtracting mechanisms. In each case the success of the new mechanism can be judged by improvements in the survival rate of the organism. In addition to providing a way to motivate theoretical mechanisms, this paradigm is also essentially the same one used for the development of genetic algorithms.

The Soar architecture is probably the pre-eminent symbolic cognitive architecture. Soar is based upon a number of crucial premises that constrain all models written in Soar (which can be considered a kind of programming environment). First, Soar is a rule-based system implemented as a production system. In the Soar paradigm the production rules represent long-term memory and knowledge. One effect of a production firing in Soar can be to put new elements into working memory, Soar’s version of short-term memory. For example, a Soar system might contain a number of perceptual productions that aim to identify different types of aircraft. When a production fires it might create a structure in working memory to represent the aircraft it identifies. This structure in turn might cause further productions to fire. Soar enforces a kind of hierarchy through the use of a subgoal system. Productions can be written to apply generally, or might only match when a certain goal is active. The combination of goals and productions forms a problem space that provides the basic framework for any task. Finally, the Soar architecture contains a single mechanism for learning called “chunking.” Essentially Soar systems learn when they reach an impasse generally created by not being able to match any productions. When impasses occur Soar can apply weak search methods to the problem space in order to discover what to do. Once a solution is found, a new production or “chunk” is created to apply to the situation.

Here is an example of a Soar production taken from the Soar tutorial [Laird, 2001]. In this example the agent is driving a tank in a battle exercise.

```
1 sp {wander*propose*move
2   (state <s> ^ name wander
3     ^io.input-linked-blocked.forward no)
4 - -
5   (<s> ^operator <o> + = )
6   (<o> ^name move
7     ^ actions.move.direction forward) }
```

In the example “sp” stands for “Soar production” and starts every production. The production is named “wander*propose*move”. The elements that come before the arrow represent the “if” part of the production. In this case the production fires only if the current subgoal is to wander and the forward direction is not blocked (input comes from a specialized structure tagged $\wedge io$). The elements that come after the arrow represent the “then” parts of the production. In this case a new working memory element is created to represent the operator for moving forward. In a typical production cycle, productions are matched in parallel and can propose operators such as the move operator in this case. Then other productions can be used to select among the proposed operators. This selection can be based upon virtually any criteria; for example cognitive productions may be selected over more reactive productions. Production matching can be done in parallel to simulate the parallelism of the brain.

Both the Soar and ACT communities are engaged in programs of simulating more and more human behavior. These simulations can be done at the level of models of simple psychological experiments, or, as is increasingly the case, they can simulate human performance on complex tasks such as flying airplanes. The implicit argument is that if they can simulate anything that humans can do then they must be modeling human cognition. On one level this argument has merit, if either architecture can accurately simulate human performance then it can be used in a predictive fashion. Tac-air Soar [Jones et al., 1999], for example, simulates the performance of combat pilots and is used to train new pilots in a more cost-effective way than if experienced pilots had to be used. On the other hand equivalent functionality is not the same thing as equivalence. As noted previously, critics point out that both Soar and Act are essentially Turing-complete programming environments and therefore are capable of simulating any computable function given clever enough programmers. The fact that both systems still rely heavily on clever programming is still a major limitation with regard to being considered a fully realized model of human cognition. Although Soar’s initial success was due in large part to its learning mechanism, for example, little progress has been made within the Soar community in building agents that exhibit any sort of developmental patterns. It is much simpler to build a Soar system that can fly planes than one that can learn to fly planes.

Gail Carpenter, Stephen Grossberg and their associates have also attacked a wide range of problems, but have done so with much more of an eye towards cognitive theory than applications. While Carpenter and Grossberg have not explicitly developed a unified theory of cognition they have modeled a remarkable range of cognitive processes and has done so using an approach more sympathetic to a systems view of cognition than is typical in connectionist modelers. A good example of this approach can be found in their Adaptive Resonance Theory (ART) [Carpenter and Grossberg, 1987; Grossberg, 1987]. Superficially ART looks similar to many connectionist learning systems in that it is essentially a classification system, but it was developed to specifically address many of the shortcomings of such models. ART takes a feature vector as an input and uses it to provide a classification of the input. For example, a typical task would be to recognize hand-written numbers. The features would consist of the presence or absence of a pen stroke at different spatial locations.

One of the problems that ART was designed to address was what Grossberg [1987] referred to as the “stability-plasticity” dilemma. This is essentially a problem of how much new knowledge should impact what has been learned before. For example, a system that has been trained to recognize horses might have a problem when confronted with a zebra. The system could either change its representation of horses to include zebras, or it could create a separate representation for zebras. This is a significant issue for neural network models because they achieve a great deal of their power by having multiple representations share structure. Such sharing is useful for building compact representations and for automatic abstraction, but it also means that new knowledge tends to constantly overwrite what has come before. Among the problems this raises, is “catastrophic forgetting” as mentioned previously.

The stability-plasticity dilemma was addressed in part in ART through the introduction of a vigilance parameter that adaptively changed according to how well the system was performing. In some cases, for example, the system would be extremely vigilant and would require an unusually high degree of match before it would recognize an input as being familiar. In cases where inputs were not recognized as familiar, novel structure was created to form a new category or prototype. Such a new category would not

share internal structure directly with previously learned categories. Essentially when vigilance is high the system creates “exemplars” or very specialized categories, whereas when vigilance is low ART will create “prototypes” that generalize across many instances. This makes ART systems attractive since they do not commit fully either to exemplar or prototype models, but can exhibit properties of both, as seems to be the case with human categorization.

In ART systems an input vector activates a set of feature cells within an attentional system, essentially storing the vector in short-term memory. These in turn activate corresponding pathways in a bottom-up process. The weights in these pathways represent long-term memory traces and act to pass activity to individual categories. The degree of activation of a category represents an estimate that the input is an example of the category. In the meantime the categories send top down information back to the features as a kind of hypothesis test. The vigilance parameter defines the criteria for whether the match is good enough. When a match is established the bottom up and top down signals are locked into a “resonant” state, and this in turn triggers learning, is incorporated into consciousness, etc.

It is important to note that ART, unlike many connectionist learning systems, is unsupervised — it learns the categories without any teaching signals.

ART has since been extended to a number of times, to models including ART1, ART2, ART3, and ARTMAP. Grossberg has also tied it to his FACADE model in a system called ARTEX [Grossberg and Williamson, 1999]. These models vary in features and complexity, but share intrinsic theoretical properties. ART models are self-organizing (i.e., unsupervised, though ARTMAP systems can include supervised learning) and consist of an attentional and an orienting subsystem. A fundamental property of any ART system (and many other connectionist systems) is that perception is a competitive process. Different learned patterns generate expectations that essentially compete against each other. Meanwhile, the orienting system controls whether or not such expectations sufficiently match the input — in other words it acts as a novelty detector.

The ART family of models demonstrate many of the reasons why working with connectionist models can be so attractive. Among them:

- The neural computational medium is natural for many processes including perception. Fundamental ideas such as representations competing against each other (including inhibiting each other) are often difficult to capture in a symbolic model. In a system like ART, on the other hand, a systemic property like the level of activation of a unit can naturally fill many roles from the straightforward transmission of information to providing different measures of the goodness of fit of various representations to input data.
- The architecture of the brain is a source of both constraints and ideas. Parameters, such as ART’s vigilance parameter, can be linked directly to real brain mechanisms such as the arousal system. In this way what is known about the arousal system provides clues as to the necessary effects of the mechanism in the model and provides insight into how the brain handles fundamental issues such as the plasticity-stability dilemma.

69.5 Summary

Unlike many disciplines in computer science there are no provably correct algorithms for building cognitive models. Progress in the field is made through a process of successive approximation. Models are continually proposed and rejected; and with each iteration of this process the hope is that the models come closer to a true approximation of the underlying cognitive structure of the brain. It should be clear from the preceding sections that there is no “right” way to do this.

Improvements in cognitive models come from several sources. In many cases improvements result from an increased understanding of some aspect of cognition. For example, neuroscientists are constantly getting new data on how neurons work, how they are connected, what parts of the brain process what types of information, etc. In the meantime models are implemented on computers and on robots. These implementations provide direct feedback about model quality and shortcomings. This feedback often will

lead to revisions in the models and sometimes may even drive further experimental work. Because of the complexity of cognition and the number of interactions amongst parts of the brain it is really the case that definitive answers can be found; which is not to say that cognitive scientists do not reach consensus on any issues. Over time, for example, evidence has accumulated that there are multiple memory systems operating at different time scales. While many models have been proposed to account for this there is general agreement on the kinds of behavior that those models need to be able to display. This represents real progress in the field because it eliminates whole classes of models that could not account for the different time scales. The constraints provided by data and by testing models work to continually narrow the field of prospective models.

Defining Terms

Back-propagation A method for training neural networks based upon gradient descent. An error signal is propagated backward from output layers toward the input layer through the network.

Cognitive band In Newell's hierarchy of cognition, the cognitive band is the level at which deliberate thought takes place.

Cognitive map A mental model. Often, but not exclusively, used for models of large-scale space.

Connectionist A term used to describe neural network models. The choice of the term is meant to indicate that the power of the models comes from the massive number of connections between units within the model.

Content addressable memory Memory that can be retrieved by descriptors. For example, people can remember a person when given a general description of the person.

Feed forward Neural networks are often constructed in a series of layers. In many models, information flows from an input layer toward an output layer in one direction. Models in which the information flows in both directions are called **recurrent**.

Graceful degradation The principle that small changes in the input to a model, or that result from damage to a model, should result in only small changes to the model's performance. For example, adding noise to a model's input should not break the model.

Necker cube A three-dimensional drawing of a cube drawn in such a way that either of the two main squares that comprise the drawing can be viewed as the face closest to the viewer.

UTC Unified Theory of Cognition.

Further Information

There are numerous journals and conferences on cognitive modeling. Probably the best place to start is with the annual conference of the Cognitive Science Society. This conference takes place in a different city each summer. The Society also has an associated journal, *Cognitive Science*. Information on the journal and the conference can be found at the society's homepage at <http://www.cognitivesciencesociety.org>.

Because of the lag-time in publishing journals, conferences are often the best place to get the latest research. Among other conferences, Neural Information Processing Systems (NIPS) is one of the best for work specializing in neural modeling. The Simulation of Adaptive Behavior conference is excellent for adaptive systems. It has an associated journal as well, *Adaptive Behavior*.

A good place for anyone interested in cognitive modeling to start is Allen Newell's book, *Unified Theories of Cognition*. While a great deal of the book is devoted to Soar, the first several chapters lay out the challenges and issues facing any cognitive modeler. Another excellent starting point is Dana Ballard's 1999 book, *An Introduction to Natural Computation*. Ballard emphasizes neural models, and his book provides good coverage on most of the major models in use. Andy Clark's 2001 book, *Mindware: An Introduction to the Philosophy of Cognitive Science*, covers much of the same ground as this article, but in greater detail, especially with regard to the debate between connectionists and symbolists.

70.1 Introduction

This chapter surveys the development of graphical models known as Bayesian networks, summarizes their semantical basis, and assesses their properties and applications to reasoning and planning.

Bayesian networks are directed acyclic graphs (DAGs) in which the nodes represent variables of interest (e.g., the temperature of a device, the gender of a patient, a feature of an object, the occurrence of an event) and the links represent causal influences among the variables. The strength of an influence is represented by conditional probabilities that are attached to each cluster of parents–child nodes in the network.

Figure 70.1 illustrates a simple yet typical Bayesian network. It describes the causal relationships among the season of the year (X_1), whether rain falls (X_2) during the season, whether the sprinkler is on (X_3) during that season, whether the pavement would get wet (X_4), and whether the pavement would be slippery (X_5). All variables in this figure are binary, taking a value of either true or false, except the root variable X_1 , which can take one of four values: spring, summer, fall, or winter. Here, the absence of a direct link between X_1 and X_5 , for example, captures our understanding that the influence of seasonal variations on the slipperiness of the pavement is mediated by other conditions (e.g., the wetness of the pavement).

As this example illustrates, a Bayesian network constitutes a model of the environment rather than, as in many other knowledge representation schemes (e.g., logic, rule-based systems, and neural networks), a model of the reasoning process. It simulates, in fact, the causal mechanisms that operate in the environment and thus allows the investigator to answer a variety of queries, including associational queries, such as “Having observed A , what can we expect of B ?”; abductive queries, such as “What is the most plausible

FIGURE 70.1 A Bayesian network representing causal influences among five variables.

explanation for a given set of observations?"; and control queries, such as "What will happen if we intervene and act on the environment?" Answers to the first type of query depend only on probabilistic knowledge of the domain, whereas answers to the second and third types rely on the causal knowledge embedded in the network. Both types of knowledge, associative and causal, can effectively be represented and processed in Bayesian networks.

The associative facility of Bayesian networks may be used to model cognitive tasks such as object recognition, reading comprehension, and temporal projections. For such tasks, the probabilistic basis of Bayesian networks offers a coherent semantics for coordinating top-down and bottom-up inferences, thus bridging information from high-level concepts and low-level percepts. This capability is important for achieving selective attention, that is, selecting the most informative next observation before actually making the observation. In certain structures, the coordination of these two modes of inference can be accomplished by parallel and distributed processes that communicate through the links in the network.

However, the most distinctive feature of Bayesian networks, stemming largely from their causal organization, is their ability to represent and respond to changing configurations. Any local reconfiguration of the mechanisms in the environment can be translated, with only minor modification, into an isomorphic reconfiguration of the network topology. For example, to represent a disabled sprinkler, we simply delete from the network all links incident to the node sprinkler. To represent a pavement covered by a tent, we simply delete the link between rain and wet. This flexibility is often cited as the ingredient that marks the division between deliberative and reactive agents and that enables the former to manage novel situations instantaneously, without requiring retraining or adaptation.

70.2 Historical Background

Networks employing DAGs have a long and rich tradition, starting with the geneticist Sewall Wright [1921]. He developed a method called *path analysis* [Wright 1934], which later became an established representation of causal models in economics [Wold 1964], sociology [Blalock 1971, Kenny 1979], and psychology [Duncan 1975]. Good [1961] used DAGs to represent causal hierarchies of binary variables with disjunctive causes. *Influence diagrams* represent another application of DAG representation [Howard and Matheson 1981]. Developed for decision analysis, they contain both event nodes and decision nodes. *Recursive models* is the name given to such networks by statisticians seeking meaningful and effective decompositions of contingency tables [Lauritzen 1982, Wermuth and Lauritzen 1983, Kiiveri et al. 1984].

The role of the network in the applications cited was primarily to provide an efficient description for probability functions; once the network was configured, all subsequent computations were pursued by symbolic manipulation of probability expressions. The potential for the network to work as a computational architecture, and hence as a model of cognitive activities, was noted in Pearl [1982], where a distributed scheme was demonstrated for probabilistic updating on tree-structured networks. The motivation behind this particular development was the modeling of distributed processing in reading comprehension [Rumelhart 1976], where both top-down and bottom-up inferences are combined to form a coherent interpretation. This dual mode of reasoning is at the heart of Bayesian updating and in fact motivated

Reverend Bayes's original 1763 calculations of posterior probabilities (representing explanations), given prior probabilities (representing causes), and likelihood functions (representing evidence).

Bayesian networks have not attracted much attention in the logic and cognitive modeling circles, but they did in expert systems. The ability to coordinate bidirectional inferences filled a void in expert systems technology of the late 1970s, and it is in this area that Bayesian networks truly flourished. Over the past 10 years, Bayesian networks have become a tool of great versatility and power, and they are now the most common representation scheme for probabilistic knowledge [Shafer and Pearl 1990, Shachter 1990, Oliver and Smith 1990, Neapolitan 1990]. They have been used to aid in the diagnosis of medical patients [Heckerman 1991, Andersen et al. 1989, Heckerman et al. 1990, Peng and Reggia 1990] and malfunctioning systems [Agogino et al. 1988]; to understand stories [Charniak and Goldman 1991]; to filter documents [Turtle and Croft 1991]; to interpret pictures [Levitt et al. 1990]; to perform filtering, smoothing, and prediction [Abramson 1991]; to facilitate planning in uncertain environments [Dean and Wellman 1991]; and to study causation, nonmonotonicity, action, change, and attention. Some of these applications are described in a tutorial article by Charniak [1991]; others can be found in Pearl [1988], Shafer and Pearl [1990], and Goldszmidt and Pearl [1996].

70.3 Bayesian Networks as Carriers of Probabilistic Information

70.3.1 Formal Semantics

Given a DAG G and a joint distribution P over a set $X = \{X_1, \dots, X_n\}$ of discrete variables, we say that G represents P if there is a one-to-one correspondence between the variables in X and the nodes of G , such that P admits the recursive product decomposition

$$P(x_1, \dots, x_n) = \prod_i P(x_i \mid pa_i) \quad (70.1)$$

where pa_i are the direct predecessors (called *parents*) of X_i in G . For example, the DAG in Figure 70.1 induces the decomposition

$$P(x_1, x_2, x_3, x_4, x_5) = P(x_1)P(x_2 \mid x_1)P(x_3 \mid x_1)P(x_4 \mid x_2, x_3)P(x_5 \mid x_4) \quad (70.2)$$

The recursive decomposition in Equation 70.1 implies that, given its parent set pa_i , each variable X_i is conditionally independent of all its other predecessors $\{X_1, X_2, \dots, X_{i-1}\} \setminus pa_i$. Using Dawid's notation [Dawid 1979], we can state this set of independencies as

$$X_i \perp\!\!\!\perp \{X_1, X_2, \dots, X_{i-1}\} \setminus pa_i \mid pa_i \quad i = 2, \dots, n \quad (70.3)$$

Such a set of independencies is called *Markovian*, since it reflects the Markovian condition for state transitions: each state is rendered independent of the past, given its immediately preceding state. For example, the DAG of Figure 70.1 implies the following Markovian independencies:

$$X_2 \perp\!\!\!\perp \{\emptyset\} \mid X_1, \quad X_3 \perp\!\!\!\perp X_2 \mid X_1, \quad X_4 \perp\!\!\!\perp X_1 \mid \{X_2, X_3\}, \quad X_5 \perp\!\!\!\perp \{X_1, X_2, X_3\} \mid X_4 \quad (70.4)$$

In addition to these, the decomposition of Equation 70.1 implies many more independencies, the sum total of which can be identified from the DAG using the graphical criterion of d -separation [Pearl 1988]:

Definition 70.1 (d -separation.) Let a path in a DAG be a sequence of consecutive edges, of any directionality. A path p is said to be d -separated (or blocked) by a set of nodes Z iff:

1. p contains a chain $i \longrightarrow j \longrightarrow k$ or a fork $i \longleftarrow j \longrightarrow k$ such that the middle node j is in Z .
2. Or p contains an inverted fork $i \longrightarrow j \longleftarrow k$ such that neither the middle node j nor any of its descendants (in G) are in Z .

If X , Y , and Z are three disjoint subsets of nodes in a DAG G , then Z is said to d -separate X from Y , denoted $(X \perp\!\!\!\perp Y \mid Z)_G$, iff Z d -separates every path from a node in X to a node in Y .

In Figure 70.1, for example, $X = \{X_2\}$ and $Y = \{X_3\}$ are d -separated by $Z = \{X_1\}$; the path $X_2 \leftarrow X_1 \rightarrow X_3$ is blocked by $X_1 \in Z$, while the path $X_2 \rightarrow X_4 \leftarrow X_3$ is blocked because X_4 and all its descendants are outside Z . Thus, $(X_2 \perp\!\!\!\perp X_3 \mid X_1)_G$ holds in Figure 70.1. However, X and Y are not d -separated by $Z' = \{X_1, X_5\}$, because the path $X_2 \rightarrow X_4 \leftarrow X_3$ is rendered active by virtue of X_5 , a descendant of X_4 , being in Z' . Consequently $(X_2 \perp\!\!\!\perp X_3 \mid \{X_1, X_5\})_G$ does not hold; in words, learning the value of the consequence X_5 renders its causes X_2 and X_3 dependent, as if a pathway were opened along the arrows converging at X_4 .

The d -separation criterion has been shown to be both necessary and sufficient relative to the set of distributions that are represented by a DAG G [Verma and Pearl 1990, Geiger et al. 1990]. In other words, there is a one-to-one correspondence between the set of independencies implied by the recursive decomposition of Equation 70.1 and the set of triples (X, Z, Y) that satisfies the d -separation criterion in G . Furthermore, the d -separation criterion can be tested in time linear in the number of edges in G . Thus, a DAG can be viewed as an efficient scheme for representing Markovian independence assumptions and for deducing and displaying all of the logical consequences of such assumptions.

An important property that follows from the d -separation characterization is a criterion for determining when two DAGs are observationally equivalent, that is, every probability distribution that is represented by one of the DAGs is also represented by the other:

Theorem 70.1 (Verma and Pearl 1990.) *Two DAGs are observationally equivalent if and only if they have the same sets of edges and the same sets of v -structures, that is, head-to-head arrows with nonadjacent tails.*

The soundness of the d -separation criterion holds not only for probabilistic independencies but for any abstract notion of conditional independence that obeys the semigraphoid axioms [Verma and Pearl 1990, Geiger et al. 1990]. Additional properties of DAGs and their applications to evidential reasoning in expert systems are discussed in Pearl [1988, 1993a], Pearl et al. [1990], Geiger [1990] Lauritzen and Spiegelhalter [1988], and Spiegelhalter et al. [1993].

70.3.2 Inference Algorithms

The first algorithms proposed for probability updating in Bayesian networks used message-passing architecture and were limited to trees [Pearl 1982] and singly connected networks [Kim and Pearl 1983]. The idea was to assign each variable a simple processor, forced to communicate only with its neighbors, and to permit asynchronous back-and-forth message passing until equilibrium was achieved. Coherent equilibrium can indeed be achieved this way, but only in singly connected networks, where an equilibrium state occurs in time proportional to the diameter of the network.

Many techniques have been developed and refined to extend the tree-propagation method to general, multiply connected networks. Among the most popular are Shachter's [1988] method of node elimination, Lauritzen and Spiegelhalter's [1988] method of clique-tree propagation, and the method of loop-cut conditioning [Pearl 1988, Ch. 4.3].

Clique-tree propagation, the most popular of the three methods, works as follows. Starting with a directed network representation, the network is transformed into an undirected graph that retains all of its original dependencies. This graph, sometimes called a Markov network [Pearl 1988, Ch. 3.1], is then triangulated to form local clusters of nodes (cliques) that are tree structured. Evidence propagates from clique to clique by ensuring that the probability of their intersection set is the same, regardless of which of the two cliques is considered in the computation. Finally, when the propagation process subsides, the posterior probability of an individual variable is computed by projecting (marginalizing) the distribution of the hosting clique onto this variable.

Whereas the task of updating probabilities in general networks is NP-hard [Rosenthal 1977, Cooper 1990], the complexity for each of the three methods cited is exponential in the size of the largest clique found in some triangulation of the network. It is fortunate that these complexities can be estimated prior to actual processing; when the estimates exceed reasonable bounds, an approximation method such as stochastic simulation [Pearl 1987, Henrion 1988] can be used instead. Learning techniques have also been developed for systematic updating of the conditional probabilities $P(x_i | pa_i)$ so as to match empirical data [Spiegelhalter and Lauritzen 1990].

70.3.3 System's Properties

By providing graphical means for representing and manipulating probabilistic knowledge, Bayesian networks overcome many of the conceptual and computational difficulties of earlier knowledge-based systems [Pearl 1988]. Their basic properties and capabilities can be summarized as follows:

1. Graphical methods make it easy to maintain consistency and completeness in probabilistic knowledge bases. They also define modular procedures of knowledge acquisition that reduce significantly the number of assessments required [Pearl 1988, Heckerman 1991].
2. Independencies can be dealt with explicitly. They can be articulated by an expert, encoded graphically, read off the network, and reasoned about; yet they forever remain robust to numerical imprecision [Geiger 1990, Geiger et al. 1990, Pearl et al. 1990].
3. Graphical representations uncover opportunities for efficient computation. Distributed updating is feasible in knowledge structures which are rich enough to exhibit intercausal interactions (e.g., explaining away) [Pearl 1982, Kim and Pearl 1983]. And, when extended by clustering or conditioning, tree-propagation algorithms are capable of updating networks of arbitrary topology [Lauritzen and Spiegelhalter 1988, Shachter 1986, Pearl 1988].
4. The combination of predictive and abductive inferences resolves many problems encountered by first-generation expert systems and renders belief networks a viable model for cognitive functions requiring both top-down and bottom-up inferences [Pearl 1988, Shafer and Pearl 1990].
5. The causal information encoded in Bayesian networks facilitates the analysis of action sequences, their consequences, their interaction with observations, their expected utilities, and, hence, the synthesis of plans and strategies under uncertainty [Dean and Wellman 1991, Pearl 1993b, 1994b].
6. The isomorphism between the topology of Bayesian networks and the stable mechanisms, which operate in the environment, facilitates modular reconfiguration of the network in response to changing conditions and permits deliberative reasoning about novel situations.

70.3.4 Recent Developments

70.3.4.1 Causal Discovery

One of the most exciting prospects in recent years has been the possibility of using the theory of Bayesian networks to discover causal structures in raw statistical data. Several systems have been developed for this purpose [Pearl and Verma 1991, Spirtes et al. 1993], which systematically search and identify causal structures with hidden variables from empirical data. Technically, because these algorithms rely merely on conditional independence relationships, the structures found are valid only if one is willing to accept weaker forms of guarantees than those obtained through controlled randomized experiments: minimality and stability [Pearl and Verma 1991]. Minimality guarantees that any other structure compatible with the data is necessarily less specific, and hence less falsifiable and less trustworthy, than the one(s) inferred. Stability ensures that any alternative structure compatible with the data must be less stable than the one(s) inferred; namely, slight fluctuations in experimental conditions will render that structure no longer compatible with the data. With these forms of guarantees, the theory provides criteria for identifying genuine and spurious causes, with or without temporal information.

Alternative methods of identifying structure in data assign prior probabilities to the parameters of the network and use Bayesian updating to score the degree to which a given network fits the data [Cooper and Herskovits 1990, Heckerman et al. 1994]. These methods have the advantage of operating well under small sample conditions but encounter difficulties coping with hidden variables.

70.3.4.2 Plain Beliefs

In mundane decision making, beliefs are revised not by adjusting numerical probabilities but by tentatively accepting some sentences as true for all practical purposes. Such sentences, often named *plain beliefs*, exhibit both logical and probabilistic character. As in classical logic, they are propositional and deductively closed; as in probability, they are subject to retraction and to varying degrees of entrenchment [Spohn 1988, Goldszmidt and Pearl 1992].

Bayesian networks can be adopted to model the dynamic of plain beliefs by replacing ordinary probabilities with nonstandard probabilities, that is, probabilities that are infinitesimally close to either zero or one. This amounts to taking an order of magnitude approximation of empirical frequencies and adopting new combination rules tailored to reflect this approximation. The result is an integer-addition calculus, very similar to probability calculus, with summation replacing multiplication and minimization replacing addition. A plain belief is then identified as a proposition whose negation obtains an infinitesimal probability (i.e., an integer greater than zero). The connection between infinitesimal probabilities and nonmonotonic logic is described in Pearl [1994a] and Goldszmidt and Pearl [1996].

This combination of infinitesimal probabilities with the causal information encoded by the structure of Bayesian networks facilitates linguistic communication of belief commitments, explanations, actions, goals, and preferences and serves as the basis for current research on qualitative planning under uncertainty [Darwiche and Pearl 1994, Goldszmidt and Pearl 1992, Pearl 1993b, Darwiche and Goldszmidt 1994]. Some of these aspects will be presented in the next section.

70.4 Bayesian Networks as Carriers of Causal Information

The interpretation of DAGs as carriers of independence assumptions does not necessarily imply causation and will in fact be valid for any set of Markovian independencies along any ordering (not necessarily causal or chronological) of the variables. However, the patterns of independencies portrayed in a DAG are typical of causal organizations and some of these patterns can be given meaningful interpretation only in terms of causation. Consider, for example, two independent events, E_1 and E_2 , that have a common effect E_3 . This triple represents an intransitive pattern of dependencies: E_1 and E_3 are dependent, E_3 and E_2 are dependent, yet E_1 and E_2 are independent. Such a pattern cannot be represented in undirected graphs because connectivity in undirected graphs is transitive. Likewise, it is not easily represented in neural networks, because E_1 and E_2 should turn dependent once E_3 is known. The DAG representation provides a convenient language for intransitive dependencies via the converging pattern $E_1 \rightarrow E_3 \leftarrow E_2$, which implies the independence of E_1 and E_2 as well as the dependence of E_1 and E_3 and of E_2 and E_3 . The distinction between transitive and intransitive dependencies is the basis for the causal discovery systems of Pearl and Verma [1991] and Spirtes et al. [1993]. (See subsection on causal discovery.)

However, the Markovian account still leaves open the question of how such intricate patterns of independencies relate to the more basic notions associated with causation, such as influence, manipulation, and control, which reside outside the province of probability theory. The connection is made in the mechanism-based account of causation.

The basic idea behind this account goes back to structural equations models [Wright 1921, Haavelmo 1943, Simon 1953] and it was adapted in Pearl and Verma [1991] for defining probabilistic causal theories, as follows. Each child–parents family in a DAG G represents a deterministic function

$$X_i = f_i(pa_i, \epsilon_i) \tag{70.5}$$

where pa_i are the parents of variable X_i in G , and $\epsilon_i, 0 < i < n$, are mutually independent, arbitrarily distributed random disturbances. Characterizing each child–parent relationship as a deterministic function, instead of the usual conditional probability $P(x_i | pa_i)$, imposes equivalent independence constraints on the resulting distributions and leads to the same recursive decomposition that characterizes DAG models (see Equation 70.1). However, the functional characterization $X_i = f_i(pa_i, \epsilon_i)$ also specifies how the resulting distributions would change in response to external interventions, since each function is presumed to represent a stable mechanism in the domain and therefore remains constant unless specifically altered. Thus, once we know the identity of the mechanisms altered by the intervention and the nature of the alteration, the overall effect of an intervention can be predicted by modifying the appropriate equations in the model of Equation 70.5 and using the modified model to compute a new probability function of the observables.

The simplest type of external intervention is one in which a single variable, say X_i , is forced to take on some fixed value x'_i . Such *atomic* intervention amounts to replacing the old functional mechanism $X_i = f_i(pa_i, \epsilon_i)$ with a new mechanism $X_i = x'_i$ governed by some external force that sets the value x'_i . If we imagine that each variable X_i could potentially be subject to the influence of such an external force, then we can view each Bayesian network as an efficient code for predicting the effects of atomic interventions and of various combinations of such interventions, without representing these interventions explicitly.

70.4.1 Causal Theories, Actions, Causal Effect, and Identifiability

Definition 70.2 A causal theory is a 4-tuple

$$T = \langle V, U, P(u), \{f_i\} \rangle$$

where:

1. $V = \{X_1, \dots, X_n\}$ is a set of observed variables.
2. $U = \{U_1, \dots, U_n\}$ is a set of unobserved variables which represent disturbances, abnormalities, or assumptions.
3. $P(u)$ is a distribution function over U_1, \dots, U_n .
4. $\{f_i\}$ is a set of n deterministic functions, each of the form

$$X_i = f_i(PA_i, u) \quad i = 1, \dots, n \tag{70.6}$$

where PA_i is a subset of V not containing X_i .

The variables PA_i (connoting parents) are considered the direct of X_i and they define a directed graph G , which may, in general, be cyclic. Unlike the probabilistic definition of parents in Bayesian networks (Equation 70.1) PA_i is selected from V by considering functional mechanisms in the domain, not by conditional independence considerations. We will assume that the set of equations in 70.6 has a unique solution for X_i, \dots, X_n , given any value of the disturbances U_i, \dots, U_n . Therefore, the distribution $P(u)$ induces a unique distribution on the observables, which we denote by $P_T(v)$.

We will consider concurrent actions of the form $do(X = x)$, where $X \subseteq V$ is a set of variables and x is a set of values from the domain of X . In other words, $do(X = x)$ represents a combination of actions that forces the variables in X to attain the values x .

Definition 70.3 (effect of actions.) The effect of the action $do(X = x)$ on a causal theory T is given by a subtheory T_x of T , where T_x obtains by deleting from T all equations corresponding to variables in X and substituting the equations $X = x$ instead.

The framework provided by Definitions 70.2 and 70.3 permits the coherent formalization of many subtle concepts in causal discourse, such as causal influence, causal effect, causal relevance, average causal effect,

identifiability, counterfactuals, exogeneity, and so on. Examples are as follows:

- X influences Y in context u if there are two values of X , x , and x' , such that the solution for Y under $U = u$ and $do(X = x)$ is different from the solution under $U = u$ and $do(X = x')$.
- X can potentially influence Y if there exist both a subtheory T_2 of T and a context $U = u$ in which X influences Y .
- Event $X = x$ is the (singular) cause of event $Y = y$ if (1) $X = x$ and $Y = y$ are true, and (2) in every context u compatible with $X = x$ and $Y = y$, and for all $x' \neq x$, the solution of Y under $do(X = x')$ is not equal to y .

The definitions are deterministic. Probabilistic causality emerges when we define a probability distribution $P(u)$ for the U variables, which, under the assumption that the equations have a unique solution, induces a unique distribution on the endogenous variables for each combination of atomic interventions.

Definition 70.4 (causal effect.) Given two disjoint subsets of variables, $X \subseteq V$ and $Y \subseteq V$, the causal effect of X on Y , denoted $P_T(y | \hat{x})$, is a function from the domain of X to the space of probability distributions on Y , such that

$$P_T(y | \hat{x}) = P_{T_x}(y) \tag{70.7}$$

for each realization x of X . In other words, for each $x \in \text{dom}(X)$, the causal effect $P_T(y | \hat{x})$ gives the distribution of Y induced by the action $do(X = x)$.

Note that causal effects are defined relative to a given causal theory T , though the subscript T is often suppressed for brevity.

Definition 70.5 (identifiability.) Let $Q(T)$ be any computable quantity of a theory T ; Q is identifiable in a class M of theories if for any pair of theories T_1 and T_2 from M , $Q(T_1) = Q(T_2)$ whenever $P_{T_1}(v) = P_{T_2}(v)$.

Identifiability is essential for estimating quantities Q from P alone, without specifying the details of T , so that the general characteristics of the class M suffice. The question of interest in planning applications is the identifiability of the causal effect $Q = P_T(y | \hat{x})$ in the class M_G of theories that share the same causal graph G . Relative to such classes we now define the following:

Definition 70.6 (causal-effect identifiability.) The causal effect of X on Y is said to be identifiable in M_G if the quantity $P(y | \hat{x})$ can be computed uniquely from the probabilities of the observed variables, that is, if for every pair of theories T_1 and T_2 in M_G such that $P_{T_1}(v) = P_{T_2}(v)$, we have $P_{T_1}(y | \hat{x}) = P_{T_2}(y | \hat{x})$.

The identifiability of $P(y | \hat{x})$ ensures that it is possible to infer the effect of action $do(X = x)$ on Y from two sources of information:

1. Passive observations, as summarized by the probability function $P(v)$.
2. The causal graph, G , which specifies, qualitatively, which variables make up the stable mechanisms in the domain or, alternatively, which variables participate in the determination of each variable in the domain.

Simple examples of identifiable causal effects will be discussed in the next subsection.

70.4.2 Acting vs Observing

Consider the example depicted in Figure 70.1. The corresponding theory consists of five functions, each representing an autonomous mechanism:

$$\begin{aligned}
 X_1 &= U_1 \\
 X_2 &= f_2(X_1, U_2) \\
 X_3 &= f_3(X_1, U_3) \\
 X_4 &= f_4(X_3, X_2, U_4) \\
 X_5 &= f_5(X_4, U_5)
 \end{aligned} \tag{70.8}$$

To represent the action “turning the sprinkler ON,” $do(X_3 = \text{ON})$, we delete the equation $X_3 = f_3(x_1, u_3)$ from the theory of Equation 70.8 and replace it with $X_3 = \text{ON}$. The resulting subtheory, $T_{X_3 = \text{ON}}$, contains all of the information needed for computing the effect of the actions on other variables. It is easy to see from this subtheory that the only variables affected by the action are X_4 and X_5 , that is, the descendant, of the manipulated variable X_3 .

The probabilistic analysis of causal theories becomes particularly simple when two conditions are satisfied:

1. The theory is recursive, i.e., there exists an ordering of the variables $V = \{X_1, \dots, X_n\}$ such that each X_i is a function of a subset PA_i of its predecessors

$$X_i = f_i(PA_i, U_i), \quad PA_i \subseteq \{X_1, \dots, X_{i-1}\} \tag{70.9}$$

2. The disturbances U_1, \dots, U_n are mutually independent, that is,

$$P(u) = \prod_i P(u_i) \tag{70.10}$$

These two conditions, also called Markovian, are the basis of the independencies embodied in Bayesian networks (Equation 70.1) and they enable us to compute causal effects directly from the conditional probabilities $P(x_i | pa_i)$, without specifying the functional form of the functions f_i , or the distributions $P(u_i)$ of the disturbances. This is seen immediately from the following observations: The distribution induced by any Markovian theory T is given by the product in Equation 70.1

$$P_T(x_1, \dots, x_n) = \prod_i P(x_i | pa_i) \tag{70.11}$$

where pa_i are (values of) the parents of X_i in the diagram representing T . At the same time, the subtheory $T_{x'_j}$, representing the action $do(X_j = x'_j)$ is also Markovian; hence, it also induces a product-like distribution

$$P_{T_{x'_j}}(x_1, \dots, x_n) = \begin{cases} \prod_{i \neq j} P(x_i | pa_i) = \frac{P(x_1, \dots, x_n)}{P(x_j | pa_j)} & \text{if } x_j = x'_j \\ 0 & \text{if } x_j \neq x'_j \end{cases} \tag{70.12}$$

where the partial product reflects the surgical removal of the

$$X_j = f_j(pa_j, U_j)$$

from the theory of Equation 70.9 (see Pearl [1993a]).

In the example of Figure 70.1, the pre-action distribution is given by the product

$$P_T(x_1, x_2, x_3, x_4, x_5) = P(x_1)P(x_2 | x_1)P(x_3 | x_1)P(x_4 | x_2, x_3)P(x_5 | x_4) \quad (70.13)$$

whereas the surgery corresponding to the action $do(X_3 = \text{ON})$ amounts to deleting the link $X_1 \rightarrow X_3$ from the graph and fixing the value of X_3 to ON, yielding the postaction distribution

$$P_T(x_1, x_2, x_3, x_4, x_5 | do(X_3 = \text{ON})) = P(x_1)P(x_2 | x_1)P(x_4 | x_2, X_3 = \text{ON})P(x_5 | x_4) \quad (70.14)$$

Note the difference between the action $do(X_3 = \text{ON})$ and the observation $X_3 = \text{ON}$. The latter is encoded by ordinary Bayesian conditioning, whereas the former by conditioning a mutilated graph, with the link $X_1 \rightarrow X_3$ removed. Indeed, this mirrors the difference between seeing and doing: after observing that the sprinkler is ON, we wish to infer that the season is dry, that it probably did not rain, and so on; no such inferences should be drawn in evaluating the effects of the deliberate action “turning the sprinkler ON.” The amputation of $X_3 = f_3(X_1, U_3)$ from Equation 70.8 ensures the suppression of any abductive inferences from X_3 , the action’s recipient.

Note also that Equations 70.1 through Equation 70.14 are independent of T ; in other words, the pre-action and postaction distributions depend only on observed conditional probabilities but are independent of the particular functional form of $\{f_i\}$ or the distribution $P(u)$, which generate those probabilities. This is the essence of identifiability as given in Definition 70.6, which stems from the Markovian assumptions 70.9 and 70.10. The next subsection will demonstrate that certain causal effects, though not all, are identifiable even when the Markovian property is destroyed by introducing dependencies among the disturbance terms.

Generalization to multiple actions and conditional actions are reported in Pearl and Robins [1995]. Multiple actions $do(X = x)$, where X is a compound variable result in a distribution similar to Equation 70.12, except that all factors corresponding to the variables in X are removed from the product in Equation 70.11. Stochastic conditional strategies [Pearl 1994b] of the form

$$do(X_j = x_j) \quad \text{with probability} \quad P^*(x_j | pa_j^*) \quad (70.15)$$

where pa_j^* is the support of the decision strategy, also result in a product decomposition similar to Equation 70.11, except that each factor $P(x_j | pa_j)$ is replaced with $P^*(x_j | pa_j^*)$.

The surgical procedure just described is not limited to probabilistic analysis. The causal knowledge represented in Figure 70.1 can be captured by logical theories as well, for example,

$$\begin{aligned} x_2 &\iff [(X_1 = \text{Winter}) \vee (X_1 = \text{Fall}) \vee ab_2] \wedge \neg ab'_2 \\ x_3 &\iff [(X_1 = \text{Summer}) \vee (X_1 = \text{Spring}) \vee ab_3] \wedge \neg ab'_3 \\ x_4 &\iff (x_2 \vee x_3 \vee ab_4) \wedge \neg ab'_4 \\ x_5 &\iff (x_4 \vee ab_5) \wedge \neg ab'_5 \end{aligned} \quad (70.16)$$

where x_i stands for $X_i = \text{true}$, and ab_i and ab'_i stand, respectively, for triggering and inhibiting abnormalities. The double arrows represent the assumption that the events on the right-hand side of each equation are the *only* direct causes for the left-hand side, thus identifying the surgery implied by any action.

It should be emphasized though that the models of a causal theory are not made up merely of truth value assignments which satisfy the equations in the theory. Since each equation represents an autonomous process, the content of each individual equation must be specified in any model of the theory, and this can be encoded using either the graph (as in Figure 70.1) or the generic description of the theory, as in Equation 70.8. Alternatively, we can view a model of a causal theory to consist of a mutually consistent set of submodels, with each submodel being a standard model of a single equation in the theory.

70.4.3 Action Calculus

The identifiability of causal effects demonstrated in the last subsection relies critically on the Markovian assumptions 70.9 and 70.10. If a variable that has two descendants in the graph is unobserved, the disturbances in the two equations are no longer independent, the Markovian property 70.9 is violated, and identifiability may be destroyed. This can be seen easily from Equation 70.12; if any parent of the manipulated variable X_j is unobserved, one cannot estimate the conditional probability $P(x_j | pa_j)$, and the effect of the action $do(X_j = x_j)$ may not be predictable from the observed distribution $P(x_1, \dots, x_n)$. Fortunately, certain causal effects are identifiable even in situations where members of pa_j are unobservable [Pearl 1993a] and, moreover, polynomial tests are now available for deciding when $P(x_i | \hat{x}_j)$ is identifiable and for deriving closed-form expressions for $P(x_i | \hat{x}_j)$ in terms of observed quantities [Galles and Pearl 1995].

These tests and derivations are based on a symbolic calculus [Pearl 1994b, 1995] to be described in the sequel, in which interventions, side by side with observations, are given explicit notation and are permitted to transform probability expressions. The transformation rules of this calculus reflect the understanding that interventions perform local surgeries as described in Definition 70.3, i.e., they overrule equations that tie the manipulated variables to their preintervention causes.

Let X, Y , and Z be arbitrary disjoint sets of nodes in a DAG G . We denote by $G_{\overline{X}}$ the graph obtained by deleting from G all arrows pointing to nodes in X . Likewise, we denote by $G_{\underline{X}}$ the graph obtained by deleting from G all arrows emerging from nodes in X . To represent the deletion of both incoming and outgoing arrows, we use the notation $G_{\overline{X}\underline{X}}$. Finally, the expression $P(y | \hat{x}, z) \triangleq P(y, z) | \hat{x} / P(z | \hat{x})$ stands for the probability of $Y = y$ given that $Z = z$ is observed and X is held constant at x .

Theorem 70.2 *Let G be the directed acyclic graph associated with a Markovian causal theory, and let $P(\cdot)$ stand for the probability distribution induced by that theory. For any disjoint subsets of variables X, Y, Z , and W we have the following rules:*

- Rule 1 (Insertion/deletion of observations):

$$P(y | \hat{x}, z, w) = P(y | \hat{x}, w) \quad \text{if } (Y \perp\!\!\!\perp Z | X, W)_{G_{\overline{X}}} \quad (70.17)$$

- Rule 2 (Action/observation exchange):

$$P(y | \hat{x}, \hat{z}, w) = P(y | \hat{x}, z, w) \quad \text{if } (Y \perp\!\!\!\perp Z | X, W)_{G_{\overline{X}\underline{Z}}} \quad (70.18)$$

- Rule 3 (Insertion/deletion of actions):

$$P(y | \hat{x}, \hat{z}, w) = P(y | \hat{x}, w) \quad \text{if } (Y \perp\!\!\!\perp Z | X, W)_{G_{\overline{X}\underline{Z}(W)}} \quad (70.19)$$

where $Z(W)$ is the set of Z -nodes that are not ancestors of any W -node in $G_{\overline{X}}$.

Each of the inference rules follows from the basic interpretation of the \hat{x} operator as a replacement of the causal mechanism that connects X to its pre-action parents by a new mechanism $X = x$ introduced by the intervening force. The result is a submodel characterized by the subgraph $G_{\overline{X}}$ (named *manipulated graph* in Spirtes et al. [1993]), which supports all three rules.

Corollary 70.1 A causal effect $q : P(y_1, \dots, y_k | \hat{x}_1, \dots, \hat{x}_m)$ is identifiable in a model characterized by a graph G if there exists a finite sequence of transformations, each conforming to one of the inference rules in Theorem 70.2, which reduces q into a standard (i.e., hat-free) probability expression involving observed quantities.

Although Theorem 70.2 and Corollary 70.1 require the Markovian property, they also can be applied to non-Markovian, recursive theories because such theories become Markovian if we consider the unobserved

variables as part of the analysis, and represent them as nodes in the graph. To illustrate, assume that variable X_1 in Figure 70.1 is unobserved, rendering the disturbances U_3 and U_2 dependent since these terms now include the common influence of X_1 . Theorem 70.2 tells us that the causal effect $P(x_4 | \hat{x}_3)$ is identifiable, because

$$P(x_4 | \hat{x}_3) = \sum_{x_2} P(x_4 | \hat{x}_3, x_2) P(x_2 | \hat{x}_3)$$

Rule 3 permits the deletion

$$P(x_2 | \hat{x}_3) = P(x_2), \quad \text{because } (X_2 \perp\!\!\!\perp X_3)_{G_{\overline{X_3}}}$$

whereas rule 2 permits the exchange

$$P(x_4 | \hat{x}_3, x_2) = P(x_4 | x_3, x_2), \quad \text{because } (X_4 \perp\!\!\!\perp X_3 | X_2)_{G_{\underline{X_3}}}$$

This gives

$$P(x_4 | \hat{x}_3) = \sum_{x_2} P(x_4 | x_3, x_2) P(x_2)$$

which is a hat-free expression, involving only observed quantities.

In general, it can be shown [Pearl 1995]:

1. The effect of interventions can often be identified (from nonexperimental data) without resorting to parametric models.
2. The conditions under which such nonparametric identification is possible can be determined by simple graphical tests.*
3. When the effect of interventions is not identifiable, the causal graph may suggest nontrivial experiments which, if performed, would render the effect identifiable.

The ability to assess the effect of interventions from nonexperimental data has immediate applications in the medical and social sciences, since subjects who undergo certain treatments often are not representative of the population as a whole. Such assessments are also important in artificial intelligence (AI) applications where an agent needs to predict the effect of the next action on the basis of past performance records, and where that action has never been enacted out of free will, but in response to environmental needs or to other agents' requests.

70.4.4 Historical Remarks

An explicit translation of interventions to *wiping out* equations from linear econometric models was first proposed by Strotz and Wold [1960] and later used in Fisher [1970] and Sobel [1990]. Extensions to action representation in nonmonotonic systems were reported in Goldszmidt and Pearl [1992] and Pearl [1993a]. Graphical ramifications of this translation were explicated first in Spirtes et al. [1993] and later in Pearl [1993b]. A related formulation of causal effects, based on event trees and counterfactual analysis, was developed by Robins [1986, pp. 1422–1425]. Calculi for actions and counterfactuals based on this interpretation are developed in Pearl [1994b] and Balke and Pearl [1994], respectively.

*These graphical tests offer, in fact, a complete formal solution to the *covariate-selection* problem in statistics: finding an appropriate set of variables that need be adjusted for in any study which aims to determine the effect of one factor upon another. This problem has been lingering in the statistical literature since Karl Pearson, the founder of modern statistics, discovered (1899) what in modern terms is called the Simpson's paradox; any statistical association between two variables may be reversed or negated by including additional factors in the analysis [Aldrich 1995].

70.5 Counterfactuals

A counterfactual sentence has the form:

If A were true, then C would have been true?

where A , the counterfactual antecedent, specifies an event that is contrary to one's real-world observations, and C , the counterfactual consequent, specifies a result that is expected to hold in the alternative world where the antecedent is true. A typical example is "If Oswald were not to have shot Kennedy, then Kennedy would still be alive," which presumes the factual knowledge of Oswald's shooting Kennedy, contrary to the antecedent of the sentence.

The majority of the philosophers who have examined the semantics of counterfactual sentences have resorted to some version of Lewis' *closest world* approach: " C if it were A " is true, if C is true in worlds that are closest to the real world yet consistent with the counterfactual's antecedent A [Lewis 1973]. Ginsberg [1986] followed a similar strategy. Whereas the closest world approach leaves the precise specification of the closeness measure almost unconstrained, causal knowledge imposes very specific preferences as to which worlds should be considered closest to any given world. For example, considering an array of domino tiles standing close to each other, the manifestly closest world consistent with the antecedent "tile i is tipped to the right" would be a world in which just tile i is tipped, and all of the others remain erect. Yet, we all accept the counterfactual sentence "Had tile i been tipped over to the right, tile $i + 1$ would be tipped as well" as plausible and valid. Thus, distances among worlds are not determined merely by surface similarities but require a distinction between disturbed mechanisms and naturally occurring transitions. The local surgery paradigm expounded in the beginning of Section 70.4 offers a concrete explication of the closest world approach which respects causal considerations. A world w_1 is closer to w than a world w_2 is, if the set of atomic surgeries needed for transforming w into w_1 is a subset of those needed for transforming w into w_2 . In the domino example, finding tile i tipped and $i + 1$ erect requires the breakdown of two mechanism (e.g., by two external actions) compared with one mechanism for the world in which all j -tiles, $j > i$, are tipped. This paradigm conforms to our perception of causal influences and lends itself to economical machine representation.

70.5.1 Formal Underpinning

The structural equation framework offers an ideal setting for counterfactual analysis.

Definition 70.7 (context-based potential response.) Given a causal theory T and two disjoint sets of variables, X and Y , the potential response of Y to X in a context u , denoted $Y(x, u)$ or $Y_x(u)$, is the solution for Y under $U = u$ in the subtheory T_x . $Y(x, u)$ can be taken as the formal definition of the counterfactual English phrase: "the value that Y would take in context u , had X been x ."^{*}

Note that this definition allows for the context $U = u$ and the proposition $X = x$ to be incompatible in T . For example, if T describes a logic circuit with input U it may well be reasonable to assert the counterfactual: "Given $U = u$, Y would be high if X were low," even though the input $U = u$ may preclude X from being low. It is for this reason that one must invoke some notion of intervention (alternatively, a theory change or a *miracle* [Lewis 1973]) in the definition of counterfactuals.

^{*}The term *unit* instead of *context* is often used in the statistical literature [Rubin 1974], where it normally stands for the identity of a specific individual in a population, namely, the set of attributes u that characterizes that individual. In general, u may include the time of day, the experimental conditions under study, and so on. Practitioners of the counterfactual notation do not explicitly mention the notions of *solution* or *intervention* in the definition of $Y(x, u)$. Instead, the phrase "the value that Y would take in unit u , had X been x ," viewed as basic, is posited as the definition of $Y(x, u)$.

If U is treated as a random variable, then the value of the counterfactual $Y(x, u)$ becomes a random variable as well, denoted as $Y(x)$ or Y_x . Moreover, the distribution of this random variable is easily seen to coincide with the causal effect $P(y | \hat{x})$, as defined in Equation 70.7, i.e.,

$$P((Y(x) = y) = P(y | \hat{x}))$$

The probability of a counterfactual conditional $x \rightarrow y | o$ may then be evaluated by the following procedure:

- Use the observations o to update $P(u)$ thus forming a causal theory $T^o = \langle V, U, \{f_i\}, P(u | o) \rangle$
- Form the mutilated theory T_x^o (by deleting the equation corresponding to variables in X) and compute the probability $P_{T^o}(y | \hat{x})$ which T_x^o induces on Y

Unlike causal effect queries, counterfactual queries are not identifiable even in Markovian theories, but require that the functional-form of $\{f_i\}$ be specified. In Balke and Pearl [1994] a method is devised for computing sharp bounds on counterfactual probabilities which, under certain circumstances may collapse to point estimates. This method has been applied to the evaluation of causal effects in studies involving noncompliance and to the determination of legal liability.

70.5.2 Applications to Policy Analysis

Counterfactual reasoning is at the heart of every planning activity, especially real-time planning. When a planner discovers that the current state of affairs deviates from the one expected, a plan repair activity needs to be invoked to determine what went wrong and how it could be rectified. This activity amounts to an exercise in counterfactual thinking, as it calls for rolling back the natural course of events and determining, based on the factual observations at hand, whether the culprit lies in previous decisions or in some unexpected, external eventualities. Moreover, in reasoning forward to determine if things would have been different, a new model of the world must be consulted, one that embodies hypothetical changes in decisions or eventualities — hence, a breakdown of the old model or theory.

The logic-based planning tools used in AI, such as STRIPS and its variants or those based on situation calculus, do not readily lend themselves to counterfactual analysis, as they are not geared for coherent integration of abduction with prediction, and they do not readily handle theory changes. Remarkably, the formal system developed in economics and social sciences under the rubric structural equations models does offer such capabilities but, as will be discussed, these capabilities are not well recognized by current practitioners of structural models. The analysis presented in this chapter could serve both to illustrate to AI researchers the basic formal features needed for counterfactual and policy analysis and to call the attention of economists and social scientists to capabilities that are dormant within structural equation models.

Counterfactual thinking dominates reasoning in political science and economics. We say, for example, “If Germany were not punished so severely at the end of World War I, Hitler would not have come to power,” or “If Reagan did not lower taxes, our deficit would be lower today.” Such thought experiments emphasize an understanding of generic laws in the domain and are aimed toward shaping future policy making, for example, “defeated countries should not be humiliated,” or “lowering taxes (contrary to Reaganomics) tends to increase national debt.”

Strangely, there is very little formal work on counterfactual reasoning or policy analysis in the behavioral science literature. An examination of a number of econometric journals and textbooks, for example, reveals a glaring imbalance: although an enormous mathematical machinery is brought to bear on problems of estimation and prediction, policy analysis (which is the ultimate goal of economic theories) receives almost no formal treatment. Currently, the most popular methods driving economic policy making are based on so-called *reduced-form* analysis: to find the impact of a policy involving decision variables X on outcome variables Y , one examines past data and estimates the conditional expectation $E(Y | X = x)$, where x is the particular instantiation of X under the policy studied.

The assumption underlying this method is that the data were generated under circumstances in which the decision variables X act as exogenous variables, that is, variables whose values are determined outside the system under analysis. However, although new decisions should indeed be considered exogenous for the purpose of evaluation, past decisions are rarely enacted in an exogenous manner. Almost every realistic policy (e.g., taxation) imposes control over some endogenous variables, that is, variables whose values are determined by other variables in the analysis. Let us take taxation policies as an example. Economic data are generated in a world in which the government is reacting to various indicators and various pressures; hence, taxation is endogenous in the data-analysis phase of the study. Taxation becomes exogenous when we wish to predict the impact of a specific decision to raise or lower taxes. The reduced-form method is valid only when past decisions are nonresponsive to other variables in the system, and this, unfortunately, eliminates most of the interesting control variables (e.g., tax rates, interest rates, quotas) from the analysis.

This difficulty is not unique to economic or social policy making; it appears whenever one wishes to evaluate the merit of a plan on the basis of the past performance of other agents. Even when the signals triggering the past actions of those agents are known with certainty, a systematic method must be devised for selectively ignoring the influence of those signals from the evaluation process. In fact, the very essence of *evaluation* is having the freedom to imagine and compare trajectories in various counterfactual worlds, where each world or trajectory is created by a hypothetical implementation of a policy that is free of the very pressures that compelled the implementation of such policies in the past.

Balke and Pearl [1995] demonstrate how linear, nonrecursive structural models with Gaussian noise can be used to compute counterfactual queries of the type: "Given an observation set O , find the probability that Y would have attained a value greater than y , had X been set to x ." The task of inferring causes of effects, that is, of finding the probability that $X = x$ is the cause for effect E , amounts to answering the counterfactual query: "Given effect E and observations O , find the probability that E would not have been realized, had X not been x ." The technique developed in Balke and Pearl [1995] is based on probability propagation in dual networks, one representing the actual world and the other representing the counterfactual world. The method is not limited to linear functions but applies whenever we are willing to assume the functional form of the structural equations. The noisy OR-gate model [Pearl 1988] is a canonical example where such functional form is normally specified. Likewise, causal theories based on Boolean functions (with exceptions), such as the one described in Equation 70.16 lend themselves to counterfactual analysis in the framework of Definition 70.7.

71.1 Introduction

The word *robot* was introduced by the Czech playwright Karel Čapek in his 1920 play *Rossum's Universal Robots*. The word *robota* in Czech means simply work. In spite of such practical beginnings, science fiction writers and early Hollywood movies have given us a romantic notion of robots and expectations that they will revolutionize several walks of life including industry. However, many of the more far-fetched expectations from robots have failed to materialize. For instance, in underwater assembly and oil mining, teleoperated robots are very difficult to manipulate due to sea currents and low visibility, and have largely been replaced or augmented by automated smart quick-fit couplings that simplify the assembly task. However, through good design practices and painstaking attention to detail, engineers have succeeded in applying robotic systems to a wide variety of industrial and manufacturing situations where the environment is *structured* or predictable. Thus, the first successful commercial implementation of process robotics was in the U.S. automobile industry; the word *automation* was coined in the 1940s at Ford Motor Company, a contraction of automatic motivation.

As machines, robots have precise motion capabilities, repeatability, and endurance. On a practical level, robots are distinguished from other electromechanical motion equipment by their dexterous manipulation capability in that robots can work, position, and move tools and other objects with far greater dexterity than other machines found in the factory. The capabilities of robots are extended by using them as a basis for *robotic workcells*. Process robotic workcells are integrated functional systems with grippers, **end effectors**, sensors, and process equipment organized to perform a controlled sequence of jobs to execute a process. Robots must coordinate with other devices in the workcell such as machine tools, conveyors, part feeders, cameras, and so on. Sequencing jobs to correctly perform automated tasks in such circumstances is not a trivial matter, and robotic workcells require sophisticated planning, sequencing, and control systems.

Today, through developments in computers and artificial intelligence (AI) techniques (and often motivated by the space program), we are on the verge of another breakthrough in robotics that will afford some levels of autonomy in *unstructured environments*. For applications requiring increased autonomy it is particularly important to focus on the design of the data structures and command-and-control information flow in the robotic system. Therefore, this chapter focuses on the design of robotic workcell *systems*. A distinguishing feature of robotics is its multidisciplinary nature: to successfully design robotic systems one must have a grasp of electrical, mechanical, industrial, and computer engineering, as well as economics and business practices. The purpose of this chapter is to provide a background in these areas so that design of robotic systems may be approached from a position of rigor, insight, and confidence.

The chapter begins by discussing layouts and architectures for robotic workcell design. Then, components of the workcell are discussed from the bottom up, beginning with robots, sensors, and conveyors/part feeders, and progressing upwards in abstraction through task coordination, job sequencing, and resource dispatching, to task planning, assignment, and decomposition. Concepts of user interface and exception handling/fault recovery are included.

71.2 Robot Workcells

In factory automation and elsewhere it was once common to use layouts such as the one in [Figure 71.1](#), which shows an assembly line with distinct workstations, each performing a dedicated function. Robots have been used at the workstation level to perform operations such as assembly, drilling, surface finishing, welding, palletizing, and so on. In the assembly line, parts are routed sequentially to the workstations by conveyors. Such systems are very expensive to install, require a cadre of engineering experts to design and program, and are extremely difficult to modify or reprogram as needs change. In today's high-mix low-volume (HMLV) manufacturing scenario, these characteristics tolled the death knell for such rigid antiquated designs.

In the assembly line, the robot is *restricted* by placing it into a rigid sequential system. Robots are versatile machines with many capabilities, and their potential can be significantly increased by using them as a basis

FIGURE 71.1 Antiquated sequential assembly line with dedicated workstations. (Courtesy of Edkins, M. 1983. Linking industrial robots and machine tools. In *Robotic Technology*. A. Pugh, Ed. Peregrinus, London.)

FIGURE 71.2 Robot workcell. (Courtesy of Edkins, M. 1983. Linking industrial robots and machine tools. In *Robotic Technology*. A. Pugh, Ed. Peregrinus, London.)

for robotic workcells such as the one in Figure 71.2 [Decelle 1988, Jamshidi et al. 1992, Pugh 1983]. In the robotic workcell, robots are used for part handling, assembly, and other process operations. The workcell is designed to make full use of the workspace of the robots, and components such as milling machines, drilling machines, vibratory part feeders, and so on are placed within the robots' workspaces to allow servicing by the robots. Contrary to the assembly line, the physical layout does not impose a priori a

fixed sequencing of the operations or jobs. Thus, as product requirements change, all that is required is to reprogram the workcell in software. The workcell is ideally suited to emerging HMLV conditions in manufacturing and elsewhere.

The rising popularity of robotic workcells has taken emphasis away from hardware design and placed new emphasis on innovative *software techniques and architectures* that include planning, coordination, and control (PC&C) functions. Research into individual robotic devices is becoming less useful; what is needed are rigorous design and analysis techniques for integrated multirobotic systems.

71.3 Workcell Command and Information Organization

In this section we define some terms, discuss the design of intelligent control systems, and specify a planning, coordination, and control structure for robotic workcells. The remainder of the chapter is organized around that structure. The various architectures used for modeling AI systems are relevant to this discussion, although here we specialize the discussion to intelligent control architecture.

71.3.1 Intelligent Control Architectures

Many structures have been proposed under the general aegis of the so-called intelligent control (IC) architectures [Antsaklis and Passino 1992]. Despite frequent heated philosophical discussions, it is now becoming clear that most of the architectures have much in common, with apparent major differences due to the fact that different architectures focus on different aspects of intelligent control or different levels of abstraction. A general IC architecture based on work by Saridis is given in Figure 71.3, which illustrates the principle of decreasing precision with increasing abstraction [Saridis 1996]. In this figure, the organization level performs as a manager that schedules and assigns tasks, performs task decomposition and planning, does path planning, and determines for each task the required job sequencing and assignment of resources. The coordination level performs the prescribed job sequencing, coordinating the workcell agents or resources; in the case of shared resources it must execute dispatching and conflict resolution.

The *agents* or *resources* of the workcell include robot manipulators, grippers and tools, conveyors and part feeders, sensors (e.g., cameras), mobile robots, and so on. The execution level contains a closed-loop controller for each agent that is responsible for the real-time performance of that resource, including trajectory generation, motion and force feedback servo-level control, and so on. Some permanent built-in motion sequencing may be included (e.g., stop robot motion prior to opening the gripper).

At each level of this hierarchical IC architecture, there may be several systems or nodes. That is, the architecture is not strictly hierarchical. For instance, at the execution level there is a real-time controller for each workcell agent. Several of these may be coordinated by the coordination level to sequence the jobs needed for a given task. At each level, each node is required to sense conditions, make decisions, and give commands or status signals. This is captured in the sense/world-model/execute (SWE) paradigm of Albus [1992], shown in the NASREM configuration in Figure 71.4; each node has the SWE structure.

FIGURE 71.3 Three-level intelligent control architecture from work by Saridis.

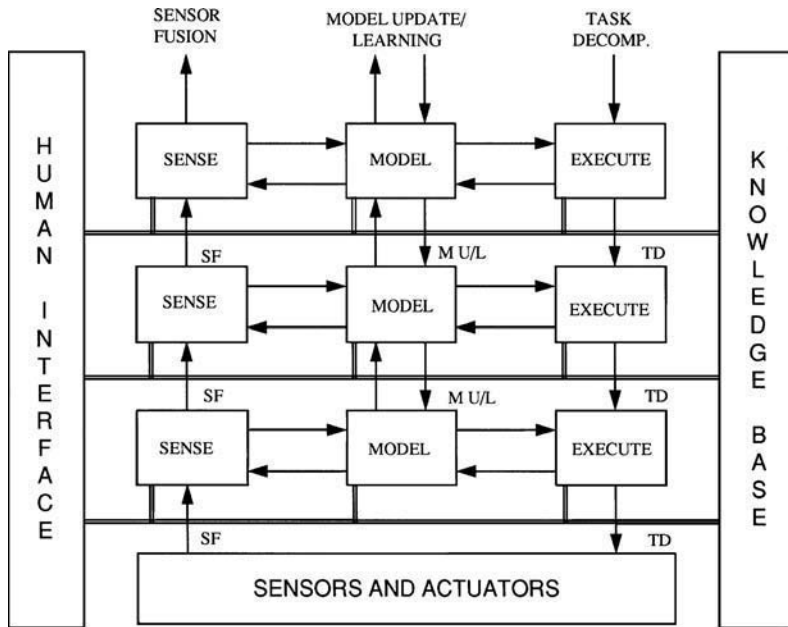

FIGURE 71.4 Three-element structure at all levels of the IC architecture: the NASREM paradigm.

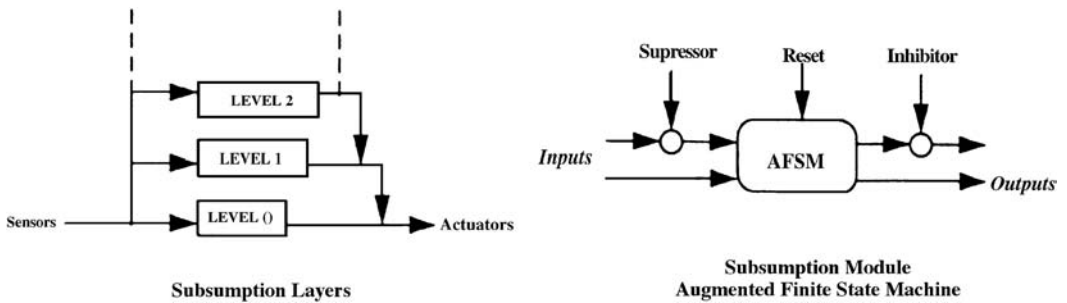

FIGURE 71.5 Behavior-based design after the subsumption technique of Brooks.

71.3.2 Behaviors and Hybrid Systems Design

In any properly designed IC system, the supervisory levels should not destroy the capabilities of the systems supervised. Thus, design should proceed in the manner specified by Brooks [1986], where *behaviors* are built in at lower levels, then selected, activated, or modified by upper-level supervisors. From the point of view of still higher level nodes, the composite performance appears in terms of new more complex or emergent behaviors. Such *subsumption* design proceeds in the manner of adding layers to an onion, as depicted loosely in Figure 71.5.

Near or slightly below the interfaces between the coordination level and the execution level one must face the transition between two fundamentally distinct worlds. Real-time servo-level controller design and control may be accomplished in terms of *state-space systems*, which are time-varying dynamical systems (either continuous time or discrete time) having continuous-valued states such as temperatures, pressures, motions, velocities, forces, and so on. On the other hand, the coordinator is not concerned about such details, but speaks in terms of *discrete events* such as “perform this job” or “check this condition.” The

FIGURE 71.6 Hybrid systems approach to defining and sequencing the plant behaviors.

theory of *hybrid systems* is concerned with the interface between continuous-state systems and discrete event systems.

These concepts are conveniently illustrated by figures such as Figure 71.6, where a closed-loop real-time feedback controller for the plant having dynamics $\dot{x} = f(x, u)$ is shown at the execution level. The function of the coordinator is to select the details of this real-time feedback control structure; that is, the outputs $z(t)$, control inputs $u(t)$, prescribed reference trajectories $r(t)$, and controllers K to be switched in at the low level. Selecting the outputs amounts to selecting which sensors to read; selecting the control inputs amounts to selecting to which actuators the command signals computed by the controller should be sent. The controller K is selected from a library of stored predesigned controllers.

A specific combination of (z, u, r, K) defines a *behavior* of the closed-loop system. For instance, in a mobile robot, for path-following behavior one may select: as outputs, the vehicle speed and heading; as controls, the speed and steering inputs; as the controller, an adaptive **proportional-integral-derivative (PID) controller**; and as reference input, the prescribed path. For wall-following behavior, for instance, one simply selects as output the sonar distance from the wall, as input the steering command, and as reference input the prescribed distance to be maintained. These distinct closed-loop behaviors are sequenced by the coordinator to perform the prescribed job sequence.

71.3.3 Workcell Planning, Coordination, and Control Structure

A convenient planning, coordination, and control structure for robotic workcell design and operation is given in Figure 71.7, which is modified from the next generation controller (NGC) paradigm. This is an operational PC&C architecture fully consistent with the previous IC structures. In this figure, the term *virtual agent* denotes the agent plus its low-level servocontroller and any required built-in sequencing coordinators. For instance, a *virtual robot* includes the manipulator, its commercial controller with servo-level joint controllers and trajectory generator, and in some applications the gripper controller plus an agent internal coordinator to sequence manipulator and gripper activities. A *virtual camera* might include the camera(s) and framegrabber board, plus software algorithms to perform basic vision processing such as edge detection, segmentation, and so on; thus, the virtual camera could include a *data abstraction*, which is a set of data plus manipulations on that data.

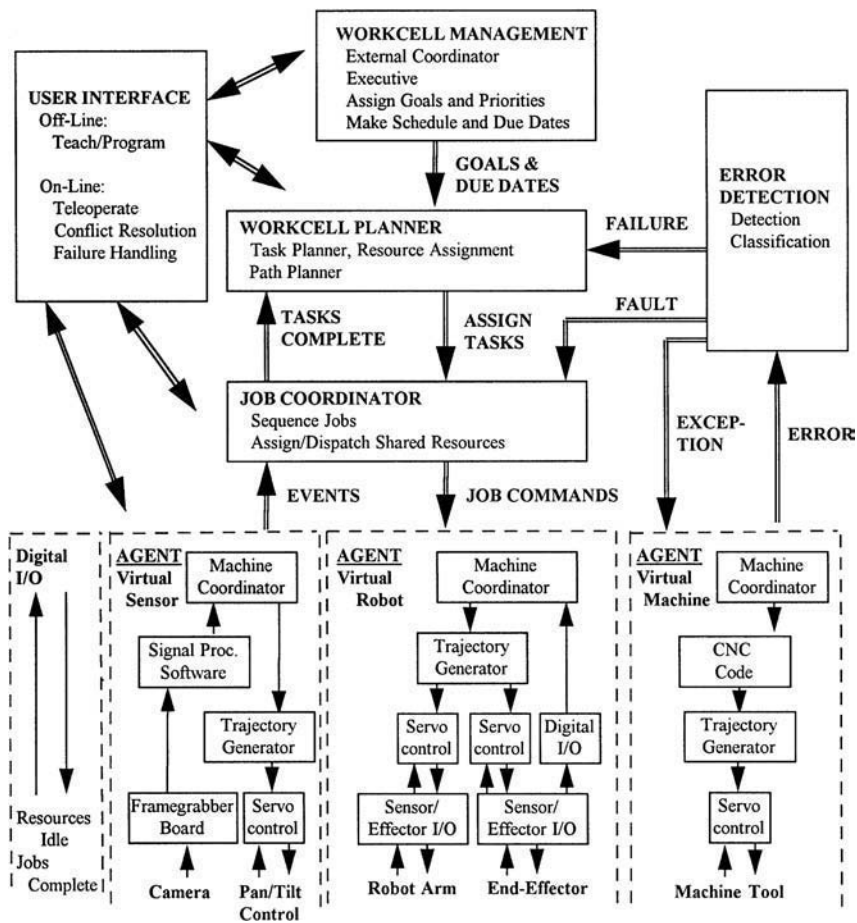

FIGURE 71.7 Robotic workcell planning, coordination, and control operational architecture.

The remainder of the chapter is structured after this PC&C architecture, beginning at the execution level to discuss robot manipulator kinematics, dynamics and control; end effectors and tooling; sensors; and other workcell components such as conveyors and part feeders. Next considered is the coordination level including sequencing control and dispatching of resources. Finally, the organization level is treated including task planning, path planning, workcell management, task assignment, and scheduling.

Three areas are particularly problematic. At each level there may be *human operator interfaces*; this complex topic is discussed in a separate section. An equally complex topic is *error detection and recovery*, also allotted a separate section, which occurs at several levels in the hierarchy. Finally, the strict NGC architecture has a component known as the *information or knowledge base*; however, in view of the fact that all nodes in the architecture have the SWE structure shown in Figure 71.4, it is clear that the knowledge base is distributed throughout the system in the world models of the nodes. Thus, a separate discussion on this component is not included.

71.4 Commercial Robot Configurations and Types

Robots are highly reliable, dependable, and technologically advanced factory equipment. The majority of the world's robots are supplied by established companies using reliable off-the-shelf component technologies. All commercial industrial robots have two physically separate basic elements, the manipulator

arm and the controller. The basic architecture of all commercial robots is fundamentally the same, and consists of digital servocontrolled electrical motor drives on serial-link kinematic machines, usually with no more than six axes (degrees of freedom). All are supplied with a proprietary controller. Virtually all robot applications require significant design and implementation effort by engineers and technicians. What makes each robot unique is how the components are put together to achieve performance that yields a competitive product. The most important considerations in the application of an industrial robot center on two issues: manipulation and integration.

71.4.1 Manipulator Performance

The combined effects of kinematic structure, axis drive mechanism design, and real-time motion control determine the major manipulation performance characteristics: reach and dexterity, payload, quickness, and precision. Caution must be used when making decisions and comparisons based on manufacturers' published performance specifications because the methods for measuring and reporting them are not standardized across the industry. Usually motion testing, simulations, or other analysis techniques are used to verify performance for each application.

Reach is characterized by measuring the extent of the *workspace* described by the robot motion and *dexterity* by the angular displacement of the individual joints. Some robots will have unusable spaces such as dead zones, singular poses, and wrist-wrap poses inside of the boundaries of their reach.

Payload weight is specified by the manufacturers of all industrial robots. Some manufacturers also specify inertial loading for rotational wrist axes. It is common for the payload to be given for extreme velocity and reach conditions. Weight and inertia of all tooling, workpieces, cables and hoses must be included as part of the payload.

Quickness is critical in determining throughput but difficult to determine from published robot specifications. Most manufacturers will specify a maximum speed of either individual joints or for a specific kinematic tool point. However, *average speed* in a working cycle is the quickness characteristic of interest.

Precision is usually characterized by measuring **repeatability**. Virtually all robot manufacturers specify static position repeatability. **Accuracy** is rarely specified, but it is likely to be at least four times larger than repeatability. Dynamic precision, or the repeatability and accuracy in tracking position, velocity, and acceleration over a continuous path, is not usually specified.

71.4.2 Common Kinematic Configurations

All common commercial industrial robots are serial-link manipulators, usually with no more than six kinematically coupled axes of motion. By convention, the axes of motion are numbered in sequence as they are encountered from the base on out to the wrist. The first three axes account for the spatial positioning motion of the robot; their configuration determines the shape of the space through which the robot can be positioned. Any subsequent axes in the kinematic chain generally provide rotational motions to orient the end of the robot arm and are referred to as *wrist axes*. There are two primary types of motion that a **robot axis** can produce in its driven link — either **revolute** or **prismatic**. It is often useful to classify robots according to the orientation and type of their first three axes. There are four very common commercial robot configurations: articulated, type I selectively compliant assembly robot arm (**SCARA**), type II SCARA, and Cartesian. Two other configurations, cylindrical and spherical, are now much less common.

71.4.2.1 Articulated Arms

The variety of commercial articulated arms, most of which have six axes, is very large (Figure 71.8). All of these robot's axes are revolute. The second and third axes are parallel and work together to produce motion in a vertical plane. The first axis in the base is vertical and revolves the arm to sweep out a large work volume. Many different types of drive mechanisms have been devised to allow wrist and forearm drive motors and gearboxes to be mounted close to the first and second axis of rotation, thus minimizing the extended mass of the arm. The workspace efficiency of well-designed articulated arms, which is the degree

FIGURE 71.8 Articulated arm; six-axis arm grinding from a casting. (Courtesy of Staubli Unimation, Inc.)

of quick dexterous reach with respect to arm size, is unsurpassed by other arm configurations when five or more degrees of freedom are needed. A major limiting factor in articulated arm performance is that the second axis has to work to lift both the subsequent arm structure and the payload. Historically, articulated arms have not been capable of achieving accuracy as well as other arm configurations, as all axes have joint angle position errors which are multiplied by link radius and accumulated for the entire arm.

71.4.2.2 Type I SCARA

The type I SCARA (selectively compliant assembly robot arm) uses two parallel revolute joints to produce motion in the horizontal plane (Figure 71.9). The arm structure is weight-bearing but the first and second axes do no lifting. The third axis of the type I SCARA provides work volume by adding a vertical or z axis. A fourth revolute axis will add rotation about the z axis to control orientation in the horizontal plane. This type of robot is rarely found with more than four axes. The type I SCARA is used extensively in the assembly of electronic components and devices, and it is used broadly for the assembly of small- and medium-sized mechanical assemblies.

71.4.2.3 Type II SCARA

The type II SCARA, also a four-axis configuration, differs from type I in that the first axis is a long vertical prismatic z stroke, which lifts the two parallel revolute axes and their links (Figure 71.10). For quickly moving heavier loads (over approximately 75 lb) over longer distance (more than about 3 ft), the type II SCARA configuration is more efficient than the type I.

71.4.2.4 Cartesian Coordinate Robots

Cartesian coordinate robots use orthogonal prismatic axes, usually referred to as x , y , and z , to translate their end effector or payload through their rectangular workspace (Figure 71.11). One, two, or three revolute wrist axes may be added for orientation. Commercial robot companies supply several types of Cartesian coordinate robots with workspace sizes ranging from a few cubic inches to tens of thousands of cubic feet, and payloads ranging to several hundred pounds. Gantry robots, which have an elevated bridge structure, are the most common Cartesian style and are well suited to material handling applications where large areas and/or large loads must be serviced. They are particularly useful in applications such as arc welding, waterjet cutting, and inspection of large complex precision parts. Modular Cartesian robots are

FIGURE 71.9 Type I SCARA arm. High-precision, high-speed midsized SCARA I. (Courtesy of Adept Technologies, Inc.)

FIGURE 71.10 Type II SCARA. (Courtesy of Adept Technologies, Inc.)

FIGURE 71.11 Cartesian robot. Three-axis robot constructed from modular single-axis motion modules. (Courtesy of Adept Technologies, Inc.)

also commonly available from several commercial sources. Each module is a self-contained completely functional single-axis actuator; the modules may be custom assembled for special-purpose applications.

71.4.2.5 Spherical and Cylindrical Coordinate Robots

The first two axes of the spherical coordinate robot are revolute and orthogonal to one another, and the third axis provides prismatic radial extension. The result is a natural spherical coordinate system with a spherical work volume. The first axis of cylindrical coordinate robots is a revolute base rotation. The second and third are prismatic, resulting in a natural cylindrical motion. Commercial models of spherical and cylindrical robots (Figure 71.12) were originally very common and popular in machine tending and material handling applications. Hundreds are still in use but now there are only a few commercially available models. The decline in use of these two configurations is attributed to problems arising from use of the prismatic link for radial extension/retraction motion; a solid boom requires clearance to fully retract.

71.4.3 Drive Types of Commercial Robots

The vast majority of commercial industrial robots use electric servomotor drives with speed reducing transmissions. Both ac and dc motors are popular. Some servohydraulic articulated arm robots are available now for painting applications. It is rare to find robots with servopneumatic drive axes. All types of mechanical transmissions are used, but the tendency is toward low- and zero-backlash type drives. Some robots use direct drive methods to eliminate the amplification of inertia and mechanical backlash associated with other drives. Joint angle position sensors, required for real-time servo-level control, are generally considered an important part of the drive train. Less often, velocity feedback sensors are provided.

71.4.4 Commercial Robot Controllers

Commercial robot controllers are specialized multiprocessor computing systems that provide four basic processes allowing integration of the robot into an automation system: motion trajectory generation and following, motion/process integration and sequencing, human user integration, and information integration.

71.4.4.1 Motion Trajectory Generation and Following

There are two important controller related aspects of industrial robot motion generation. One is the extent of manipulation that can be programmed, the other is the ability to execute controlled programmed motion. A unique aspect of each robot system is its real-time servo-level motion control. The details of real-time control are typically not revealed to the user due to safety and proprietary information secrecy reasons.

(a)

(b)

FIGURE 71.12 Spherical and cylindrical robots. (a) Hydraulic powered spherical robot. (*Source:* Courtesy of Kohol Systems, Inc. With permission.) (b) Cylindrical arm using scissor mechanism for radial prismatic motion. (Courtesy of Yamaha Robotics.)

Each robot controller, through its operating system programs, converts digital data from higher level coordinators into coordinated arm motion through precise computation and high-speed distribution and communication of the individual axis motion commands, which are executed by individual joint servocontrollers. Most commercial robot controllers operate at a sample period of 16 ms. The real-time motion controller invariably uses classical independent-joint proportional-integral-derivative control or simple modifications of PID. This makes commercially available controllers suitable for point-to-point motion, but most are not suitable for following continuous position/velocity profiles or exerting prescribed forces without considerable programming effort, if at all.

71.4.4.2 Motion/Process Integration and Sequencing

Motion/process integration involves coordinating manipulator motion with process sensors or other process controller devices. The most primitive process integration is through discrete digital input/output (I/O). For example, a machine controller external to the robot controller might send a 1-b signal indicating that it is ready to be loaded by the robot. The robot controller must have the ability to read the signal and to perform logical operations (if then, wait until, do until, etc.) using the signal. Coordination with sensors (e.g., vision) is also often provided.

71.4.4.3 Human Integration

The controller's human interfaces are critical to the expeditious setup and programming of robot systems. Most robot controllers have two types of human interface available: computer style CRT/keyboard terminals

for writing and editing program code off line, and *teach pendants*, which are portable manual input terminals used to command motion in a telerobotic fashion via touch keys or joy sticks. Teach pendants are usually the most efficient means available for positioning the robot, and a memory in the controller makes it possible to play back the taught positions to execute motion trajectories. With practice, human operators can quickly teach a series of points which are chained together in playback mode. Most robot applications currently depend on the integration of human expertise during the programming phase for the successful planning and coordination of robot motion. These interface mechanisms are effective in unobstructed workspaces where no changes occur between programming and execution. They do not allow human interface during execution or adaptation to changing environments.

71.4.4.4 Information Integration

Information integration is becoming more important as the trend toward increasing flexibility and agility impacts robotics. Many commercial robot controllers now support information integration functions by employing integrated personal computer (PC) interfaces through the communications ports (e.g., RS-232), or in some through direct connections to the robot controller data bus.

71.5 Robot Kinematics, Dynamics, and Servo-Level Control

In this section we shall study the kinematics, dynamics, and servocontrol of robot manipulators; for more details see Lewis et al. [1993]. The objective is to turn the manipulator, by proper design of the control system and trajectory generator, into an *agent with desirable behaviors*, which behaviors can then be selected by the job coordinator to perform specific jobs to achieve some assigned task. This agent, composed of the robot plus servo-level control system and trajectory generator, is the *virtual robot* in Figure 71.7; this philosophy goes along with the subsumption approach of Brooks (Figure 71.5).

71.5.1 Kinematics and Jacobians

71.5.1.1 Kinematics of Rigid Serial-Link Manipulators

The kinematics of the robot manipulator are concerned only with relative positioning and not with motion effects.

71.5.1.1.1 Link A Matrices

Fixed-base serial-link rigid robot manipulators can be considered as a sequence of joints held together by links. Each joint i has a **joint variable** \mathbf{q}_i , which is an angle for revolute joints (units of degrees) and a length for prismatic or extensible joints (units of length). The *joint vector* of an n -link robot is defined as $\mathbf{q} = [\mathbf{q}_1 \ \mathbf{q}_2 \ \cdots \ \mathbf{q}_n]^T \in \mathfrak{N}^n$; the joints are traditionally numbered from the base to the end effector, with link 0 being the fixed base. A robot with n joints has n degrees of freedom, so that for complete freedom of positioning and orientation in our 3-D space \mathfrak{N}^3 one needs a six-link arm.

For analysis purposes, it is considered that to each link is affixed a coordinate frame. The *base frame* is attached to the manipulator base, link 0. The location of the coordinate frame on the link is often selected according to the *Denavit–Hartenberg* (DH) convention [Lewis et al. 1993]. The relation between the links is given by the *A matrix for link i* , which has the form

$$A_i(\mathbf{q}_i) = \begin{bmatrix} R_i & \mathbf{p}_i \\ 0 & 1 \end{bmatrix} \quad (71.1)$$

where $R_i(\mathbf{q}_i)$ is a 3×3 rotation matrix ($R_i^{-1} = R_i^T$) and $\mathbf{p}_i(\mathbf{q}_i) = [x_i \ y_i \ z_i]^T \in \mathfrak{N}^3$ is a translation vector. R_i specifies the rotation of the coordinate frame on link i with respect to the coordinate frame on link $i - 1$; \mathbf{p}_i specifies the translation of the coordinate frame on link i with respect to the coordinate frame on link $i - 1$. The 4×4 *homogeneous transformation* A_i thus specifies completely the orientation and translation of link i with respect to link $i - 1$.

The A matrix $A_i(\mathbf{q}_i)$ is a function of the joint variable, so that as \mathbf{q}_i changes with robot motion, A_i changes correspondingly. A_i is also dependent on the parameters link twist and link length, which are fixed for each link. The A matrices are often given for a specific robot in the manufacturers handbook.

71.5.1.1.2 Robot T Matrix

The position of the end effector is given in terms of the base coordinate frame by the *arm T matrix* defined as the concatenation of A matrices

$$T(\mathbf{q}) = A_1(\mathbf{q}_1)A_2(\mathbf{q}_2) \cdots A_n(\mathbf{q}_n) \equiv \begin{bmatrix} R & \mathbf{p} \\ 0 & 1 \end{bmatrix} \quad (71.2)$$

This 4×4 homogeneous transformation matrix is a function of the joint variable vector \mathbf{q} . The 3×3 cumulative rotation matrix is given by $R(\mathbf{q}) = R_1(\mathbf{q}_1)R_2(\mathbf{q}_2) \cdots R_n(\mathbf{q}_n)$.

71.5.1.1.3 Joint Space vs. Cartesian Space

An n -link manipulator has n degrees of freedom, and the position of the end effector is completely fixed once the joints variables \mathbf{q}_i are prescribed. This position may be described either in joint coordinates or in Cartesian coordinates. The joint coordinates position of the end effector is simply given by the value of the n -vector \mathbf{q} . The Cartesian position of the end effector is given in terms of the base frame by specifying the orientation and translation of a coordinate frame affixed to the end effector in terms of the base frame; this is exactly the meaning of $T(\mathbf{q})$. That is, $T(\mathbf{q})$ gives the Cartesian position of the end effector.

The Cartesian position of the end effector may be completely specified in our 3-D space by a six vector; three coordinates are needed for translation and three for orientation. The representation of Cartesian translation by the arm $T(\mathbf{q})$ matrix is suitable, as it is simply given by $\mathbf{p}(\mathbf{q}) = [x \ y \ z]^T$. Unfortunately, the representation of Cartesian orientation by the arm T matrix is inefficient in that $R(\mathbf{q})$ has nine elements. More efficient representations are given in terms of quaternions or the *tool configuration vector*.

71.5.1.1.4 Kinematics and Inverse Kinematics Problems

The robot *kinematics problem* is to determine the Cartesian position of the end effector once the joint variables are given. This is accomplished simply by computing $T(\mathbf{q})$ for a given value of \mathbf{q} .
